Boy: *Equals [parenthesis] A2 minus 2 -- this gives the... what's on each edge... and now multiplied by 12...*
Girl: *and divided by 2, because this is the price.*

Topic	Version #	Formula	Rationale	Cause for revision
Price of 3-sided slices	1.1	8	Considering the number of slices (and not their price).	Peer discussion (first attempt).
	1.2	4	Applying the principle "*all* slices cost 1/2".	Neighbor intervention.
	1.3	12	Adjusting the price of a slice to 1 1/2.	Neighbor intervention.
Price of 2-sided slices	2.1	(A2 - 2)*12	Considering the number of slices (and not their price).	Peer discussion (first attempt).
	2.2	(A2 - 2) * 12 / 2	Applying the principle "*all* slices cost 1/2".	Peer discussion.
	2.3	(A3 - 2) * 12 / 2	Adjusting the variable for the third line of the table.	Peer discussion (confronting unreasonable computer output).
	2.4	(A3 - 2) * 12	Adjusting the price of one slice to 1.	Peer discussion.
Price of one-sided slices	3.1	(A3 - 2) ^ 2 / 2	Considering the price of 1/2 per slice (ignoring the cube's 6 faces).	Peer discussion (first attempt).
	3.2	(A3 - 2)^2 * 6 / 2	Considering the fact that the cube has 6 faces.	Teacher intervention.
Total price	4.1	A3 + B3 + C3	Totaling the first three columns.	Peer discussion (first attempt).
	4.2	B3 + C3 + D3	Adjusting the sum to the second to fourth column.	Peer discussion (confronting unreasonable computer output).

Even constant numbers were sometimes introduced as formulae (e.g., =8 in [1.1]). In most cases, however, the students employed the language of Excel as a means of communication, without further interpretation. From their discussions, it is clear that both students were aware of the general nature of their expressions. Sometimes, they stated this specifically (*G: For the three-sided slices, the price is always 8.*) The students' awareness of the general nature of their solution can also be deduced from their copying of the formulae for Cake Numbers 2 to 20, as opposed to their separate handling of Cake Number 1.

However, the students' familiarity with generalizing in a spreadsheet format did not prevent some technical errors. Thus, the use of cell names as variables caused some difficulties. During their first steps, the students used A2, rather than A3, as a variable in their expressions [2.1, 2.2]. This shift in the referred cell was probably due to previous experiences in which the students wrote their formulae in the second row (with the first row containing the column headings). Later on, the boy also attempted to find the cakes' total price by summing the numbers in columns A, B and C [4.1], rather than those in columns B, C and D.

Some of these errors could be prevented, by pointing and clicking with the mouse to the referred cell, rather than keying the referred cell's name into the formula. Sutherland and Rojano (1993) observe that pointing at cells can be advantageous and cognitively easier. However, our project staff frequently observed that a pair of students working together on a computer tend to divide between them the manipulation of the mouse and the keyboard. This division of work makes the method of reference by pointing and clicking almost impossible.

b) Analyzing results. The students scrutinized the numbers produced by each of their expressions. If the numbers seemed reasonable, they moved on to the next step of their solution, without any further remarks. There were two instances, however, when numerical results in the table created conflicts. In one case, the girl noted that the total price of Cake Number 2 should be 12 and not 14, as it appeared on their screen. This triggered a further inquiry that led to the necessary correction of the formula for the total price [4.1, 4.2].

In the second case, both students were puzzled by the negative numbers produced by their (wrongly referenced) formula for the price of the two-sided slices [2.2] First they wrote it in the cell corresponding to Cake Number 2. When they received a negative number (-6) they attributed this to the fact that, in this case, the number of two-sided slices is zero. They replaced the formula by zero and wrote the same formula again [=(A2 - 2)*12/2] in the next line for Cake Number 3, and copied it downwards. Again, they received a sequence of numbers increasing by 6 and starting with -6. The following conversation took place at this stage:

Both: *Why -6 !?!*
Girl: *Let's see, 3 less 2 is 1, multiplied by 12 it's 12, divided by 2 it's 6. Why -6?*
Boy: *I'm sure that the computer is wrong...*
Girl: *[Pointing at the lower part of the same column] Look... look - here it's positive.*
Boy: *Let's see till where it's negative.*
Girl: *What's this negative?*
Boy: *This doesn't make sense. Here it's zero? At [Cake No.] 4 it's zero?!*
Girl: *4 less 2 is 2, multiplied by 12 it's 24, divided by 2 it's 12.*
Boy: *[Looking at the edit section of the spreadsheet that shows the formula for Cake No. 4] A3... A3... Why A3?!*
Girl: *Wow!! because A2 is this [points at the top of the first column]*
Boy: *Then, we should have done here...*
Girl: *[Referring to Cake No. 2] Right! Write A3.*

As a result of this revision, they wrote a formula that had the correct reference and produced positive numbers, but still gave an incorrect price [2.3].

The episodes described above provide additional evidence that problem solving with a computer, naturally shifts the traditional emphasis from computational work to the design of a corresponding model for the problem situation, and to monitoring the out coming results (Heid, 1995).

However, as shown in three of the cases described above [2.3, 3.1, 4.1], monitoring and reflection on the nature of the numerical output is not always sufficient. For example, the pair did not detect their error regarding the price of the one-sided slices [3.1], since the formula produced positive and reasonably sized numbers. This error was corrected only as a result of teacher intervention. In this and many other cases, we have seen that the fact that computers provide large quantities of data in a short time may cause an over-reliance on "reasonable" data, as opposed to monitoring solution processes and reasoning.

c) *Explaining and justifying.* During a relatively short period of 20 minutes, the observed pair produced 26 explanations of various kinds and length. About two thirds of these explanations were given by one of the students as answers to the other's question, or in order to help the partner understand a certain aspect of the solution. The issues discussed in these explanations can be categorized as follows:

- General explanations -- relating to the (correct or incorrect) generalizations made about the price of different kinds of slices. These explanations employed general terms relating to the cube's structure, the pricing policy etc.

For example, when dealing for the third time with the price of the two-sided slices, the boy realized that there is no need to divide by 2, as they had done before, when they considered the price of 1/2 for one unit area, but disregarded the fact that these slices are iced on two area units. He provided the following explanation:

Boy: *Why divide by 2?*
Girl: *To find the price.*
Boy: *Why do we have to divide by 2? Are we stupid!!*
Girl: *Why not?*
Boy: *Because each of them is 1 in any case.*
Girl: *But thus we get the number of slices - right?*
Boy: *But each of them equals one A.U. [He means one zooz] and this is how it should be - without dividing by 2.*
Girl: *Right, right...*

- Local explanations -- relating to Cakes Number 1 and 2. The first case requires a separate solution. The general formulae can be applied for Cake No. 2. However, whenever a general formula did not produce a reasonable output, the students used numbers and tried to generalize for Cake No. 3. They explained their local solution by the fact that Cake No. 2 has "zero" one-sided, and two-sided slices -- thus implying that these are exceptions.
- Explanations of context -- were provided as reasons to correct errors that resulted from disregarding the characteristics of the problem (for example, when they considered the price of any slice to be 1/2 or disregarded the fact that the cube has six faces), or to remind the partner about a context-related conclusion, already reached in a previous stage of the solution (for example, the girl constantly reminded the boy to divide by 2, to get the formula for the price).
- Technical explanations -- relating to some computer technicalities (e.g., how to drag two cells in order to get the sequence of natural numbers), the change of the variable from A2 to A3 (see the section on generalizations), or the boy's passing remark that "the computer is wrong", since it produced negative numbers.

More than 40 percent of the explanations were of a general nature (i.e., they referred to all the cakes, they employed general terms and many of them were related to algebraic expressions) and the rest were equally divided among the three other categories. The large number of explanations can be attributed to the complex nature of the investigative task and to the pair's interactive work, but a main cause for their high level is the nature and the requirements of a spreadsheet environment.

Conclusion

The observation of the cognitive processes involved in solving an algebraic problem with Excel, showed some significant advantages for using spreadsheets in algebra.

Work with Excel allows a natural transition between the world of particular numerical cases and the general world of algebra. The need to use formulae as a means to produce many numerical examples, emphasizes the general nature of the algebraic expressions. The observed students considered spreadsheet formulae a natural tool, that creates numerical data needed to understand, analyze and solve a problem situation. As a result of using spreadsheets, they could develop cognitive and metacognitive skills (transitions between numerical and algebraic representations, generalization and justification of patterns, discussions of solution methods, analyzes and evaluation of outcomes) of a wide variety and at a high level. The students were also released from the burden of calculations and algebraic manipulations.

Besides these advantages, the observed students encountered some cognitive difficulties. Some of these can be attributed to spreadsheets. The spreadsheet syntax, although relatively simple, seemed to cause some difficulties -- such as the use of an incorrect reference as a variable. Spreadsheet capabilities can also turn out to be obstacles. Thus, the creation of numerical data in large quantities can cause an over-reliance on the "reasonability" of the output and diminish the need for an in-depth understanding of the problem at hand.

EXPLORING STUDENTS' IMAGES AND DEFINITIONS OF AREA

Fulvia Furinghetti* & Domingo Paola**
*Dipartimento di Matematica dell'Università di Genova. Italy
**Liceo Scientifico 'A. Issel', Finale Ligure (Sv). Italy

ABSTRACT. *This study examines several aspects of the images and definitions that eight students of high school (16 years old) have regarding area. The analysis is performed through 10 open questions to which students answered through written statements, drawings, concept maps. The protocols shed light on the ways used by students to communicate their ideas and on the role they ascribe to definitions in their mathematical experience.*

INTRODUCTION

In studying the various aspects of proof we became aware of the crucial role of definitions. In particular, we have often observed that some cause of failures are due to the role students ascribe to them and how they deal with them. What happens can be explained considering the statement to prove as having a hypertext structure: it contains 'hot words' that the student has to single out and on which to 'click' when necessary. The operation of clicking establishes a link between hot words, concept images and concept definitions (henceforth called images and definitions) behind them to get the information useful to go on in proving. If one of these procedures (recognising hot words, clicking on them, getting information) is not activated the statement is obscure and to prove is a hard task. The research reported in (Furinghetti & Paola, 1997) may be an exemplification of this hypertext metaphor. We have found that the statement 'Prove that the product of any three consecutive natural numbers is divisible by 6' resulted difficult to prove for most students (aged from 14-17) because they did not recognised that 'divisible' was a 'hot word' in the statement to prove or, when they did, were not able to use the definition of 'divisible' that has been introduced to them previously. In that case we had the impression that students did not ascribe cognitive value to definitions, they seemed to perceive them only as labels which are not relevant to the mathematical work. Other authors have observed analogous students' behaviour. Rasslan and Vinner (1998, p.33) write that the student 'does not necessarily use the definition when deciding whether a given mathematical object is an example or non example of the concept. In most cases, he or she decides on the basis of the concept image, that is. the set of all the mental pictures associated in his/her mind with the name of the concept, together with all the properties characterising them'. Bills and Tall (1998, p.105) have introduced the expression 'formally operable' for a given individual to indicate a (mathematical) definition or theorem which an individual is able to use 'in creating or (meaningfully) reproducing a formal argument'. We can say that for our students the definition of 'divisible' was not operable.

We quote the following passage, taken from Wheeler (1991, p.1), to summarise some important points on the role of definitions in proving:

'When we talk about proof, it seems very often that we shift quite unconsciously between talking of proof as something technically proven and proof as a sign for formalism. I wish we would give more attention to the business of definition rather than that of proof *per se*, or at least that we would really take into account of the act of making definitions, because if one's talking about the normalization of mathematics it seems to me that it's in the definitions that we find the vectors of mathematics: these are things that we choose to define this way because they have a future, because they will go somewhere, because we can do something with them. Now, proof when it's finished, is finished. Of course, there are proof techniques that we can apply in other cases, so I mustn't be unfair to proof and say that we can't do anything with it other than just prove one particular theorem, but definitions *always* have to be shaped in order to point us onwards, so that we can go somewhere, otherwise they would be bad definitions that we would abandon, that somebody subsequently would change'.

OUR STUDY: METHODOLOGY AND AIMS

On the ground of the previous observations we consider very important to explore students' behaviours in defining and to promote classroom activities which lead students to reflect on definitions. In the present paper we report an activity of this kind centered on the concept of area. In carrying out this activity our aim was twofold: from one hand it was to investigate which images students have elaborated of the concept of area and how make them explicit, from the other hand our aim was to promote cognitive activities about area. The concept considered is recognised as very difficult, see (Douady & Perrin, 1989), but is not studied so much from the educational point of view, in particular at the level of high school.

The population is constituted by eight 16 years old students of a Scientific Lyceum, an Italian high school in which mathematics plays an important role. They were requested to answer the questions reported in Table 1 (next page), using written statements, drawings, concept maps. We explained them our purposes and asked for an active collaboration. They worked with good willingness and fulfilled our expectation. The allowed time was 50 minutes.

We tried to structure the questionnaire in such a way that students' thoughts and possible inconsistencies could emerge. Question Q.1 is aimed at verifying whether students' images of plane regions are only based on elementary patterns (polygons, circle) or include any kind of shapes. The distinction is significant since in the first case students may have difficulties in thinking to situations in which a formula to compute area based on elementary operations does not exist. Question Q.2 is aimed at outlining the nature of the concept in question through links established with other mathematical concepts. Questions Q.3, Q.4, Q.5 and Q.6 were conceived to stress the specificity of the languages used in different school situations. These questions were inspired by Austin and Howson (1979) who observe that in classroom there are different mathematical languages: the language used with mates, with the teacher and the language of mathematics. The remaining questions are mainly aimed at orienting students towards activities of metacognition, that is to say, using the Schoenfeld (1987) expression 'thinking about thinking'. In particular

Question Q.8 is focused on the possible origin of students' misunderstandings. Question Q.9 is addressed to see whether new forms of representation of knowledge may act as a stimulus to make explicit concept images.

Q. 1. When one talks about the *area* of a plane figure, which images are evoked to you? Represent some of them (three or four) in your protocol.
Q. 2. Which parts and which topics of mathematics do you link to the notion of *area of a plane figure*? Write in your protocol and try to give an explicatory example for each issues you refer to.
Q. 3. To explain to a fourth-fifth grade student what *area of a plane figure* means, what would you say?
Q. 4. To explain to an eighth grade student what area of a plane figure means, what would you say?
Q. 5. To explain to a mate of yours what *area of a plane figure* means, what would you say?
Q. 6. To say to your teacher what *area of a plane figure* means for you, what would you say?
Q. 7. Are you surprised about the questions 3, 4, 5, 6? In other words is it possible to use different characterisations of the same concepts according on the person you are addressing to?
Q. 8. Are there analogies and differences between the use and the meaning of the word *area* in the common and in the mathematical language.
Q. 9. Construct a concept map about the concept of *area*.
Q. 10. Reconstruct the didactic path followed in your school career until now as for the concept of *area*.

Table 1. The questionnaire on the students' images and definitions of area

ANALYSIS OF THE ANSWERS

In analysing the protocols we have singled out key elements and orientations. We have reported them in Table 2 (which takes the next two pages) to give a synoptic view of answers. In abbreviating and translating sentences some nuances of meanings are lost, but we feel that the basic issues of the students' reactions are kept. Table 2 has two entries: reading horizontally we have the answers to the same question by the eight students, reading vertically we have the picture of each student's images and definitions as emerged from protocols. In the following we give our interpretation of the findings reported in Table 2.

Question Q.2 offers insights on the *students' difficulties* about area. Only two students (Protocols 3 and 6) mention the 'measure'. Nobody refers to real numbers, which for us was the most obvious association. Another missing link for all students except one (Protocol 7) is that with the concept of function. In comparing the answers to Q.1 and Q.2 we find inconsistencies (see rows referring to Q.1 and Q.2 in Table 2) which are generated by the passage from the simple geometrical/visual

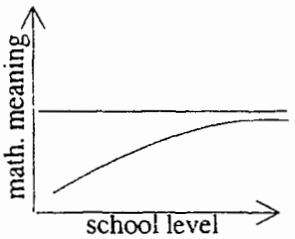
Table 2. Schema of the main points in students' answers

Q	Protocol 1	Protocol 2	Protocol 3	Protocol 4	Protocol 5	Protocol 6	Protocol 7	Protocol 8
1	Polygons, circle, other figures	Polygons, circle	Polygons, circle, other figures	Polygons, circle	Polygons	Polygons, circle	Polygons, circle	Polygons
2	Intersection of at least 3 half-planes	Algebraic inequations (first degree, absolute value)	Word definitions, formulas to compute areas, unit of measure	Concept of measure, number, Eucl./anal. geom., algebra, computer	Algebraic inequations and systems of inequat. (I and II degree)	Plane geometry, computing the measure of an area	Set intersection, set theory, inequations, functions, linear programming	Geometry
3	Portion of the plane contained in curved lines	The space occupied by the figure	Quantity of substance covering up the figure	I would draw a figure and would hatch the area	Space delimited by segments or closed curved lines	Space inside to the segments used to draw the figure	Space contained in the perimeter of the figure	I would draw and color with a pencil
4	Portion of the plane contained in segments or curved lines	Portion of the plane contained at the interior (of the figure)	Part of the plane defined by the sides of the figure	Part of the plane delimited by a closed broken line	Set of points interior to the perimeter	Measure of its surface	Space occupied by the figure in the plane	Definition: area is all is contained in the segments of the figure
5	The same as in 4	Portion of the plane contained at the interior	I don't know	Portion of the plane delimited by a closed broken line with only two dimensions	Intersection of half-planes defined by inequations	Measure of its surface which is delimited by its perimeter	Measure of the surface of the figure	It is called area of a plane figure the part of the plane contained in the perimeter of the figure (concave or convex)
6	Portion of the plane which is the intersection of many half-planes delimited by a system of equations	As in 5	I don't know	As in 5	As in 5	As in 5	As in 5	As in 5

Q	Protocol 1	Protocol 2	Protocol 3	Protocol 4	Protocol 5	Protocol 6	Protocol 7	Protocol 8
7	Not surprised because it is necessary to use known concepts and to consider the capacity of understanding. I don't remember what I knew	Not surprised. It is correct to use different languages according to the age	Not surprised. It is correct to use different languages according to the age	Not surprised. It is correct to use different languages according to the age	Not surprised. It is correct to use different languages according to the age	Not surprised. It is correct to use different languages according to the age	Not surprised. It is correct to use different languages according to the age	Not surprised. It is correct to use different languages according to the age
8	Analogies: an interior surface. Differences: in the common language is only a measure	In the common life the area is only a surface and not a portion of plane	No: the concept is always one, the differences between the common life are in the fact that there is a practical use	Analogies: it is a zone delimited by a broken closed line. Differences: it is of 3 dimensions in common language, of 2 in math	No answer	I am not able to answer	In the common language the area is confused with the surface, while in math are different concepts	I don't know
9	Half-planes, systems of inequations, Cartesian plan. *Double arrows, single in-out*	Figures, formulas, the four arithmetic operations, transformation of figures in rectangles, pi. *Double arrows*	Figure, definitions rules, unit of measure. *Single arrows*	Equations, real numbers, measure, geometry, drawing, computer. *Double arrows, single in-out*	No answer	Plane geometry, definition of plane figure, concept of surface. *Single arrows*	Figure, plan, surface, measure. *Double arrows*	Def. of plane figures, def. of area of a figure, formulas to compute area. *Single arrows, single in-out*
10	I have not retentive memory	In primary: formulas without explanation. In High School: the teacher tells where formulas come from	I don't remember	Both in primary and secondary: measure. In High School there is more abstraction	No answer	Examples, definitions of figures, concept of area and surface. I don't remember other things	In primary: a precise concept, but easy to understand. Increasing the school level definitions are more complete, but more abstract	I don't remember

The italic indicates the style of the signs in concept maps. *Single in-out* means at most one arrow going in and out from a node

context to richer contexts encompassing arithmetic, algebra, analytical geometry. In Protocols 1, 2, 5 the geometrical shapes mentioned in the row of Q.1 are not in relation with the answers to Q.2. In principle, we consider important to encourage students to go across different parts of mathematics: this could promote the flexibility advocated by Tall and Gray (1993). Our findings show that this process needs of careful control. Going across contexts does not always create meaning, in some cases may cloud the existing one so that what is generated is not fruitful communication between contexts, but rather *contamination of contexts.*



Questions Q.3, Q.4, Q.5, Q.6 shed light on *the evolution of the way used to communicate mathematical ideas according to the interlocutor.* At the primary level there are manifest references to concrete elements: 'space occupied by the figure' (Protocol 2), 'quantity of substance covering up the figure' (Protocol 3), 'to hatch the figure' (Protocol 4), 'to colour the figure with pencil' (Protocol 8). There is a precise use of efficient 'ostensives' (hatching, colour). Things change when the school level increases: already in the statements addressed to eight grade students the language is more formal, which does not mean necessarily more precise, nor more oriented to generalisation and abstraction. Students do not add useful information, they only paraphrase the statements addressed to younger students eliminating ostensives and concrete ideas and adding negligible details. For example, in Protocol 2 the expression addressed to the fourth-fifth grade student 'space occupied by a figure', which evokes a physical situation, is substituted by 'portion of plane contained at the interior' when addressing to the eight grade student. The loss of spontaneity is evidenced in Protocol 8 where we observe a real escalation: - the ostensive for the fourth-fifth grade (coloured pencil), - the semi-intuitive for the eight grade ('what is contained in the segments') - the formal expression ('It is called'). It is curious to observe that to use the words 'It is called' was advocated by Smith (1911) in his famous treatise on mathematics teaching to 'mark the statement at once as a definition' (p.158), that is to say to distinguish it from a theorem. Protocol 8 evidences a different behaviour according to the age of the interlocutor: with the youngest the student tries to make understandable his message using the 'common sense', with the oldest and with the teacher he is only interested in conveying the idea that he is defining something, no matter if what he is saying is understandable or not. Another aspect of the evolution in the way of communicating according to the school level is the relationship general/generic/particular. In Protocol 8 the student adds the adjectives 'concave or convex' to the word 'figure' for mates and for the teacher. In Protocol 1 we find a similar behaviour: to the fourth-fifth grade student it is said 'portion of plane contained in *lines*', while for the older students the sentence becomes '[...] *segments or curved lines*' [emphasis is our].

As for Question Q.7 all students agree that there has to be a distinction between the languages used in the four different situations of Questions Q.3 to Q.6, but from their explanations we infer that the difference is in the form, not in the substance. Advancing in the age there is no gain in generality, abstraction or elegance, while

there is loss in meaning. The creativity seems inhibited along the years; the students' behaviour can be referred to the ritual and symbolic schemes discussed by Harel and Sowder (1996) in their studies on proof.

Question Q.8 adds further information *about the relationship between mathematical knowledge and common sense*. In Protocol 1 it is pointed out that in the common language the area is considered *only* [emphasis is our] as a measure. The student is not able to accept the right suggestions coming from the common sense, even more it seems that the common sense is perceived as something against mathematics.

Analysing our findings we feel that the students' capacity to grasp mathematical meaning through personal and autonomous elaboration of ideas has the asymptotic trend illustrated in the figure beside. At the age of the students examined (16 years) the upper bound seem to be already reached. In Protocol 2 we found the statement

'At the lyceum the teacher tells us where formulas come from', which is not the same as saying that the teacher explains how to find formulas. Freudenthal (1973) has criticised the teachers' practice of providing students with definitions given a priori instead of constructing them together with students. May we interpret the student's statement as a criticism in this direction?

Concept maps

At the moment of answering questions students did not know what 'concept map' means. We simply explained them that it is 'a graphical representation of domain material generated by the learner in which nodes are used to represent domain key concepts, and links between them denote the relationship between these concepts', see Jones (1998, p.161). To analyse the students' protocols we have considered:
- the number of issues reported in the concept map
- if arrows are single or double, how arrows go in and out at the nodes
- the presence and the kind of explanations of links
- the presence of the word definition or its derivative
- the type of iconic representations used (only words, words in boxes, etc.)

To single out the differences when using the verbal language or concept maps we have compared the number and the type of issues in the answers to Q.2 (that about the links with parts of mathematics) and in the concept map. Protocol 4 has the same number of issues (six, the highest among the eight students examined) and of the same type in both cases. The concept map of this protocol is very rich and it is the only in which links have a written explanation. In Protocol 7 there is the same number of issues (four) in Q.2 and in the concept map, but the issues mentioned are different. In Protocol 5 there is one issue in the answer to Q.2 and there is not the concept map. In the other protocols the number of issues appearing is higher in concept map than in Q.2.

About the different styles we can distinguish:

- those who simple translate into the iconic form their word statements (for example, Protocol 1)
- those having a linear pattern to approach the concept ((for example, Protocol 3). The arrows are single, at most one arrow arrives to and leaves from nodes. The focus is on the order of facts more than on links between them. The word definition appears among the nodes
- those who really add information making the links more explicit and finding new issues ((for example, Protocol 4).

PRELIMINARY CONCLUSIONS

The concept of area, through its epistemological and conceptual aspects and its character of being a cross-roads of different parts of mathematics has revealed itself suitable to show that students have in their mind a jungle of concept images, concept definitions, which are not completely under their control. Moreover for them the problem is not only to elaborate images which can flow into definitions mathematically acceptable, but to find means which may make them explicit, consistent and clear to others and to themselves. From our study we have obtained a number of indications for the classroom practice as well as topics which deserve attention for future research. A point we would like to stress as a first preliminary conclusion is the importance of making students to reflect not only on their way of thinking, but also on the way of representing their thoughts, so that to the Schoenfeld's expression 'thinking about thinking' we may add its paraphrase 'thinking about representing'.

A NUMERACY ASSESSMENT FRAMEWORK FOR THE INTERNATIONAL LIFE SKILLS SURVEY

Iddo Gal

University of Haifa, Israel

Abstract. *This paper describes a conceptual framework for defining and assessing numeracy of adults as part of the planned International Life Skills Survey. The paper reviews some differences between assessment of mathematical knowledge of adults and younger students, discusses the notion of numerate behavior, presents a definition used to guide construction of assessment tasks, and outlines some dilemmas involved in conducting a large-scale assessment of adults' numeracy.*

Background

This paper describes a conceptual framework developed for assessing numeracy of adults as part of the International Life Skills Survey (ILSS) planned for the year 2001. This comparative survey is being jointly developed by Statistics Canada and by the United States' National Center for Education Statistics (NCES), in cooperation with the Organisation for Economic Cooperation and Development (OECD). This paper is based on a report prepared for the ILSS project by the Numeracy Working Group[1], comprised of individuals from Israel, Australia, Holland, United States, and Canada.

The ILSS project is a follow-up to the international Adult Literacy Survey (IALS), the world's first large scale comparative assessment of adult literacy. In the first phase of IALS, almost 21,000 adults from 7 countries, including the U.S., Canada, Germany, the Netherlands, and others, were tested based on survey methodology that combined household survey research and methods of educational testing. Key reports from the IALS were published starting in 1996 (e.g., Statistics Canada and OECD, 1996). Using a similar approach involving home interviews, ILSS will test nationally representative samples of adults aged 16 and over in multiple countries. Tasks will

[1] **Acknowledgments**: The Numeracy Working Group: Iddo Gal, University of Haifa, Israel; Dave Tout, Language Australia; Mieke van Groenestijn, Hogeschool van Utrecht and the Freudenthal Institute, Netherlands; Mary Jane Schmitt, National Center for the Study of Adult Learning and Literacy, Harvard University, USA; Myrna Manly, El Camino College, California; Stan Jones, Statistics Canada. assess performance in several skill domains, including *Numeracy* as well as *Literacy*, *Problem Solving*, and *Practical Cognition*; other variables will be assessed via a background questionnaire. The domain of Numeracy is planned as an elaboration on the domain of Quantitative Literacy previously included in IALS and in prior studies. .

Feasibility studies involving sample tasks from the Numeracy scale have started and results are expected in summer 1999. At this point, this paper is presented to share with researchers and educators interested in mathematics education the conceptualization of Numeracy planned for the ILSS, and to outline some of the issues involved in the development of a scale for assessing Numeracy of adults.

Introduction

Numeracy is becoming a growing concern for diverse education sectors, following its apparent low profile for many years. As countries increasingly attend to topics such as improving workplace efficiency and quality processes, to resulting continuous learning needs, and to civic participation (European Commission, 1996), it is seen as vital that nations will have information about their citizens' numeracy, among other skills, if they want to plan effective education and lifelong learning opportunities.

The concept of numeracy is specifically related to the dialogue about the goals and especially *outcomes* and *impact* of school mathematics education. More educators now encourage links between knowledge gained in the mathematics classroom and students' ability to handle real-life situations that require mathematical or statistical knowledge and skills (Gal, 1997; Packer, 1997). However, while numeracy may be a key skill area, its conceptual boundaries, cognitive underpinnings, and assessment, have not received much scholarly attention so far.

With the above in mind, this paper is organized in five parts. Part 1 contrasts some ideas behind assessments of school-based mathematical skills and of adults knowledge. Part 2 outlines key knowledge bases used to inform our conception of adult numeracy. Part 3 presents a working definition of numerate behavior to be used to guide item development for the ILSS. In Part 4 we comment on several decisions that underlie scale development, such as task range, scoring, and difficulty of items. Lastly, a Summary section outlines resulting challenges in conducting a credible assessment of adult's numeracy in a large-scale context. (Due to space limitations, the discussion of all topics in this paper is understandably brief).

1. On large scale assessments of mathematical knowledge

The IALS, following on a framework established in prior studies in the U.S. and Canada, made use of three literacy scales, Prose Literacy, Document Literacy, and Quantitative Literacy, to operationalize its conception of literacy. Quantitative Literacy (QL) was defined as: *The knowledge and skills required to apply arithmetic operations, either alone or sequentially, to numbers embedded in printed materials.*

such as balancing a cheque book, figuring out a tip, completing an order form, or determining the amount of interest on a loan from an advertisement.

Some key distinguishing features of all three IALS scales were: (a) Respondents have to deal with information embedded in *text*. (b) Tasks involve genuine or realistic stimulus materials such as those found in newspapers or official forms and documents. (c) Tasks require performance that is "realistic", i.e., what may be expected of a person in real life. (d) Use of "correct/incorrect" scoring scheme. These features, especially the emphasis on the embedding of all tasks in text, including of Quantitative Literacy tasks, were an outgrowth of IALS' mission to assess dynamic and functional perspective of literacy as a purposeful skill area in adults' life.

In contrast, large-scale assessments of mathematical skills aimed at school-age student populations have taken quite different approaches. A review of large-scale assessments of mathematical skills is beyond the scope of this paper (see Robitaille & Travers, 1992). Yet, we reiterate here that large-scale assessments made in a *schooling* context usually start from the assumption that students should have learned symbol-manipulation competencies (and hopefully understood underlying "big ideas" along the way). Such assessments (legitimately) use a certain degree of formalization of math symbols, may employ tasks which are quite contrived or relatively devoid of a realistic context, and expect some memorization of formulas and notations. This is true, for example, of the mathematical tests included in the National Assessment of Educational Progress in the U.S., of the recent TIMMS study, or even of many existing nationally-recognized tests used to qualify knowledge of *adults*, such as the national vocational qualifications system in the U.K, or the GED in the United States.

The above, of course, is not a criticism of such assessment initiatives, but just a reminder that designers of *all* assessments make conscious decisions regarding what it means to "know math" or "be able to do math", in light of their overall mission and the information needs of the end-users of the assessment. School-based assessments concentrate on how students understand, use and apply mathematical skills and mathematize problems which are related to their *formal* mathematics curriculum. An emphasis on realism of tasks is secondary, given that most students have limited world experience. Though word problems are used, large-scale assessments are not explicitly interested in performance on text-rich tasks. (Yet, many quantitative situations adults face involve mathematical or statistical information embedded in diverse and sometimes complex or terse texts).

The notion of numeracy, however, implies a bridge that links mathematics and the real world. Our goal was to develop a conceptual framework of "numeracy" that is couched in assumptions about how *adults* "know" and "do" math in the real world, using not only their formal knowledge (of mathematics, of literacy, and so forth), to the degree it exists, but also other, experience-based knowledge.

2. Perspectives on adult numeracy

Our thinking about the nature and scope of adult numeracy, and about approaches to its assessment, is informed by prior work and publications in five interrelated areas:

1. General developments in continuing and vocational education in many countries, such as in the U.S., U.K, Denmark, and Australia, showing that educational systems now recognize the need to employ skills frameworks that include numeracy.

2. Work on the nature of adult *literacy* and on the different life functions/needs served by adults' literacy and numeracy skills. In one project (Kindler, Kenrick, Marr, Tout, & Wignall, 1996), for example, numeracy is organized according to its different purposes: *Numeracy for practical purposes*, *Numeracy for interpreting society*, *Numeracy for personal organisation*, and *Numeracy for knowledge*.

3. Recent thinking about the goals of learning mathematics and about "good" assessment in this domain. Influential perspectives were, e.g., those presented following the Realistic Mathematics Education movement in the Netherlands, emphasizing the need to develop (and assess) use of formal and informal reasoning strategies (Groenestijn, 1998), the curriculum and assessment frameworks of the National Council of Teachers of Mathematics (NCTM, 1995), or suggestions from those interested in school-work links (e.g., Packer, 1997).

4. Research on the nature of adult's mathematical thinking, mathematical practices, the cognitive processes underlying how people cope with out-of-school quantitative situations (Nunes, 1992), and the impact of attitudes and beliefs on performance.

5. Current thinking about adult numeracy, both at the conceptual level as well as in terms of needed skills and needed curriculum. Various views in this area have emerged from diverse workers and groups. Two key examples are:

- Work as part of the Numeracy Project at the National Center for Adult Literacy (NCAL) in the U.S. has began to formulate the processes that may comprise numerate behavior, based on an assumption that "numeracy" refers to the capacity for effective *management* of quantitative situations (Gal, 1997). It has been proposed that adults manage situations, using both generative and interpretive skills and supporting knowledge and dispositions, and that adults do not necessarily cope with problems in ways that can be classified as right or wrong, in contrast to how students solve word problems, even if these are supposed to simulate real-life situations. Cumming, Gal, & Ginsburg (1998) have argued that several aspects of numerate behavior are not reflected in how tests aimed for adults are created, scored, and interpreted.
- Work conducted by the Adult Numeracy Network (Curry, Schmidt, & Waldron, 1996) in the U.S. consolidated perspectives from the NCTM Curriculum Standards (NCTM, 1989), the U.S. Secretary's of Labor Commission on Achieving Necessary Skills (Packer, 1997), and results of

interviews with adult learners, numeracy teachers, and employers. Seven broad themes emerged, consistent with those offered by NCTM and using similar titles, but with numerous adaptations to adults: relevance/connections; problem solving/reasoning/decision-making; communication; number and number sense; data; geometry: spatial sense and measurement; algebra: patterns and function.

3. A working definition of numerate behavior

Based on the above and other related literatures, we have sought a view of numeracy that acknowledges the diverse purposes served by adults' mathematical (and statistical) knowledge, that encompasses the different suggestions regarding the skills adults need to effectively function in home, work, community, and other contexts, and that takes into account the cognitive, metacognitive, and dispositional processes that support or affect adults' numeracy.

However, one cannot assess numeracy, but *behavior* (broadly defined). We have thus chosen to focus on *numerate behavior*, which is revealed in the response to mathematical information that may be represented in a range of ways and forms. The nature of a person's responses to mathematical situations critically depends on the activation of various enabling knowledge bases, practices, and processes.

Table 1 (next page) presents our working definition of numerate behavior. It will be used to guide development of items for a Numeracy Scale for the ILSS. The definition in Table 1 distinguishes five facets, each with several components. (Space limitations prevent the presentation of further explanations of the logic behind the choice of these facets, and sample items. Further information is available upon request).

4. Scale development, scoring, and background data issues

Range of tasks. An item pool is being developed to span different combinations of the components in each numeracy facet. (Not all tasks will be given to all respondents: the ILSS will use a "task-spiraling" design, as in TIMSS, where each respondent will be given a subset of the tasks in the item pool for each of the scales). Regarding the fifth facet, "Enabling knowledge," the main component we will utilize is the first, 'Mathematical knowledge and understanding'. This is so the content of the tasks can be understood by *users* of the assessment results in terms of common school based mathematics topics (i.e., whole numbers, basic operations; percents, decimals and fractions; measurement; geometry; algebra; statistics and probability, etc.).

Contexts. All tasks will be derived from real life situations and embedded in a real life context. In the ILSS there will be no context-free tasks, which do appear in many school-based math surveys. Stimulus material will be chosen to have different levels of embeddedness in text, from text-rich to almost text-free. (As the assessment is based on a home interview format, verbal instructions will be pre-arranged for some items).

Table 1: Numerate behavior and its five facets

Numerate behavior involves...

...Managing a situation or solving a problem in a real context...
(contexts include: everyday life; work; societal; further learning)

...By responding...
(responses to quantitative situations can involve: identifying; interpreting; acting upon; communicating about)

...To mathematical information...
(this information may involve: numbers; statistical data; measurements; money; time; shape; direction; pattern and relationships)

...That is represented in multiple ways...
(the actor in a given situation may encounter: objects; pictures; numbers; symbols; formulae; diagrams & maps; graphs; tables; math information in text) (separately or in some combination, possibly with surrounding text)

...And requires activation of a range of enabling knowledge, behaviors, and processes.
(people's thinking about and actual behavior in response to quantitative situations is supported or influenced by: mathematical knowledge and understanding; mathematical problem solving skills; literacy skills; beliefs and attitudes; background world knowledge).

Scoring. Many math surveys use a "correct/incorrect" scoring scheme. In ILSS, selected numeracy tasks will use a 3-level "correct--partial credit--incorrect" scheme, to accommodate answers to some interpretive questions, as well as for cases where adults adopt reasonable strategies but reach incorrect answers.

Difficulty. To ensure a distribution of items at different difficulty levels, the complexity of items will be pre-estimated on the basis of five general factors gleaned from prior assessments of adult literacy or of mathematical skills: (1) complexity of Mathematical information / data; (2) Type of operation / skill; (3) Expected number of operations; (4) Plausibility of distractors (including in text); (5) Type of match / problem transparency. These factors can determine, separately and in interaction, the difficulty level of most numeracy tasks. For some tasks, such as those that are more interpretive in nature, other factors that affect complexity will also be considered.

Background variables. To shed a broader light on factors related to the distribution of numeracy skills across the adult population, additional data will be gathered through a background questionnaire, regarding three topics: school mathematics experience; numeracy practices (e.g., use of calculators, getting help from others, activity

structures); and dispositions (e.g., anxiety, confidence, interest). This is in addition to information about demographic variables and about *literacy* practices at home and at work that will be collected to support interpretation of results from all the ILSS scales.

5. Summary

Key motivations for conducting the ILSS are: to inform policymakers and educators regarding levels (distributions) of various skills, including of numeracy; to explore factors associated with observed skill levels (e.g., literacy); and to examine links between numeracy (or other skills) and important social variables, such as earnings, labor-force participation, unemployment, or health-related behaviors. However, the inclusion of a Numeracy scale in the ILSS also offers a significant opportunity to develop a new conceptual framework of adult numeracy, which should be of interest to educators and researchers interested in the development and application of mathematical knowledge in purposeful contexts.

Overall, numeracy is a multifaceted and sometimes slippery construct. Our basic premise is that numeracy is the bridge that links mathematical knowledge, whether acquired via formal or informal learning, with functional and information-processing demands encountered in the real world. An evaluation of a person's numeracy far from being a trivial matter, as it has to take into account task and situational demands, type of mathematical information available, the way in which that information is represented, prior practices, individual dispositions, cultural norms, and more.

Numerate behavior obviously includes the ability to calculate or manipulate symbols but is far from being limited to it. In a large-scale survey context, assessment of numerate behavior can be accomplished through tasks couched in realistic non-school settings, with limited usage of formal notations (unlike school-based assessments), and with significant presence of text-rich tasks (given their ubiquity, at least in industrial countries), as well as of some tasks where opinions rather than computation are called for (e.g., when interpreting statistical messages). Yet, while the scale we envision may cover a broad mathematical terrain, it may still fall short of encompassing the full scope of numerate behavior, due to pragmatic considerations. Some aspects of people's numeracy skills, such as those pertaining to problem-solving strategies, or to interpretive responses and their underlying reasoning processes, cannot be fully reliably and validly assessed with the methodology presently available in the ILSS.

Full assessment of adults' numerate behavior requires further work on the conceptualization of some the facets and components of adult numeracy, as well as grappling with a host of pragmatic challenges, such as translation to different languages that will retain task characteristics, training of interviewers regarding follow-up questions or scoring of partial responses, and more. It is hoped that this brief report will facilitate a dialogue on these and other issues raised in this paper among researchers and educators interested in mathematics education.

RESEARCH REPORTS

Continued from Vol. 2

"What can we all say?" Dynamic geometry in a whole-class zone of proximal development.

John Gardiner, Brian Hudson, Hilary Povey
Sheffield Hallam University,UK

This paper first considers aspects of the literature relevant to class and group teaching in a social context. Ideas of socio-mathematical norms and argumentation, on the significance of local communities of practice and on the development of a whole-class ZPD are examined. These ideas have been used to influence classroom approaches to the use of dynamic geometry (Cabri II on the TI 92 with 11-14 year old pupils in the UK) and analysis of classroom observation is presented. Conclusions are drawn about the interaction of these ideas with the technology and how the alignment of mathematical meaning-making might be promoted.

Introduction

There are bodies of current research which consider, from different perspectives, the dynamics of social meaning-making in classrooms. Cobb and Yackel (1996), Winbourne and Watson (1998), and Hedegaard (1990) and Lerman (1998) all have viewpoints which can be used to inform an analysis of classroom interaction. This paper reports on the development and use of classroom material using dynamic geometry on the TI92 in lower secondary classrooms (age 11-14) in the UK. Classroom dialogue from lessons taught by the researcher was transcribed from audio recordings. This dialogue is analysed from a socio-cultural perspective, making reference to the viewpoints referred to above, and seeking to illuminate the ways in which students make mathematical meaning in areas such as construction and proof.

Literature and Theoretical Background

Vygotsky(1962) proposed a social background to learning and formulated the Genetic Law of Cultural Development, with learning moving from the social to the personal. He took up the idea of the Zone of Proximal Development as the area where interaction between the individual and the social leads to development. Lerman (1998) says of the ZPD 'it provides the framework, in the form of a symbolic space ,.....for the realisation of Vygotsky's central principle of development.'(p71) Of particular interest here is a definition of the ZPD which includes the classroom as a whole, in this case incorporating the teacher, the pupils and the technology Hedegaard (1990) has reported in terms of the development of a whole-class ZPD rather than the consideration of an individual's learning:

This activity, in principle, is designed to develop a zone of proximal development for the class as a whole, where each child acquires personal knowledge through the

activities shared between the teacher and the children and among the children themselves (p 361).

Hedegaard reports in the same paper a motivational shift in children's focus, from an interest in the concrete to interest in the derivation of principles which can be applied to the concrete. Lerman (1998) takes the discussion further.

The ZPD is the classroom's, not the child's. In another sense it is the researcher's: it is the tool for analysis of the learning interactions in the classroom (and elsewhere) (p 71).

Insights into factors which might influence meaning-making in a whole-class or group ZPD can be drawn from the literature and indicate socio-cultural vectors which may operate for meaning-making. These include Local Communities of Practice, Socio-mathematical Norms and Choice of Materials.

Local Communities of Practice and Telos

Drawing on work by Lave and Wenger (1991) and Lave (1993), Winbourne and Watson (1998) have used the idea of 'local communities of (mathematical) practice'. They identify features of a local community of (mathematical) practice :

- pupils see themselves as functioning mathematically within the lesson;
- within the lesson there is public recognition of competence;
- learners see themselves as working together towards the achievement of a common understanding;
- there are shared ways of behaving, language, habits, values and tool-use;
- the shape of the lesson is dependent upon the active participation of the students;
- Learners and teachers see themselves as engaged in the same activity.'(p 183)

They examine classroom interaction in terms of such a community and go on to discuss the idea of 'telos', of the meaning-making of the whole class being aligned in directions generated by social interaction. They see telos as a unification of small scale 'becomings' by which many learners join a community of practice. They see:

a link between our notion of LCP and the situated abstraction of Noss and Hoyles (1996). Just as they claim the computer provides domains which support students' abstraction, so we claim LCPs support students' growing image of themselves as someone who is legitimately engaged in mathematical practice, as someone, in other words, who is becoming a mathematician. (p183)

Socio-mathematical Norms and Argumentation

This approach is echoed in the work of Cobb and Yackel (1996), who have analysed mathematics classrooms in terms of the negotiation and maintenance of social and socio-mathematical norms. Social norms include

- insistence on explanation of answers
- respecting the contribution of others
- making clear agreement as well as disagreement.

Socio-mathematical norms would include

- some notion of what constitutes a valid, complete solution
- agreement on the worth of alternative solutions
- negotiated agreement between teacher and students on the mutual acceptability of solutions.

Social norms will exist in all classrooms, and will bear a direct relationship to the society in which the classroom is situated. Because social norms will affect the negotiation of socio-mathematical norms, Apple (1992) has argued that the classroom is firmly situated in the wider context of the practices of school and society. Yackel and Cobb (1996) discuss the influence of socio-mathematical norms on argumentation in the classroom. They draw on the ideas of Toulmin (1969) as developed by Krummheuer (1995), seeing argumentation as made up of conclusion, data, warrant and backing. Yackel (1998) says of argumentation:

it clarifies the relationship between the individual and the collective, in this case between the explanations and justifications that individual children give in specific instances and the classroom mathematical practices that become taken-as-shared. As mathematical practices become taken-as-shared in the classroom, they are beyond justification and, hence, what is required as warrant and backing evolve. Similarly, the types of rationales that are given as data, warrants and backing for explanations and justifications contribute to the development of what is taken-as-shared by the classroom community, that is to the mathematical practices in the classroom. (p210)

Thus argumentation is seen as a social, rather than a logical process, a means of establishing that which is held in common about the topic in question and moving forward the 'held in common' by classroom interaction. Voigt (1995) discusses the reflexivity between learning and interaction and speaks of this reflexivity contributing to a classroom microculture which in turn affects the meaning-making which is taking place.

Choice of Material

Lave and Wenger (1991, pp102,103) address the issue of the transparency of a resource, and this is further examined by Adler (1998, pp8-11). A resource used in a mathematics classroom can be so visible to students that it obscures the mathematics and prevents meaning making. At the same time some visibility is necessary. We want the resource to be visible in the sense that it should direct the gaze of students, so enabling their meaning-making.

Invisibility of mediating technologies is necessary for allowing focus on, and thus supporting the visibility of, the subject matter. Conversely, visibility of the significance of the technology is necessary for allowing its unproblematic- invisible - use. This interplay of conflict and synergy is central to all aspects of learning in practice: it makes the design of supportive artifacts a matter of providing a good balance between these two interacting requirements.(Lave and Wenger, 1991 p103)

Clearly the familiarity of students with technology such as the TI 92 governs its use, in a way which is informed by arguments such as this. As they become more familiar with the software the teacher will be able to introduce the use of more complicated functions without losing transparency.

It is proposed here that these approaches, of a whole class ZPD, of a recognition of local communities of practice, and of negotiated socio-mathematical norms and argumentation have much to offer in looking at how technology, appropriately transparent, can be used in the classroom. In this study such approaches are used, in particular, to analyse social meaning-making in the area of construction and proof using Cabri with the TI 92 hand-held computer with lower school (11-14 years) pupils.

Methodology and Data Collection

A qualitative and ethnographic approach to research has been adopted, with case studies used to provide instances of rich incidents for subsequent analysis. These were subjected to microethnographic interpretive procedures (Erickson, 1986 and Voigt, 1990) Classroom interaction between teacher/researcher and individuals in whole class and group situations was audio recorded and the transcriptions of these recordings analysed. In addition, field notes of memorable incidents were recorded.

Each student had a TI 92 hand-held computer and used the dynamic geometry environment Cabri as available on this machine. An overhead projector version was available for demonstration by pupils and the teacher to the whole class. The following examples were an attempt to set up possibilities for whole class meaning-making with the minimum of previous knowledge of the TI92. The pattern followed was for the class to generate and discuss a simple dynamic image, and to record the result in exercise books as a diagram after the dynamic image had been appreciated. The hand-held nature of the TI92 is particularly suitable for pair discussion and, indeed, for consigning to a corner of the desk when work on paper is preferred.

Collection and Discussion of Data

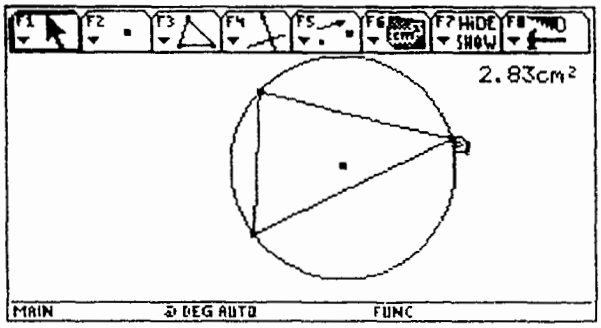

Fig 1

1. The class was asked to draw a circle and a triangle with its vertices on the circle, then to measure the area of the triangle (Fig 1).They were then asked to investigate the effect of dragging **one** of the vertices, and to look for the maximum area of the triangle. In jointly exploring the same screen in this way, but each on their own machine, a telos is created and students are aligned in the domain provided by the technology.

The following dialogue ensued.[1]

JG	What area have you got?	
Class	General response	*There was no restriction on the original diagram, a wide range of areas was possible.*
JG	Why do we all get different answers?	
Alison	Because we all used different circles	*Use of 'we' suggests the possibility of an LCP*
Barry	And different points	
JG	Look at mine while I move the point. Tell me when it will be greatest. What can we all say about our diagrams?	
Barry	It's across from the centre	*Later discussion showed that Barry appreciated the co-linearity of the mid point of one side of the triangle, the centre of the circle and the other vertex. Leanne had realised that the triangle was isosceles*
JG	Yes. good. Anyone else?	
Leanne	It's in the middle	

[1] Throughout this paper the teacher/researcher is JG and pseudonyms are used for pupils.

BEST COPY AVAILABLE

Here the technology could be said to be driving along the LCP. Spontaneous concepts are developed by the participants by looking at the dynamic image, which can then be used by the teacher to interact with scientific concepts (Gardiner and Hudson, 1998), so that that which is 'taken as shared' is moved forward.

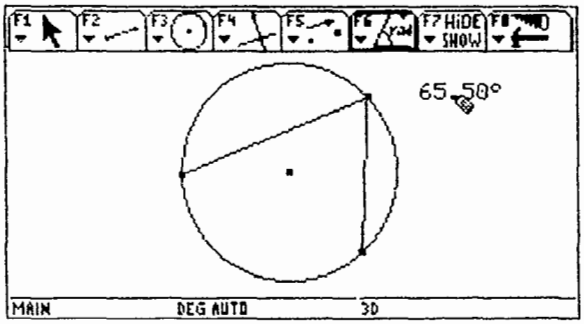

Fig 2

2. Another exercise which is available after only the briefest of introductions to the technology is based on a diagram such as Figure 2. Here pupils were asked to define and measure an angle in a circle as shown and to investigate the effect of dragging any one of the defining points along the circumference of the circle.[2] Transcription of classroom audio recordings resulted in the following dialogue.

JG	Does anyone want to tell me what they have found?		
Sonia	As you move this down it stays the same angle until you reach this point, then it changes to a completely different angle and stays the same.	*In this version of Cabri, if the vertex is moved round the circle until it passes one of the other points, the angle in the other segment, the supplement of the first, is measured*	*'conclusion'*
Nigel	Oh Yeah *(Wonderingly)*		*Drawn into a community of practice*
JG	Will you come and show us		
Sonia	It might not work you know... it might just be because of the shape of this one	*In order to demonstrate the OHP version of the machine had to be used.*	
Tom	It will work.. I got it to work		*Supporting the community of practice*
JG	Watch while she drags this. Watch the angle. Moving up .....angle getting bigger	*Dragging one of the non-vertex points*	

[2] An idea suggested by Geoff Wake of Manchester University

Nigel	If you change the middle one, watch the middle one, it stays the same and after a certain point it changes		*Now a more assured member of the practice*
JG	What's going to happen now?	*Dragging the vertex point*	
Chorus	Stays the same		
Nigel	Until you pass the point, then it will stay the same again		
JG	Look at the angle, it stays at 52.77 degrees, doesn't matter that the line goes through the centre, stays at 52.77. Now changes to.....127.23 *(to Sonia at front)*Can you make it flip between those two angles? *(to class)*What can you tell me about those two angles?		
Anne	Does it add up to 180?		*'conclusion'*
David	Ooo *(realising)*		
JG	Check that those results are true for your diagram		

Referring to criteria mentioned earlier for an LCP (Winbourne and Watson. 1998), here pupils can be said to be sharing tool use and purpose by being aligned in the task and their use of the technology. They are functioning and participating mathematically and recognising the competence of others. There is also, in this dialogue, a sense of telos, in which the pupils are aligned by the technology in a way which drives forward the meaning-making of the community.

Socio-Mathematical Norms and Argumentaion

In the passage quoted above there is evidence of two 'conclusions' (Yackel, 1998 p210) being reached (as indicated), without oral evidence of warrant and backing. However it appears that, in this dynamic geometry environment, warrant and backing are supplied by the shared experience of data generated by the technology.

Conclusion

This research has indicated how, with a background of individual and class development within a Zone of Proximal Development, the ideas of local communities of (mathematical) practice, telos, socio-mathematical norms and argumentation can be used to indicate how mathematical meaning making in the classroom might be analysed. In particular it demonstrates the benefit of suitably transparent use of technology in promoting alignment of pupil becomings within a whole-class ZPD.

Thanks are due to pupils and staff at Hope Valley College, Hope, Derbyshire

Abstract: The capacity of detecting conceptual mistakes and overcoming them by general explanation is important in the approach to theoretical knowledge, and its development in students calls for the teacher's intervention. Our working hypothesis is that the "voices and echoes game" can function as an appropriate methodology to this end. In order to explore this perspective in depth, a teaching experiment was performed in six classes (grades V and VII). This report provides a partial account of this complex experiment, presents some results and highlights some open research questions.

1. Introduction

Since 1995, the problem of approaching theoretical knowledge in compulsory school has been of major concern for our research group. We have produced an innovative methodology, the "voices and echoes game" (VEG), which is mainly based on Vygotskian elaboration concerning common and scientific concepts and Baktin's idea of "voice". This has been used as a guideline to plan and analyse teaching experiments intended to mediate crucial aspects of theoretical knowledge (see Boero et al., 1997, 1998; Garuti, 1997; for a brief account, see Subsection 2.1).

The research reported in this paper focuses on one aspect of the mastery of theoretical knowledge not yet considered in preceding papers and that is especially relevant to mathematics education: the capacity to detect conceptual mistakes and overcome them by general explanation. The development of this capacity in students calls for the teacher's intervention; our working hypothesis is that the VEG is an appropriate methodology for achieving such development (see Subsection 2.2). In order to explore this perspective in depth, a teaching experiment was performed in six classes (grades V and VII). The object of the experiment was a well known piece of the Plato's "Meno", that concerning the problem of doubling the area of a given square by constructing a suitable square (this means overcoming the mistake which consists of doubling the side length). This report provides a partial account of this complex experiment (see Section 3), presents some results (see Section 4) and puts some open research questions into evidence (see.Section 5).

2. Theoretical background

The purpose of this section is to provide essential background information, as well as (in Subsection 2.2.) some development of the theoretical framework related to the issue dealt with in this study.

2.1. About the VEG

What is the VEG? Some verbal and non-verbal expressions (especially those produced by scientists of the past) represent in a rich and communicative way important steps in the evolution of mathematics and science. Referring to Bachtin (1968) and Wertsch (1991), we called these expressions *'voices'*. Performing suitable tasks proposed by the teacher, the student may try to make connections between the voice and his/her own interpretations, conceptions, experiences and

personal senses (Leont'ev, 1978) and produce an *'echo'*, i.e. a link with the voice made explicit through a discourse. The 'echo' was an original idea through which we intended to develop our new educational methodology. What we have called the *VEG* is an educational situation aimed at activating students to produce echoes through specific tasks, for instance: *"How might.... have interpreted the fact that...?"*

Students' echoes: students may produce echoes of different types (depending on the tasks and personal adaptation to them). In Boero et al. (1997), ***individual and colletive echoes*** were classified. In this report we will focus particularly on *individual resonance echoes*. In this case the student appropriates the voice as a way of reconsidering and representing his/her experience: the distinctive sign is the ability to change linguistic register or level by seeking to select and explore pertinent elements *('deepening')*, and finding examples, situations, etc. which actualize and multiply the voice appropriately *('multiplication')*.

What are the aims of the VEG? Our general, *initial* hypothesis on this issue was that the VEG might broaden the students' cultural horizon, embracing some elements of theoretical knowledge that are difficult to construct in a constructivist approach and difficult to mediate through a traditional approach (see Boero & al, 1997). The need to exploit the potentialities that emerged in the first series of teaching experiments led us to try to *characterize better the elements of theoretical knowledge* to be mediated through the VEG (cognitive strategies, methodological requirements, speech genre, etc.), in order to organize and analyse better their interiorization by students (see Boero & al, 1998)

2.2. Conceptual mistakes and the VEG

The research reported in this paper concerns another important potential of the VEG, namely the possibility of intervening in aspects of the student's mastery of theoretical knowledge - those related to detecting conceptual mistakes and overcoming them by general explanation.

The Vygotskian elaboration about consciousness as a condition for accessing scientific concepts, clearly pointed out by Vygotskij in his seminal work about "common concepts" and "scientific concepts", seems to be useful to frame this complex operation. According to Vygotskij (1990, chap. VI), consciousness is related to mastery of scientific concepts for different reasons: "scientific" concepts are not isolated (and consciousness is needed to control connections and inner coherence of the system); "scientific" concepts are explicit (and consciousness is needed to manage explicitation and especially the relationship between mediating signs and meaning); "scientific" concepts are in dialectic relationship with common ones (and consciousness is needed to be aware of the borders between them). During an activity in which students participate effectively in examining their conceptual mistakes, all these aspects where consciousness intervenes can come into play: contradictions with known properties are frequently a motive the teacher advocates for helping students recognize a conceptual mistake; explicitation of some concepts is needed in order to point out ambiguities that may be the root of mistakes; in many cases the teacher must point out that common intuition is a possible source of mistakes.

But how can productive classroom activities concerning students' conceptual mistakes be organised? According to Bachelard (1977) many conceptual mistakes come from ancient knowledge that is appropriate in earlier situations but which is no longer suitable. The teacher must take the responsibility for selecting and proposing appropriate tasks (those which lead to crisis of the ancient knowledge) and for helping the student to overcome his/her mistakes. The teacher's role is central for other conceptual mistakes as well: for instance, those related to misunderstandings or ambiguities. What's more, the student must be aware of the role played by the teacher and his own role as a condition for being able to reproduce by himself, in the future, the sequence of actions needed to detect and overcome conceptual mistakes (cf. Brousseau, 1997).

Our working hypothesis was that the VEG could intervene as an appropriate educational methodology for attaining both the aims pointed out in preceding analyses: to develop students' consciousness about the functioning of theoretical knowledge when conceptual mistakes come into play; and to promote awareness of the teacher's and student's roles during classroom activities concening conceptual mistakes. Indeed, detecting and overcoming conceptual mistakes plays a crucial role in the evolution of mathematics and science. It is therefore natural that the history of mathematics and, more generally, the history of culture should offer "dialogical voices" that speak about this issue (exchange of letters, imaginery debates, etc). The production of "echoes" of well chosen "dialogical voices" during suitable tasks could lead students to participate consciously in the process of detecting and overcoming conceptual mistakes as a preliminary step towards interiorization.

The teaching experiment reported in this paper was planned and performed in order to test and develop our working hypothesis.

3. Method

3.1. The choice of voice

Plato's "Meno" presents some crucial aspects of Plato's theory about learning (how the "learner" can reach truth) and teaching (how the "teacher" can help the "learner" to reach truth). Plato's general, underlying hypothesis is that forgotten truth can be restored ("recollection") through an effort by the "learner" led by the "teacher" and motivated by the fact that "*now not only is he ignorant[...] but he will be quite glad to look for it*". The crucial mediational tool is the "socratic dialogue", i. e. a dialogue intended to provoke crisis and then allow it to be overcome. In this framework, the excerpt concerning doubling the area of a given square is crucial as a practical demonstration:

Phase A) Socrates asks Meno's slave to solve the problem of doubling the area of the square by constructing a suitable square; the slave's answer (side of double length) is opposed by Socrates through direct, visual evidence (based on the drawing of the situation).

Phase B) Then the slave is encouraged to find a solution by himself - but he only manages to understand that the correct side length must be smaller than three halves of the original length. Socrates' comment is that from this moment on, the slave can learn: *"Nor indeed does he know it* [the solution] *now, but then he thought he knew it* [...] *Now however he does feel perplexed. Not only he does not know the answer; he doesn't even think he knows".*

Phase C) Socrates interactively guides the slave towards the right solution (achieved through a construction based on the diagonal of the original square).

We may remark that in Phase A) the slave's answer is similar to those usually produced by young students when they tackle the same problem - this fact offers an opportunity to involve students strongly in the VEG! And we may recognize in Phases A), B), C) a sequence of activities not dissimilar from some present-day views about how to guide students towards taking into charge and overcoming their conceptual mistakes. This is true especially from a Vygotskian perspective, where the teacher takes a strong mediating role in the evolution of students' culture.

We chose to ignore "recollection theory" in classroom activities. This entails a violation of the authenticity of the historical source. But our aim was to lead students to grasp that a general explanation must be reached in order to definitively overcome a mistake. And, in general, compromises of this kind appear unavoidable if we want to exploit historical sources in the classroom (cf. Fauvel, 1991).

3.2. The choice of classes

Six classes (114 students) took part in this teaching experiment: five fifth-grade classes and two seventh-grade classes.These classes belonged to different school settings (four primary school classes and two junior high school classes) and to different educational contexts (in particular, three fifth-grade classes were following the Modena Group Project on "mathematical discussion", one was following the Genoa Group Project). Their socio-cultural backgrounds were extremely different. This set of classes was chosen in order to reveal "invariant" elements and significant conditions for the productivity of the methodology.

As concerns the mathematical background, the students were able to measure lengths and construct squares; they had met the concept of area of a plane surface in the preceding months and knew how to calculate the area of a given square.

3.3. Teaching sequence planning and observations

The teaching sequence can briefly be described as follows:

i) students are briefly informed about the whole activity to be performed; then they individually try to solve the same problem posed by Socrates to the slave. The aim of this activity is to involve students in the problem dealt with in the voice;

ii) students approach the voice under the teacher's guidance: firstly, they read and try to understand (with the help of the teacher) the three phases of the dialogue; then they read the whole dialogue aloud (some students playing the different characters); finally, they discuss (Disc. I) the content and the aim of the whole dialogue, trying to understand (under the teacher's guidance) the function of the three phases. After negotiation with students, a wall poster is put up summarising the three phases in concise terms. This suggests the structure of the following echo;

iii) the teacher presents the students with some, possible mistakes that could become the object of a dialogue similar to Plato's, and they are invited to propose other mistakes. The aim is to negotiate and agree on a mistake that is appropriate for the echo (i.e. a relatively frequent student mistake that is recognized as a mistake by students and can be exhaustively explained through a discussion guided by the teacher). Here is a sample of the 5 mistakes that were chosen in the 6 classes:

"By dividing an integer number by another number, one always gets a number smaller than the dividend" (the two seventh-grade classes: see Annexe for two examples of echoes).

"By multiplying an integer number by another number, one always gets a number bigger than the first number" (one V-grade class).
"By multiplying tenths by tenths, one gets tenths" (another V-grade class).

iv) students discuss (Disc. II) about the chosen mistake, trying to detect (under the teacher's guidance) good reasons explaining why it is a mistake, then trying to find partial solutions, and finally arriving to a general explanation. The aim of this discussion is to create the common base of mathematical knowledge needed to construct the echo, and prepare its three phases;

v) students individually try to produce an echo, i.e. a "socratic dialogue" about the chosen mistake;

vi) students compare and discuss (under the teachers' guidance) some individual productions.

All the individual productions and recordings of the Disc. I and II are available; for the other discussions the teachers took notes.

3.4. Analysis of students' behaviours

In line with the educational aims of the teaching experiment we drew up the following guidelines for the analysis of students' protocols:

I. How the student keeps to the roles of Socrates and the slave in each phase of the dialogue. This point is related to the aim of developing awareness about the teacher's and the student's roles in the activities concerning conceptual mistakes;

II. How the student appropriates the roles of the phases of the dialogue in detecting and overcoming the mistake. This point is related to the aim of promoting consciousness about the mechanisms of detecting and overcoming mistakes;

III. How the targeted mathematical content (the knowledge allowing the students to overcome the mistake) is appropriated by the student: are the choice and presentation of counter-examples appropriate? Is the guiding of the slave performed through general, theoretical considerations about the knowledge in play?

4. Some Results

This section reports a selection of results we consider to be of interest.

Here we will consider only the 102 students from grade V to VII who took part in the whole activity. Only 6 students completely fail their echo (do not produce a dialogue, or mixed up Plato's original dialogue with the new situation).

Roles in the echo: Among the other 96, 10 show serious difficulties in keeping to the roles of Socrates and the slave in Phase I. Appropriate "deepenings" (including original expressions intended to highlight the mistake and provoke the slave's crisis) and "multiplications" (including choice of appropriate counter-examples not presented in Disc. II) are found in almost all the other students' texts.

Detailed comparison between fifth- and seventh-graders is inappropriate, as different mistakes were tackled in different classes. However, the percentages related to success in keeping to the roles in Phase I do not differ much.

It is not easy to detect Phase 2 in the students' protocols: students were not asked to separate the three phases. And for some of the mistakes chosen it is objectively difficult to create a specific Phase-II dialogue!

At least 67 (out of the 96 students) have serious difficulties keeping to the roles of Socrates and the slave in the last phase of the echo. In many cases the quality of the interaction between Socrates and the slave suddenly changes from

BEST COPY AVAILABLE

Socrates' questioning in order to make the slave understand, to Socrates' presenting some formulas or procedures in order to avoid the mistake, (see end of TEXT 1) with the slave reduced to a passive role of listener. In the same cases the quality of deepenings and multiplications falls: the expressions become "assertive", not "explanatory", and the examples (if any) stick closely to those discussed in Disc. II.

Consciousness about how to detect and overcome mistakes: We obtained good overall results about the consciousness of the fact that appropriate counter-examples can reveal the mistake. This kind of consciousness was attained by practically all the students (86) who kept to the roles in the first phase of the dialogue, as shown by the "multiplications" and "deepenings" in their echoes.

At least 50 students out of these try to give a general "explanation" of the mistake or find a general "rule" in the third phase of the dialogue, showing to be aware of the necessity of doing it.

Mathematical content: We must distinguish between: **I)** consciousness about the fact that a statement is false; **II)** consciousness about the reasons that may provoke the mistake; and **III)** consciousness about the theoretical reasons "why it is false" and how to overcome the mistake in general (i.e. the connection with systematic mathematical knowledge that can frame the mistake and the correct solution). As remarked above, the first level of consciousness seems to be reached by all the students who keep to the roles during the first phase of the dialogue. One half of these students reach the second level of consciousness (see TEXT 1 and TEXT 2).It is interesting to note that there is also an almost complete coincidence, across tasks and classes, between the students who are able to attain the third level of consciousness and those who are able to keep to the roles throughout the third phase of the dialogue (see TEXT 2). The breaking point in reaching the third level is well exemplified in TEXT 1: the student tries to explain why the result of the division is larger than the dividend if the divisor is smaller than one. An appropriate geometric example (similar to those considered during Disc. II) is provided. The interactive structure of the presentation is kept. Then the student tries to move to a general explanation. Some lines are written and then crossed out. At the end, a rather confused rule is provided and Socrates takes the role of he who "gives the rule". Compare with TEXT 2: here a real interaction is maintained in the last phase as well, and seems to be perfectly functional to the development of a complex inner discourse concerning the mathematical knowledge in play. Remarkably, "Socrates" considers both the operational side (how to divide an integer number by a fraction) and the explanatory side (why it is necessary to behave in such a way). The dialogue allows these two sides to be represented in a clear way.

5. Discussion

The above description of students' behaviours raises an interesting research question about the reasons why there is an almost complete coincidence between students who keep to their roles during the different phases of the discussion, and students who reach the different levels of consciousness about the knowledge in play. A possible interpretation refers to the dialogical nature of the acquisition of theoretical knowledge (cf. Brown, 1997, Chapter 2, for some hints in this direction) and could be summarised as follows: Plato's voice presents a model of

dialogical treatment of mistakes; at the beginning, by echoing this voice, students are forced (during both the discussions and the individual production of the echo) to make explicit the knowledge which originated the mistake. Indeed the need to keep to the roles can entail a shift to an inner questioning: *"What idea about the knowledge in play should the slave bear"*. This interpretation is justified by the fact that (as happens in TEXT 1 and in TEXT 2: see (°)) the *"idea about the knowledge in play"* is expressed in most cases by the slave and not by Socrates. In this way the transition to the second level of consciousness about the knowledge in play is realised. The passage to the third level is performed in two steps: first, by considering examples (with the dialogical function of bringing the slave to see how the appropriate knowledge could work, and the inner function of better understanding how it does work); and second, by shifting to theoretical framing of the examples. Here, the breaking point described at the end of Section 4 could be interpreted as follows: under the necessity of posing appropriate questions to the slave, some students are able to answer the inner question: *"How is the correct rule related to the meaning?"*- i. e. to the examples tackled by the slave. Indeed in these cases (see TEXT 2) Socrates keeps to his questioning role: the inner question is transformed into appropriate questions posed to the slave. The other students are not able to keep to the role of Socrates: perhaps because the shift to the inner question *"How is the good rule related to the meaning?"* is too difficult. Or, more probably, because it no longer concerns the slave in an immediate way and it is difficult to find appropriate questions for him, and so a traditional model of teaching prevails (it is the teacher who provides the rule!).

Further experiments (possibly with on-the-spot interviews with students who fail at the "breaking point") are needed to test the validity of this interpretation, whose research and didactical implications might be significant as concerns the potential of exploiting dialogical voices for the VEG.

Seventh graders. Mistake chosen: *"Dividing an integer number by another number, one always gets a number smaller than the dividend."* Two texts from the same classroom.

SQ=Socrates, SL=Slave

TEXT 1 (mean level production)

SQ:*Tell me, my boy, do you know the result of this division: 15:5?* SL: *It is simply 3, Socrates.* SQ: *And now try to perform the following division: 15:3 What is the result?* SL: *Clearly 5.*

Socrates. SQ*: Look at the results and try to tell me how they compare to the dividend.* SL*: They are smaller, Socrates.* SQ*: In your opinion, does this happen for all divisions?* SL*: Yes, surely* SQ*: Could you explain why?* SL*:(°)Naturally: this happens because if I divide one thing I do not have it, but only one piece of it, so the part is smaller in relationship to the whole.* SQ*: Fine. Can you tell me the result of the following division: 15:1 ?* SL*: Fifteen, Socrates.* SQ*: Look at this number and think. How does it compare with the dividend?* SL*: It is equal. Socrates.* SQ*: So then a division does not always generate a result smaller than the dividend!* SL*: My Zeus! It is true.* SQ*: Now try to perform the following division: 15:0.5. What is the result?* SL*: Thirty, Socrates.* SQ*: But 30 is greater than the dividend 1.* SL*: It is true!*

II- SQ*: Tell me, slave: which divisions generate a result that is smaller, equal to or bigger than the dividend?* SL*: Smaller: 15:3=5; equal: 15:1=15; bigger: 15:0.5=30*

SQ*: How do the three divisors compare with one?* SL*: In the first division, greater; in the second, equal; in the third, smaller.* SQ*: Is there any link?* SL*: There may be.* SQ*: Could you say what it is?* SL*: For Zeus, no!* SQ*: You see, Meno: before your slave was sure in answering, while now he finds himself in difficulties. Before he was convinced he knew, while now he does not know. But he knows his mistakes and will no longer fail.*

III - SQ*: Slave, could you say how many times 0.5 is contained in 1?* SL*: Twice, Socrates.*

SQ*: And 0.25?* SL*: Four times, Socrates.* SQ*: Try to write the decimal number 0.5 as a fraction.* SL*: The fraction is 1/2.* SQ*: But how much is 1/2 compared to 1?* SL*: It is one half.* SQ*: Then if 1 is contained an integer number of times in another number, how many times one half will be contained?* SL*: Double, Socrates.* SQ*: But in your opinion is it correct to divide a division by another division?* SL*: No.* SQ*: Indeed you have now seen that one half of one is contained twice. It will be sufficient to turn over the division, i.e. to perform the multiplication of the given integer number by the denominator and we will got the result. What we have performed shows us how many times a decimal number can be contained in an integer number.* SQ *we have got a ratio between them.* SL*: Now I understand my mistake. Bye, Meno is calling me.*

TEXT 2 (High level production)

SQ*: Tell me, my boy, what is the result of 15:3?* SL*: Five.* SQ*: Is it smaller than 15?* SL*: What a question! That is clear!* SQ*: And yet, how much is it 20:5?* SL*: Obviously 4, Socrates* SQ*: Then is it smaller than 20?* SL*: Exactly.* SQ*: Then, how do you think that results of the divisions are?* SL*: I think that they are always smaller than the dividend.* SQ*: Are you sure?* SL*:(°) Yes, because "to divide" means "to break in equal parts."*SQ*: Now perform this division: 15:1.* SL*: Uhm, ...it makes 15.* SQ*: But 15 is equal to the dividend.* SL*: It is true.* SQ*: Why is it equal?* SL*: Because dividing by one is how to give an amount to one person, it remains equal.* SQ*: So does your theory still work?* SL*: Not completely. Now I see that in some cases it does not work.* SQ*: Are you still sure you are right?* SL*: Yes... Pehaps... No... Perhaps there is one case in which the result is larger...or perhaps not... My Zeus, I understand nothing! (five minutes elapse).* SQ*: What is the result of 2:0.5?* SL*: These are difficult questions. I am no longer able to answer.* SQ*: Take this square* (drawing)*and divide it into small squares!* SL*: This way?*(the drawing is divided into 16 pieces by drawing 3 horizontal and 3 vertical lines, all equally spaced) SQ*: Yes, good. Now the unit is the small square* [drawing]*. How much is 0,5 compared to 1?* SL*: One half.* SQ*: Now make one half of the small square.* SL*: Done.* SQ*: Do the same for all the small squares.* SL*: Just a moment...Done.* SQ*: How many halves?* SL*: 1,2,3... 32, Socrates.* SQ*: How many unit squares, at the beginning?* SL*: Sixteen, Socrates.* SQ*: Then you got a result greater than the starting number.* SL*: Uhm... Of course.* SQ*: And how is one half written as a fraction?* SL*: Uhm... perhaps 1/2.* SQ*: Good! Are you able now to divide a number by a fraction?* SL*: Yes, surely!* SQ*: Then divide 2 by 1/2. How many times is 1/2 contained in 2?* SL*: According to the preceding rule, I must invert the fraction and then multiply. OK, it makes 4.* SQ*: How can you represent this?* SL*: I'll try... Two squares..*[drawing] *One half twice for each* [drawing] *It works: 4.* SQ*: Good!* SL*: I understand: the division is not only "breaking into equal parts", but also seeing how many times a number is contanined in another!* SQ*: Make an example by yourself!* SL*: 1:1/4* [he performs and illustrates it]

MALE AND FEMALE CALCULUS STUDENTS' USE OF VISUAL REPRESENTATIONS

Elizabeth Ann George
Ball State University

The frequency with which mathematically capable high school students utilized visual representations in their written solutions to applied calculus problems and the nature of the visual representations they created were analyzed in this study. Several gender differences with respect to visual representation use were identified. Females drew diagrams more often than did males and were more likely to create complex visual representations by modifying given diagrams. Males, who were more successful in solving these problems, tended to construct fewer and simpler diagrams.

Students encounter visual representations throughout their study of mathematics. Diagrams, figures, and graphs are frequently components of instructional explanations offered by teachers and in textbooks. In addition, many mathematical problems found in written curricular materials or on tests include an accompanying visual representation which students must interpret or may modify. In solving problems in which no visual representation is given, construction of a visual representation is often helpful, advantageous, or, moreover, an essential component of the solution process. There is great diversity in the types of mathematical problems whose solutions require or are facilitated by reasoning with visual representations and in the ways that students can use visual representations when solving these problems.

Reasoning with visual representations is particularly crucial in understanding the theories and applications of calculus. Understanding fundamental calculus concepts (e.g., limit, derivative, and integral) requires significant use of visualization, and the ability to successfully solve many problems using calculus is dependent on visual images, either in the form of diagrams or graphs (Zimmerman, 1991). Yet throughout their study of mathematics, students' demonstrate a reluctance to visualize (Eisenberg & Dreyfus, 1991), and this behavior is particularly disturbing when displayed by students studying calculus (Vinner, 1989).

Though reasoning with diagrammatic representations offers many potential benefits, students who use visual representations are not necessarily more successful in their mathematical studies. Presmeg (1985) observed that high school students who preferred to use visual methods in solving mathematical problems often experienced difficulties in learning mathematics, while students who were identified as higher achievers in mathematics classrooms were almost always nonvisualizers. This pattern may prevail in college-level mathematics courses as well. College

calculus students who indicated a stronger preference for using visual methods achieved lower scores in calculus, while those students who showed less preference for visual methods achieved higher scores (Galindo, 1995).

Differential mathematics achievement of male and female students has been studied at various age levels and in many areas of mathematics during the past twenty-five years (Fennema & Hart, 1994). Gender differences in mathematics learning appear to be more pronounced for older than for younger students, most notably on problem-solving tasks and application problems (Friedman, 1989). Significant gender differences in mathematical achievement have been identified on national assessment tests (i.e., NAEP), as high school males consistently outperformed their female classmates (Fennema & Carpenter, 1981; Silver et al., 1988). Observing that the magnitude of the difference between male and female students' performance increased in relation to the amount of mathematics studied, Meyer (1989) suggested that gender differences in mathematics achievement resulted from the best males performing at a higher level than the best females. When examining mathematical achievement in actual classroom settings, Seegers and Boekaerts (1996) found that tests reflecting classroom content also showed marked gender differences, with males outperforming females. They also observed that the differences increased when the items covered topics that were more complex.

Several studies have identified gender differences when investigating the relationship between mathematics achievement and the use of visual representations. When solving tasks where males were more successful than females, females reported a greater use of pictures, though the pictures that males drew were more accurate and contained more pictorial information than those drawn by females (Fennema and Tartre, 1985). A stronger relationship between high spatial visualization ability and mathematical problem-solving success was found for females than for males. Battista (1990) concluded that males were more successful than females in solving geometry problems and that spatial visualization and logical reasoning were important factors in geometry problem solving for both male and female students, but that they contributed in different ways to achievement, depending on gender. Gender differences in visualization skills and the calculus achievement of college students were also identified by Ferrini-Mundy (1987). Explicit training in spatial skills, particularly in visualizing a three-dimensional solid of revolution from a two-dimensional representation, positively affected female students' abilities to draw visual representations of the solids of revolution and improved their mathematical problem-solving performance in the applications of integral calculus. No such effect was identified for male students.

Further research regarding gender differences in mathematics learning has been advocated (Leder, 1992), particularly the need for studies that focus on young women who have been successful in their mathematical studies (Becker, 1991). This study, whose purpose includes an investigation of the ways that mathematically

capable male and female students reasoned with visual representations in solving applied calculus problems, aspires to provide further insight into gender similarities and differences in mathematical problem solving.

Specifically, this study investigated the frequency of visual representation use and the nature of the visual representations created in students' written solutions to five free-response problems presented on the 1996 BC Level Advanced Placement Calculus Examination. Gender differences in achievement favoring males were significant for each of these free-response problems, as well as for overall scores on this examination (Morgan, 1996). Therefore, differences in the frequency of visual representation use and in the nature of the diagrams, figures, and graphs created were analyzed for subgroups of students, based upon gender and problem-solving success.

Frequency of Visual Representation Use in Solving Calculus Problems

Randomly selected from the approximately 21,000 high school students who took the BC level Advanced Placement Calculus Examination in May 1996 were 600 students' written solutions to the free-response questions. This sample was partitioned into subgroups along two dimensions, gender and overall performance level on the Advanced Placement Calculus Examination, as shown in Table 1. For purposes of this study, the five levels of overall AP scores were collapsed into three performance levels. There was no significant difference in the gender distribution between the sample and the population.

Table 1

Number of Students Achieving at Each Performance Level

	Males	Females
High scorers (5 or 4)	251	97
Moderate scorers (3)	82	65
Low scorers (2 or 1)	56	49

Students' solutions to five free-response problems were coded with respect to visual representation use. Three of the free-response problems included a given diagram in the problem statement; therefore, visual representation use included modification of the given diagram or construction of a new diagram. Construction of a new diagram constituted visual representation use in the other two free-response problems whose problem statements did not include a given diagram. A visual representation use (VRU) score was computing for each student, measuring the number of free-response problems for which evidence of diagram use was identified in the written solutions. The distribution of VRU scores for the 600 students in the sample is shown in Table 2.

Table 2

Distribution of VRU Scores

	VRU score					
	5	4	3	2	1	0
Number of students	44	147	169	134	84	22
Percent of students	7.3	24.5	28.2	22.3	14.0	3.7

The mean VRU score for the sample was 2.78, and the mean VRU scores for various subgroups of students are shown in Table 3. Using a two-factor analysis of variance and an alpha level of .05, differences in the frequency of visual representation use associated with gender ($F(1,594) = 36.51$, $p < .001$) and with performance level ($F(2, 594) = 4.42$, $p = .012$) were significant. The interaction effect of gender and performance level was not significant.

Table 3

VRU Score Means and Standard Deviations for Subgroups of Students

	Males	Females	Total
High scorers	2.73 (1.24)	3.26 (1.16)	2.88 (1.24)
Moderate scorers	2.33 (1.28)	3.09 (1.20)	2.67 (1.29)
Low scorers	2.23 (1.31)	3.04 (1.15)	2.61 (1.30)
Total	2.57 (1.27)	3.16 (1.17)	2.78 (1.27)

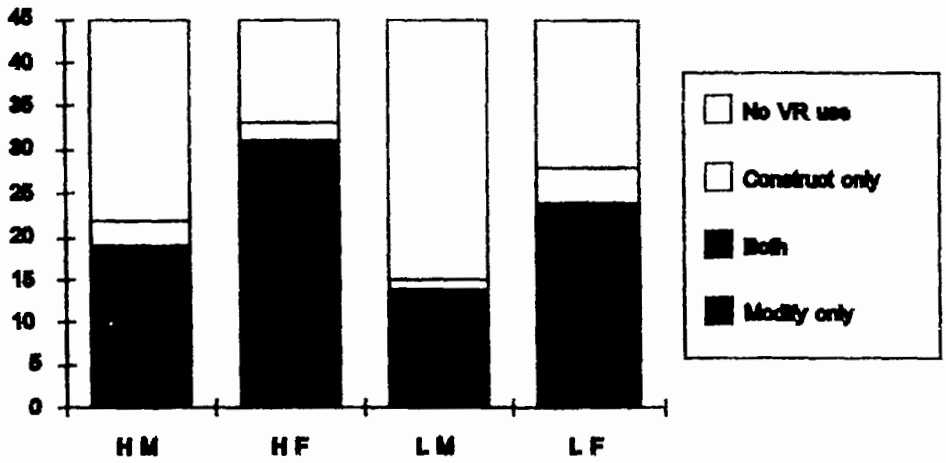
Determination of whether the pattern of visual representation use identified from the aggregated VRU score held for each free-response problem prompted further investigation. Thus, a within-question analysis of the frequency of visual representation use was conducted and revealed that, when solving each of the five free-response problems, the written work produced by females included use of visual representations more often than did the written work completed by males (George, 1998). The differences in frequency of visual representation use between male and female students were statistically significant at an alpha level of .01 in three of the five free-response questions. Recall that for both this sample and the population of students who took the 1996 BC Level Advanced Placement Calculus Examination, males significantly outperformed females, as measured by mean scores achieved on the examination and mean scores achieved on each free-response problem. Therefore, female students demonstrated more evidence of visual representation use in their written solutions and were less successful in solving the

posed problems than were male students, who produced fewer visual representations and were more successful.

Descriptive Analysis of the Visual Representations Students Created

Gaining further understanding into the relationship between students' visual representation use and problem-solving success required that the wide variety of diagrams, figures, and graphs modified or constructed in their written solutions be described and compared. Therefore, a qualitative analysis was conducted to more closely examine the visual representations students produced in solving selected free-response problems. The written solutions of 180 of the 600 students were further analyzed with respect to visual representation use. Specifically, similarities and differences were identified in the ways visual representations were modified and constructed by 45 students in each of four subgroups (i.e., high- and low-scoring males and females). Results of the analysis of one of the free-response problems is presented below.

One application of differential calculus which depends heavily on reasoning with visual representations is the solving of related rates problems. A common feature of this type of problem is the implicit variable of time. In these problems, several piece of descriptive information are given: the relationships of quantities in general regardless of time, the relationship of quantities at a specific moment in time, and information about the direction and rate of change. The dynamic nature of such problem situations often must be represented in diagrams that are static. Initially, such diagrams are drawn and labeled to illustrate only one moment in time. Subsequently, the problem solver must impose motion on these drawn diagrams in deciding whether specific quantities remain constant or change over time.



The following related rates problem was presented on the 1996 BC level Advanced Placement Calculus Examination (College Board, 1995):

> An oil storage tank has the shape shown above, obtained by revolving the curve $y = \frac{9}{625}x^4$ 0 from $x = 0$ to $x = 5$ about the y-axis, where x and y are measured in feet. Oil weighing 50 pounds per cubic foot flowed into an initially empty tank at a constant rate of 8 cubic feet per minute. When the depth of the oil reached 6 feet, the flow stopped. Let h be the depth, in feet, of oil in the tank. How fast was the depth of oil in the tank increasing when $h = 4$? Indicate units of measure.

Although all the information necessary to construct a visual representation of this problem situation was stated in words, an accompanying diagram was given. The graph of the function was drawn on the coordinate plane and reflected over the y-axis. Perspective was added to illustrate the oil tank and its radius of 5 feet and height of 9 feet were explicitly labeled.

A frequency distribution of the ways in which visual representations were used by the four groups of students in solving this related rate problem is displayed in Figure 1. Overall, the written solutions of females indicated use of a visual

representation significantly more often than did the written solutions of males (68% and 41%, respectively). Eighty-eight given diagrams were modified and 20 new diagrams were constructed in students' solutions. Female students were significantly more likely to only modify the given diagram than were males (58% and 29%, respectively). More high-scorers than low-scorers both modified the given diagram and constructed a new diagram within their written solution.

0

Figure 1. Frequency of visual representation modification and construction by high- and low-scoring male and female students in solving the oil tank problem.

A closer examination of the nature of the visual representations created by male and female students was accomplished by identifying the features which students highlighted when modifying the given diagram or which they included when constructing a new diagram. Four categories were identified in the oil tank problem to describe students' modification of the given visual representation: adding pictorial elaboration, labeling with numerical constants, labeling with variables, and marking of cross-sections. Overall, half of the students who modified the given diagram did so by simply adding pictorial elaboration and/or labeling with numerical constants; the other 50% produced more complex diagrams by labeling with variables and/or drawing a cross section. Females produced more complex diagrams than did males, as 56% (31 of 55) of the females and 39% (13 of 33) of the males who modified diagrams labeled the given visual representation with variables and/or drew cross sections. Of the four subgroups of students, high-scoring females produced the largest number of complex modified diagrams (61%); their solutions often included both labeling of variables and drawing of cross sections. While 50% of low-scoring females' solutions also contained complex modified diagrams, only 42% of high-scoring males and 36% of low-scoring males demonstrated this level of complexity in their modified diagrams.

Three categories were used to describe the new visual representations students constructed: a graph of the function on the x-y plane, isolated three-dimensional figures, and isolated cross-sections. Nearly half of the students

who only constructed a new diagram (9 of 20) produced a graph of the given function on the coordinate plane, then labeled and marked this graph in various ways. The others drew isolated figures, either three-dimensional solids or cross sections which were removed from the coordinate plane. Males tended to construct simpler diagrams than did females.

Similar analyses conducted on other free-response problems revealed that the nature of the visual representations used by males and females differed primarily in the complexity level of the diagrams they created (George, 1998). Males tended to focus more narrowly on the graph of the function or the geometric figure on which the problem situation was based. More females than males chose to only modified the given visual representations, often combining actions of pictorial elaboration, highlighting of cross sections, and algebraic labeling to create more complex visual representations. For all students there was greater diversity displayed in the ways they modified the given diagrams than in the ways they constructed new diagrams.

Results of this study show that mathematically capable high school students frequently used visual representations in their solutions to applied calculus problems and that there was great diversity in the visual representations they created. Recognition of the gender differences identified in this study can lead mathematics educators to make more explicit and informed decisions about visual representation use in curriculum materials, classroom instruction, and assessment both prior to and during the study of calculus, providing opportunities for all students to become more successful mathematical problem solvers.

Abstract

In this paper, we are presenting the results of a quantitative study concerning the effect of an innovative teaching model, based on Problem Solving approach, on the ability of 11th grade students in solving Real Problems and purely Mathematical Exercises. The research indicates that emphasis on this kind of teaching improves not only students' abilities in handling Real Problems themselves, but also it improves their abilities in dealing with pure mathematical ideas.

1.Introduction

The general goal of this research is to examine under which conditions, high school students can use their acquired mathematical knowledge in solving Real Problems. More precisely the research intends to study:

a) The effectiveness of Modelling Orientated Teaching, described below, as a general frame of learning mathematics, in the development of mathematical concepts and the ability of handling Real Problems.

b) The role of the Context of Real Problems at student's performance.

2. A theoretical framework

Questions concerning the adoption of applications and real problems have attracted the attention of many researchers the last years. Some of these questions are about the educational philosophy and goals that are served by mathematical applications. Others are about the way we will be able to incorporate mathematical applications in the schoolbooks and in everyday educational practice, in order to achieve specified goals.

Berry et al (1984), Berry et al (1986), Berry et al (1987), Blum, Niss, Huntley (1989), Blum et al (1989), Niss et al (1991), De Lange et al (1993), have been concerned with these questions.

Blum (1991), in order to accommodate Applications and Modelling in schoolbooks, put forward three aims of mathematical teaching, (see also Blum and Niss (1991)):

1. Pragmatic aims: Mathematics helps us describe, comprehend, explain and handle real situations.

2. Formative aims: Mathematics help us develop general skills, for example, the formulation of a mathematical model for a real situation, or attitudes, such us the desire for mental work.

3. Cultural aims: Mathematics as a reason for philosophical and scientific thought, as a science and as a part of the human history and civilization.

Blum and Niss (1989,1991) categorized the various approaches in organizing the teaching of Problem Solving, Modelling and Applications as follow:

1) The Separation Approach

2) The Two Compartment Approach

3) The Island Approach

4) The Mixing Approach

5) The mathematics Curriculum Integrated Approach

6) The Interdisciplinary Integrated Approach.

We are particularly interested in the Island Approach, since it is quite widespread and it is the approach used in throughout Greek high schools. According to this approach the book is organized in units, each one introducing the material in a definition-theorem-proof-corollary-exercise scheme, and then applications follow, directly connected with the material just presented. According to Blum and Niss (1989,1991), in this approach « the closer in time and content the relationship is between pure mathematics sections and subsequent sections concentrating on problem solving, modelling and applications, the more the latter sections tend to assume the character of being traditional exercises».

In an attempt to improve upon the Island Approach, Klaoudatos (1994) developed a teaching model, which he calls "Modelling Orientated Teaching". Klaoudatos' model consists of three stages:

1. Conceptual modelling:

In this part, mathematical modelling develops the conditions in which the need arises for the introduction of a concept. For this purpose we select the appropriate problems, the solution of which calls for the introduction of the concept we want to teach, while the didactical activities and in particular the didactical situations we design for the

occasion are aimed at developing a conjecture about the *hidden* concept.

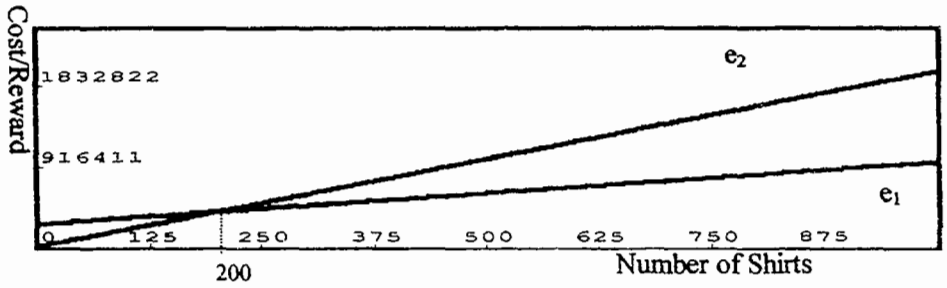
2. Abstraction and formalization of mathematical concepts:

This part includes the development, the mathematical processing and the formation of a mathematical theory for the concept we want to teach about. This part is not a *substitute* for the traditional theory, as we know it, but attempts to ensure the independence of the concept from the specific contexts in which it was presented in part 1. In particular, the concept we have developed in part 1, must become a *mathematical object*, i.e. it must be viewed in mathematical context, regardless of any specific problem or individual. This aim is achieved by means of control and verification of the conjecture, as well as through deductions, generalizations and proofs. Consequently, the didactical activities are aimed at *institutionalizing* the knowledge.

3. Applied modelling:

Part three brings into focus all the possibilities of the modelling circle and it is here that the ideas and concepts we have taught are consolidated, reinforced and extended. In this part the concept or concepts are considered as already known and we use them in order to solve problems and applications.

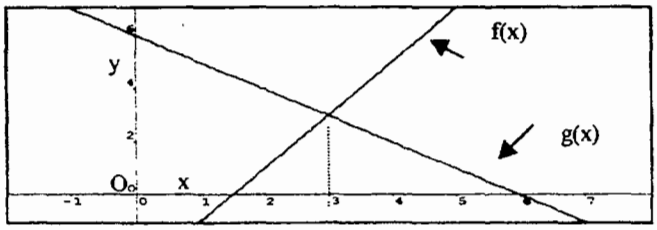
Klaoudatos' model is an extension and elaboration of a teaching model proposed by de Lange (1987, 1989) within the realm of "Realistic Mathematics Education", in which the "abstraction and formalization of mathematical concepts" does not appear as a special part.



3.The methodology of the research

The research was designed for students of the 11^{th} grade. It was realized at a senior high school in Athens during the school year 1997-98.Four sections participated, sections A, B, C, D (a total of 97 students). A teacher experienced in practicing the Modelling Oriented Teaching taught students of sections C and D (experimental group), by this teaching method, through the whole year. On the other hand, an experienced teacher who used the traditional Island Approach way of teaching taught students of sections A and B (control group). Both the assignments of students and teachers to the various sections were completely random. Throughout the previous academic year 1996-97, the same students were taught in a homogeneous fashion, following the Island Approach.

We gave two tests to the students. The tests were administered one month before the end of the school year 1997-98. Test 1 deals with "raw" Real Problems (R.P.), taken from real situations, described in layman's language, where Test 2 was composed of typical Mathematical Exercises (M.E.) stated in a formal mathematical language. Test 1 was given first and Test 2 followed one week apart. The questions of these two tests were in a strict one to one correspondence, corresponding questions were requiring exactly the same mathematical tools for their solution. Just the language used was different. Here are two examples:



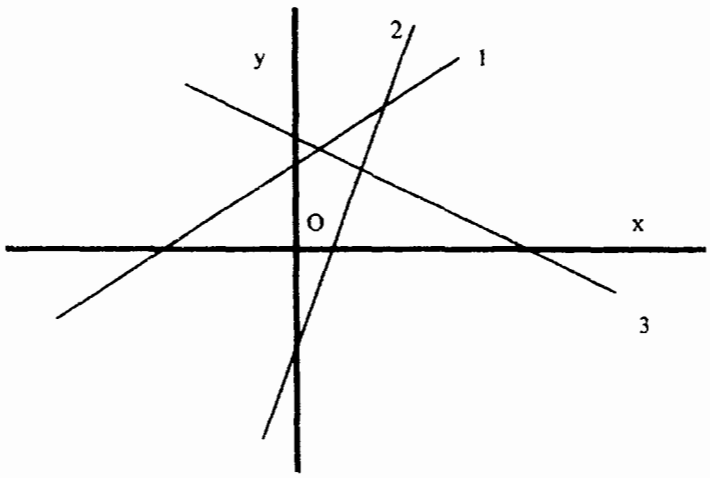
R.P.2 (the second question of test 1): The problem of handcraft

In the next diagram the lines e_1 and e_2 have been drawn. Line e_1 represents the cost of a handicraft in relation to the number of shirts produced and line e_2 represents the corresponding rewards. Find the number of shirts that the handicraft has to produce in order to start receiving a profit.

M.E.2 (The second question of test 2)

Solve the inequality $f(x) > g(x)$, by using the diagram below.

R.P.5 (the fifth question of test 1): Children go to school



"It was a warm day. A student's team started walking to school from the usual meeting point. They were talking to each other loudly, on their way to school. When they realized that they were getting late, a student suggested to the others to hurry up. Then the students started walking faster. But the day was really warm and the conversation quite interesting, so after a while they started walking slowly again..."

Try to depict the above story in a diagram, in which the horizontal axis will represent the time t and the vertical axis the distance d.

M.E.5 (the fifth question of test 2)

The numbers a1, a2, a3 with $a1 < a2 < a3$, are representing the gradients of the lines, of the following diagram. Find the line corresponding to each number.

4. Some sample and results

The statistical analysis was based on linear regression, of the form $Y=\beta_0+\beta_1X_1+\beta_2X_2$, where Y is the dependent variable and X_1, X_2, are the independent variables.

The major dependent variables of the regression analysis we were interested in are:

TOT_R.P. is the cumulative grade of a student in Test 1

TOT_M.E. is the cumulative grade of a student in Test 2

The major covariate independent variable was

MATH_97, which is the grade that the student received in Mathematics in school in the year 1997, while

TREAT is the nominal independent variable taking the values 0 and 1 depending whether the student belonged in the control group or in the experimental group.

The main interest of the research lies in the coefficient of TREAT. If the coefficient of TREAT is positive and big, that means not just that the experimental group performed much better, but that the treatment produce a tangible increase of the students performance. The variable MATH_97 is the grade that student received at the end of the previous academic year in Mathematics, on the basis of his/her performance throughout the year. It is an objective homogeneous and very rigorous measure of student's performance throughout the school, and in our statistics MATH_97 serves as a measure of student's mathematical capabilities *before* our tests. We note that both the Mann-Whitney test and the Two-Sample Kolmogorov-Smirnov test, at 95% significance level, do not reject the hypothesis that the experimental group and the control group have the same mathematical capabilities *before* the administration of our tests. Nevertheless the Linear Regression model, by itself takes care of the fact that the control group and the experimental group, could have not the same mathematical capabilities *before* the tests. Because in the Linear Regression equation, the coefficient

of TREAT provides the *added value* to the student's mathematical capabilities through the problem solving teaching.

Linear regression of the dependent variable TOT_M.E. vis a vis the independent variables MATH_97 and TREAT, gives the coefficient of TREAT lying in the interval [2.423, 5.999], at 95% significance.

Linear regression of the dependent variable TOT_R.P. vis a vis the independent variables MATH_97 and TREAT, gives the coefficient of TREAT lying in the interval [2.448, 5.551], at 95% significance.

The above two regressions show that the experimental group performed significantly better, not only in the Real Problems Test 1, (something that may not constitute a surprise), but also in the Mathematical Exercises Test 2.

The above analysis provides strong indications that the Modelling Orientated Teaching offers a more complete teaching approach, in comparison with the Island Approach. In the Modelling Orientated Teaching, the student approaches the concept intuitively, via a real problem close to his experiences. Subsequently the concept is incorporated in his broader mathematical structure, and connected with other related concepts. This way the student becomes an active participant in the *mathematical discovery,* which results to an in depth understanding of the concept. Actually through interviews that we had with students, we realize that many good (in the sense of **MATH_97)** students of the control group, had difficulty in grasping the interplay between the real situation at hand and the underline mathematical structure. It was exactly in this domain that the experimental group was more at home.

5. The Context of the Real Problem

Up to now, the arrangement of having the questions of Test 1 and Test 2 in one to one correspondence, corresponding questions requiring the same mathematical tools for their solution, has played no role. It is our intention in a different paper to study conclusions connected with this very arrangement. For the purposes of this paper, we would like to point out a phenomenon that we observed, which in one hand stresses the superiority of the Modelling Orientated Teaching, on the other hand indicates a direction for further improvement of it.

The common sense would indicate that each question of Test 1 would be more difficult for the students to tackle than the **corresponding** question of Test 2, since the purely mathematical content was the same and the questions of Test 1 have the extra burden of a real situation *scenario*. Actually the grading of the tests indicated exactly that in most of the cases, **but not in all cases.** Among the notable exceptions were the questions R.P.2 and M.E.2, and R.P.5 and M.E.5, that were mentioned earlier in the paper, where students performed better in the Real Problem question instead of the Mathematical Exercise counterpart. Detailed tables are presented below.

Group ▶ Question ▼	Control	Experimental
R.P.2	49.0%	78.0%
M.E.2	19.6%	46.0%

Group ▶ Question ▼	Control	Experimental
R.P.5	36.4%	54.0%
M.E.5	35.3%	44.0%

(Percentage of correct answers in each group)

It seems to us that an interesting kind of conjecture is in order: **If the Context of the Real Problem is familiar to the students, that enhances their understanding of the mathematics of the situation.** This deserves further investigation.

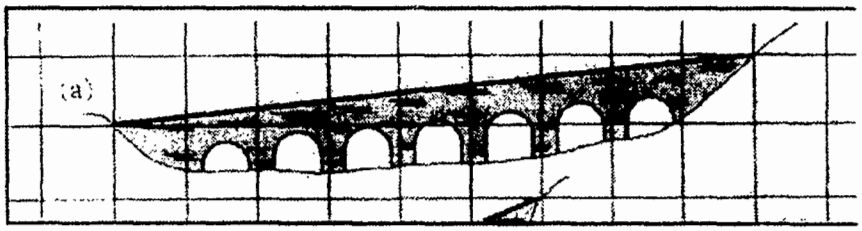
PEDAGOGY AND THE ROLE OF CONTEXT IN THE DEVELOPMENT OF AN INSTRUMENTAL DISPOSITION TOWARDS MATHEMATICS



Simon Goodchild

College of St Mark and St John, Plymouth UK

A student's response to a routine task set in a 'real world' context raises questions about the origins of instrumental approaches to learning mathematics. In particular the unconvincing application of mathematics to contexts that contradict students' experience is conjectured as a possible root of a disposition towards mathematics that interferes with learning.

The Scene

Paul (15 years old, below average attainment) is working out the gradients of railway tracks; in each question the track is shown along a viaduct crossing a valley, the diagram is drawn on a one-centimetre grid.

(School Mathematics Project, 1986: 50)

When I asked Paul how he had worked out his answer he explained:

> Paul I've got my ruler and then I've measured along there [along the track] or I could have counted the squares.

The first part of his response suggests that he is working out the sine of the angle of inclination rather than the tangent, but as he continues he reveals a misconception. When I asked Paul to measure both lengths he does indeed find them to be the same within the limits of accuracy of his ruler; applying Pythagoras' rule reveals the sides to be: 1 cm, 9 cm and 9.055 cm. The evidence appears to confirm Paul's misconception, but does he really believe it?

> I Does that surprise you?
>
> Paul Yeah, a bit because I would've thought that there ... but if you add that black one [the track] down on to there [horizontal line of the grid] they're longer.

I suggested that he tested the three other similar questions in the exercise, the triangles' sides are 3 cm, 7 cm, 7.615 cm; 6 cm, 8 cm, 10 cm; and 1 cm 14 cm, 14.035 cm. Paul observes the difference he expects for two but not for the last one.

To explore how Paul accommodates this discrepancy between his expectation and experience I try to get him to reflect on the evidence:

BEST COPY AVAILABLE

I Do you think that really is the same, that length there [the track in the first question] really is the same as that length [horizontal on the grid] there?

[pause, 18 seconds]

Paul It must be really.

I Why must it be?

Paul Because it's from there to that line there it's nine centimetres and you measure up there from there to there, it's nine centimetres.

In Piagetian terms I interpret Paul's statement as confirmation of his conception of the conservation of length. He has used his ruler to measure both line segments and this has revealed their lengths to be the same. Does this make sense to Paul, or is he experiencing 'disequilibrium'?

I Does it make sense?

Paul No. Them two there, if you done the same as done there, on there it's totally different it's that there smaller along the bottom than it is going up the hill.

I Does that bother you?

Paul I just think, figure out one way to work this out and then you go on to the next one and then you have to find another way to work it out.

From a constructivist perspective, in this episode Paul reveals a disposition towards mathematics (NCTM, 1989) that enables him to dismiss experiences that might result in cognitive conflict, reflection, accommodation and learning. He merely needs to find the new rule to work out each type of question. However, before continuing with the discussion about Paul's response and the possible roots of his 'disposition' I will outline the circumstances in which the conversation arose.

Methodological context

The conversation with Paul arose during a longer research programme in which I spent almost one complete school year attending every mathematics lesson of a class of 14-15 year old students. The students, described by the school as 'intermediate tier,' revealed a wide variation of attainment across the class; Paul was at the lower end of the attainment range of the class. The research adopted an ethnographic style of enquiry following Eisenhart (1988). During my time with the class I observed and audio-taped periods of whole class teaching and when students were engaged in individual activity or small group work I conversed with them about their work and tried to elicit evidence of the goals towards which they were working. Lessons followed a regular pattern of short teacher expositions and prolonged periods of individual or collaborative activity during which the students worked on exercises in the SMP 11-16 texts (School Mathematics Project, 1986) widely used in the UK. Key features of the students' experience were the teacher's attempts to familiarise novel tasks

(Doyle, 1986) and the fragmentation of mathematics into discrete, unconnected routines (Ernest, 1996). The students' response was to adopt an instrumental approach to their work (Skemp, 1976; Mellin-Olsen, 1981).

I spent substantial periods of time (10 - 20 minutes) observing, listening and conversing with students about their work; the time spent with individual students enabled me to expose their beliefs, attitudes, goals and understanding. The background and school experience of the students was remarkably similar to those at 'Amber Hill' in Boaler's study (Boaler, 1998), it is unsurprising, then, that the outcomes also matched those reported by Boaler, in her words, 'the students developed an inert, procedural knowledge' (1998: 59).

In the following discussion of Paul's responses to my probing I want to consider what associations there may be between his experience and disposition towards mathematics, especially I want to suggest that setting mathematics in a 'real-world' context may be a contributory factor.

Paul's beliefs about mathematics

Paul's response to my probing is remarkably reminiscent of 'Benny' described by Erlwanger in his seminal paper (1973).

> Benny believed that there were rules for different types of fractions, as illustrated by the following excerpt:
>
> B: In fractions we have 100 different kinds of rules ...

Erlwanger goes on to remark:

> (Benny) has developed consistent methods for different operations which he can explain and justify to his own satisfaction. He does not alter his answers or his methods under pressures.
>
> ... learning mathematics has become a "wild goose chase" in which he is chasing particular answers. Mathematics is not a rational and logical subject ... (Erlwanger, 1973: 10, 12, 16)

Commenting on the influence of Erlwanger's paper Steffe and Kieren (1994) observe "In one ingenious stroke Erlwanger was able to falsify the behaviorisitic movement in the practice of mathematics teaching." (1994: 717). Erlwanger's paper may have been influential in guiding curriculum planners, text book writers and teachers, it does not however, appear have led to developments in learning. And although we might not describe Paul as having a 'behavioristic' approach to learning, in Mellin-Olsen's terms Paul displays characteristics of 'instrumentalism' (Mellin-Olsen, 1981).

I want to conjecture that Paul has acquired a disposition towards mathematics that makes cognitive conflict or unanticipated interruptions to the flow of activity (Raeithel, 1990) that might provoke reflection problematic. In the conversation with Paul the basis for conflict has been laid but he is able to dismiss the contradiction he perceives when he claims: "I just think, figure out one way to work this out and then you go on to the next one and then you have to find another way to work it out."

Possible sources of instrumentalism

Boaler (1998) suggests that it is the approaches adopted by the two schools in her study that account for differences between students' progress and attitudes towards mathematics. Additionally, Schoenfeld (1992) relates students' beliefs about mathematics to classroom practice. My own research supports this and I want to look more closely at a number of features of traditional approaches to mathematics, and one feature in particular, that may provide an explanation for Paul's disposition.

First, I want to consider what similarities there may be between Paul and Benny's experiences of mathematics. Benny's class was 'using Individually Prescribed Instruction' (Erlwanger, 1973: 7); Paul had followed an individualised scheme for the first two years of his secondary education, using the small booklets of the SMP 11-16 scheme (School Mathematics Project, 1986). Many teachers using this scheme continue to use an individual approach into and beyond the third year despite the scheme's transition to more traditional textbook format; I cannot, however, be certain that this was Paul's experience. The teacher of Paul's class approached the subject through short, whole class, introductory expositions with the major part of class time spent by students engaged in individual and collaborative activity as they worked at their own pace through the exercises. However, Boaler's research (Boaler, 1998) suggests that the earlier influence of an individualised learning scheme may not be a crucial factor in accounting for student performance beyond the immediate experience of the individual scheme.

Secondly, as noted above, a significant feature of the teacher's approach was to familiarise the work for the students. This action has been discussed by Doyle (1986). To facilitate students' activity in their tasks the teacher breaks them into small steps that provide little or no challenge. Students are left with the task of memorising the sequence of steps without necessarily understanding the orchestration or meaning in the context of the task. Doyle has explained how teachers are under pressure from pupils to familiarise tasks as a means of maintaining control. Woods' studies of schools confirms this, he observes "for pupils ... the most important attributes of good teachers are that they should ... be able to 'teach' and make you work and keep control." (Woods, 1990: 17).

Thirdly, and possibly related to the above is that students experience mathematics as a fragmented collection of discrete rules, routines and skills. An analysis of the mathematics experienced by the students in the class I studied revealed little sense of coherence between different topics studied; the only common themes that ran throughout the year were elementary number operations (supported by calculators) and measuring skills. Ernest (1996) attributes this fragmentation, in part, to the notion of the 'spiral curriculum'.

Fourthly, the regime of the National Curriculum (in the UK) and the pressure upon schools to raise standards which are narrowly defined in terms of test and examination results, has an impact upon students' experience of mathematics. Hoyles explains: "Regular assessment is also expected to enhance pupil

motivation through mastery of short term goals, and 'knowing clearly where you are and where you are going.'" (1990: 116). The effect of assessment on learning styles has been demonstrated in the research of Entwistle who remarks:

> ... the type of questions given in a test can induce a surface approach to studying and that the factual overburdening of syllabuses and examinations may be responsible for the low level of understanding exhibited by students when prevented from reproducing answers by well-rehearsed methods. (Entwistle, 1981: 81).

The fifth feature of students' experience that may contribute to their instrumental approach to learning, which I will examine in more detail than the foregoing, is the contextualisation of mathematics. I want to argue that rather than making the mathematics meaningful or, possibly, demonstrating its application, context can often persuade students that the activities of the classroom have little to do with their everyday experience outside the classroom and this leads them to lay aside their expectations of rationality, meaning and consistency for the duration of mathematics lessons. The use of 'real world' contexts merely serves to convince some students that they are situated in a practice that is remote from their lives outside the classroom. And rather than providing a tool that might be called upon to provide a superior rationality, as Lave (1988) observed in her subjects, school mathematics is perceived by some students as a set of meaningless routines to be memorised.

Negative reactions to context

When questions are set in contexts in which students may have 'expert' knowledge the simplification of the context to make the mathematics accessible may help to convince the student that mathematics has little to do with 'real life' and does not make 'sense' because it does not fit with their understanding or experience. Consider, for example, another episode that arose from my time with Paul's class. A student was confronted by a question about the probability of a football team winning successive matches. The student was a keen soccer player and he could not engage meaningfully with the problem because it did not fit with his experience. The task suggested that the probability of winning successive matches remained constant irrespective of what happened in the matches. The student argued that this would not be the case because the result of the first match would influence the team's morale for the second match, also the comparative strengths of the teams would differ between matches. The question that, I guess, was intended to demonstrate an application of the mathematics studied served rather to convince the student that mathematics has little to do with his 'reality'.

Alternatively the contextualising may introduce complication and make a familiar situation inaccessible. An example of this is provided by Goodchild (1995) who illustrates his discussion using an episode with a student who is confronted with a question based on purchasing a quantity of fertiliser. The student is given the price of 4 kg, told that the cost is proportional to the amount, and asked to calculate the cost of 20 kg. Goodchild argues that the

student finds this question inaccessible in part because of its use of technical vocabulary, 'proportional,' thus setting the question in a classroom context in which the student has to know the 'special rule'. The context does not contribute towards the student's construction of a conception of proportionality. Instead, the language and classroom context separates the question and mathematical activity from a 'real' situation in which the student would have little difficulty.

Contextualising mathematics may convince the student that special rules are invented for the classroom. A fascinating example of this is provided by Brink (1991) when discussing the 'realistic mathematics programme.'

> All the children (aged 5-6) had recently travelled on a city bus; it had stopped repeatedly at bus-stops. In the Wiskobas project the bus is an important model for introducing addition and subtraction. We re-created the bus situation in the classroom: one pupil is the driver and wears a cap; the other children, standing in a line behind him, are the passengers.
>
> At the first stop all the children got off, which was not what the teacher expected. Some of the children thought they were on a school-trip and not on the city bus. Others thought they were on the city bus and were going to 'granny' but they failed to notice that the bus had stopped repeatedly. That did not matter to them on their real way with mother to see 'granny'. Others wondered whether the 'game' had finished at the first stop –
>
> Each child had his or her own particular idea which fitted into the play-situation of getting off. The surprise shown by the teacher however quickly put an end to the confusion. The children revised their ideas and quickly hopped on to the bus.

Brink remarks:

> With the help of such instructional manoeuvres (play acting and showing surprise) we can develop meaningful knowledge in children, in the sense of knowledge that fits into a situation as envisaged by radical constructivism. (Brink, 1991: 197)

The point I want to make here is that for the context to work in support of the didactics the teacher had to impose a special rule. In doing so the situation was not merely enacting a bus journey, it had become relocated as a 'classroom' activity. A similar situation became evident in the conversation with Paul from which the extracts above are drawn. I wanted Paul to reflect upon the meaning of change in height, as used in the formula presented in the text for calculating gradient: change in height/horizontal distance. Because he does not give me the answer anticipated I rephrase the question several times. Paul is consistent with his explanation, I reproduce just two, out of his five attempts:

> Instead of the going along the flat it'd just, it's going up the hill

> ... the train's coming along, and along a flat surface and then it comes to a hill which it climbs but it needs more speed to get up the hill and if it's a steep hill it will need quite a lot of speed to get up to the top

I conjecture that Paul is interpreting change in height as 'changing' height. His experience of hills is partly dynamic, which is evident from his references to motion, and partly it arises from looking at road and track *surfaces* rather than the cross sections conveniently arranged in the mathematics text. The mathematics requires Paul to adopt an alternative meaning for change in height. He might be able to accept this meaning and remember it for the classroom context but it removes the context from his real, lived-in-world experience outside the classroom.

English and Halford (1995) draw attention to how stereotypical views can interfere with students' problem solving. In one example they explain how a female student attempted to solve a logic problem making the assumption that women do not play chess or golf. Again, if it is necessary for the teacher to contradict the stereotype *in support of the mathematics*, the possibility exists that students might listen to their teacher and follow the 'rules' within the classroom and, rather than adapting their expectations outside the classroom, they will develop a belief in two non-intersecting practices. In particular, the 'real life' practice of their lives outside the classroom and a 'classroom' practice where 'normal' beliefs and rules must be suspended and the teacher's rules followed and memorised.

I believe few would want to argue that instrumentalism has roots in traditional pedagogy but that contextualising mathematics may also be a root is a conjecture that may be contentious. Setting mathematics in contexts to reveal applications and facilitate meaning-making appears to be widely accepted without question. Admittedly my argument rests, largely, on the idiosyncratic responses of one student (as, we note, did Erlwanger's seminal and influential paper). However, I hope I have demonstrated that it is possible to interpret other evidence to support the argument; I believe the significance is such as to require further investigation.

THE ENCULTURATION OF MATHEMATICIANS IN GRADUATE SCHOOL

A Research Report Proposal for PME 23

DANIEL L. GOROFF
HARVARD UNIVERSITY

Abstract" Earning a Ph.D. changes people's attitudes and values in ways that reverberate throughout the educational system, especially because the graduate students who become professors also end up teaching teachers. Many public policy issues, for example about the balance between research and teaching at research universities, also focus on graduate education. The many suggestions for reforming the Ph.D. therefore require careful analyses that discuss both philosophical underpinnings and empirical data. Recent studies expose some of the myths, realities, and mysteries of the enculturation process that turns graduate students into faculty.

1. Focus

One surprisingly effective way to understand complicated systems is to examine extreme cases. Analyzing behavior when parameters are pushed towards their limits can establish boundary conditions that help explain how the system functions under more typical circumstances. This paper argues that certain features of the highly complicated system of education in the United States can be understood as reflecting what does and does not go on in the special case of graduate education.

Graduate study represents the outer limits of educational activity along many dimensions. Compared to other degrees, earning a Ph.D. simultaneously involves more specialization and breadth, more time and pressure, more maturity and infantilization, more isolation and socialization, more research and teaching, more prestige and risk, more freedom and tradition, more intimacy and anonymity, more convention and originality, etc. By stretching people to their limits, these tensions of Ph.D. study end up powerfully enculturating those who survive to the norms and expectations of their discipline.

Both the process and content of graduate student enculturization have far reaching consequences. For example, graduate students become the professors who teach undergraduates in general, and who teach teachers in particular. Pedagogical practices picked up in graduate school can therefore propagate easily throughout the educational system. This is the argument that "teachers teach as they were taught," which may or may not be entirely true in

BEST COPY AVAILABLE

mathematics. Attitudes towards the history and philosophy of mathematics especially do seem to play a large role in teaching decisions in any case, and these attitudes do get passed on implicitly or explicitly. Most graduate students are enculturated to be Platonists on weekdays and Formalists on weekends. Both these philosophies are at odds, though, with the explicit Constructivism that is popular among K-12 teachers and teacher educators. This helps explain the rift many feel between mathematicians and mathematics educators.

Thinking about graduate student socialization not only reveals much about the internal workings of the educational system, but also about its treatment by outside policy makers. American research universities are often described as products of an uneasy marriage between the British college system and the German research institute system. The integration of research with education makes a great slogan, especially among government agencies seeking to protect budgets for either purpose (though not when the same agencies calculate indirect cost reimbursement rates). Yet no one seems able to articulate precisely what this slogan is supposed to mean in practice, and it is an especially important question concerning graduate programs. Whether Ph.D. candidates who teach and conduct research should be treated as employees or students when it comes to grants, taxes, and unionization rights are matters currently being thrashed out in American courts. At a time when consumerism, for-profit competition, and political expediency also pose threats to the traditional role and funding of research universities, a great deal may depend on how we describe what graduate study is supposed to accomplish.

2. Framework

Like much educational research, this project seeks to illuminate some current policy debates. Despite or perhaps because graduate school occupies an extremal position in the education system, many of the standard reform recommendations for K-12 seem designed to make students from kindergarten onwards behave more like Ph.D. candidates. For example, reformers often emphasize the importance to children of inquiry, group projects, constructing concepts, data gathering, standing on a par with teachers, and learning to think like scientists and mathematicians. Conversely, many of the standard reform recommendations for Ph.D. programs seem designed to treat those students more like school children. For example, reformers often emphasize the importance to graduate students of hands-on learning, of practical problem solving and real world experiences, of work on communications skills like how to write and speak, and of better supervision, mentoring, and help with decision making.

However well-intentioned, recommendations like these seem confusing and misdirected. Whereas it was once popular to discuss the stages that individuals and institutions pass through as they learn, the reforms as presented seem not to acknowledge the idea of progress over time. Such a stance is fundamentally uneducational, and particularly at odds with the cumulative nature of mathematics and science education. To help make sense of what might be valid in these recommendations, it is therefore necessary to reexamine what we mean by progress beyond just accumulating more content knowledge. For individuals, this project entails an investigation of epistemological development through schooling that locates kindergarten at one end of the spectrum and graduate programs at the other. For institutions, this project entails an investigation of historical development that locates current calls for reform within the context of previous successes and failures.

3. Literature

American graduate education is often touted as the best in the world. Especially in science and mathematics, professors often say that it is the one part of the educational system that works well and attracts the most able students from the world over. Yet prominent critics of the Ph.D. date back as far as the degree itself, including the article by William James entitled "The Ph.D. Octopus." There is no end of serious reports, panels, and studies filled with sober recommendations. Samples are listed in the bibliography below. The same themes run through nearly all of them: Ph.D. training is too narrow; it does not prepare people well to become faculty, let alone anything else; there is an overemphasis on research at the expense of teaching; there are not enough jobs; Ph.D. programs are exploitative, expensive, elitist, demeaning, and drawn-out; etc. In short, the critics maintain that Ph.D. programs enculturate graduate students too well in ways that society does not need. It is hard to tell if these critics are representative of academia, employers, or society, or if they are merely the most vocal, since those who are relatively content with graduate education may have little incentive to write about it.

Most of the statistical studies of Ph.D. education concern the supply and demand for academic jobs. As well, there is also a great deal of controversy about methods of ranking graduate programs, especially in science and mathematics. Research into broader questions about the attitudes, expectations, and experiences associated with graduate education, however, is just beginning to produce intriguing results. Maresi Nerad at UC Berkeley, for example, has conducted a comprehensive survey of Ph.D. recipients ten years after completing their degrees in seven fields including mathematics. Her statistics permit comparative analysis not only of their employment patterns, but also of

rich qualitative data about the strengths and weaknesses of their graduate experiences as seen with a decade of perspective. Another survey by Chris Golde at the University of Wisconsin asks current graduate students and faculty about their socialization with respect to teaching, ethics, and service. Moreover, Jody Nyquist at the University of Washington is collecting and synthesizing both written and interview data concerning Ph.D. reform in general. These results can be contrasted with a recent OECD study that places such efforts in an international context.

Background data concerning the attitudes of mathematicians in particular towards academic culture and priorities has been collected by the Joint Policy Board for Mathematics in their unusual "Recognition and Rewards" study. Shirley Malcom of AAAS has compiled powerful interviews and statistics concerning the graduate experience of traditionally underrepresented groups in science and mathematics. There are also several volumes that document and promote specific kinds of reform projects in mathematics departments, mainly about either the mentoring of graduate students or their training as teachers.

4. Position

At a time when there are so many forces for change acting on the American educational system, the one sector of it that seems most successful should proceed with caution. Especially because changes in graduate education resonate throughout the system, it is important to tease out myth from reality concerning Ph.D. programs and the ways they enculturate future faculty. For example, the integration of research and teaching on university campuses in the United States has clearly helped shape graduate education. Thus while reformers oppose one with the other too quickly and easily, it might be better to reexamine and reconcile research with teaching more carefully. Lee Shulman, for example, has pioneered one approach for accomplishing this by giving the "scholarship of teaching," as advocated by Ernest Boyer, a subject matter that Shulman calls "pedagogical content knowledge."

To make better decisions, graduate students need to understand issues like the balancing of research vs. teaching in mathematics programs, both in theory in terms of the purposes of higher education, and in practice in terms of career consequences. Although most reform efforts target the enculturation future faculty do or do not receive in graduate school, receiving institutions arguably have an even greater responsibility, and should more actively orient and mentor new hires. While many senior faculty perhaps are not yet well-equipped to take on this role, this situation is changing. For example, Project NExT and Project Kaleidoscope are two highly successful national efforts to provide such support

to young mathematics and science professors who are unlikely to receive it locally.

5. Implications

Investigating the enculturization of mathematicians in graduate school should help with clarifying and evaluating the many calls for Ph.D. reform in particular and higher education reform in general. Viewing the problems and successes of graduate programs through this particular lens not only highlights certain results and questions in educational research, but also suggests the need for further experiments, examinations, and explanations. Establishing a stronger sense of the direction and range of cognitive development in schooling through the Ph.D. could help organize better thinking about the entire educational system.

IMAGES AND THEIR FRAMES OF REFERENCE:
A Perspective on Cognitive Development in Elementary Arithmetic

Eddie Gray
Mathematics Education Research Centre
University of Warwick
COVENTRY CV4 7AL, UK

Demetra Pitta
Psevdas Primary School
Larnaca
CYPRUS

This paper explores the relationship between children's numerical understanding and the frames of reference of their images. Embedded within psychological approaches that evoke imagery through verbal and visual cues, the study explores the different kinds of imagery identified from elementary school children's responses to such cues and links them to levels of numerical achievement. The results suggest that images with descriptive qualities manifest through specific and/or episodic references are common to both high and low achievers. However, the images of high achievers, in contrast to those of low achievers, display a spectrum of quality that have a more generic core. Such differences may have consequences for successive process–to-concept encapsulations.

INTRODUCTION

Our efforts to gain insight into why some succeed in mathematics and others fail has consciously taken a route that considers cognitive development. Whilst acknowledging the existence of a wide range of social and cultural influences on this development, (see for example Cobb, 1987; Gruszczyk-Kolczynska & Semadeni, 1988) our interest is manifest in seeking answers to the question "*What are children really doing in their heads?*"

This paper reports part of a wider study designed to investigate the ways in which different kinds of mental image may influence children's approaches to elementary arithmetic. It is not the purpose of the paper to become caught up in the format of mental image from a propositional or visual point of view. A guiding principle is that, irrespective of such format, there are other aspects of mental imagery that requires further discussion. These may prove to be important to our understanding of cognitive development and in particular to our understanding of divergence in numerical thinking.

Drawing upon work in cognitive psychology, the paper initially considers the existence of different kinds of image with particular reference to those identified by De Beni & Pazzagalia (1995). It continues by broadening the debate and illustrating how these different kinds of image may be associated with different levels of arithmetical achievement. Images children project when stimulated by single verbal and visual cues, in concrete and abstract form, suggest that those of children with lower levels of numerical achievement are of essentially of a descriptive kind. In contrast, those who are more successful project, in an 'integrated' way, a spectrum of the different kinds of mental images that reflect descriptive and relational characteristics.

840

THEORETICAL BACKGROUND

Setting the Scene

The concept of image has become less clear as more progress is made on the research front (Cooper, 1995) and this paper recognises that human cognition requires different representational constructs to describe it. Consequently in our context the term image may be seen as a mental reference which is a product of imaging in any modality whether it be visual, verbal, olfactory, auditory or kinesthetic.

Images are significant components of cognition and the notion of mental reference has particular relevance for the study of mathematics. Its association with a conception of 'thing' or 'object' draws our attention to a quality of abstraction that ranges from a mental analogue of a real object to a linguistic description or a symbol (see also Pavio 1986). Such a distinction would seem to be particularly relevant for cognitive development in elementary arithmetic which, it is suggested, is grounded in successive process-to-concept encapsulations (Tall (1995)

The issue for this paper is whether those who are less successful appear to have a disposition towards particular kinds of image that are qualitatively different to those projected by children who are more successful.

Different Kinds of Mental Representation

Thomas, Mulligan and Goldin (1996) have suggested that children's internal systems of representation of numbers go through a series of changes, from a semiotic one in which meaning is established through previously constructed representations, to an autonomous stage in which a new system of representation functions independently of its precursor. Pirie & Kieran (1994) indicate that a learners strong early attachments to particular dominant images can seriously influence the development of understanding The relationship between the understanding and imagery suggests that abstract imagery appears to dominate amongst relational thinkers, concrete and memory images amongst relational thinkers (Brown & Presmeg, 1993). In elementary arithmetic such differences may emerge because those who predominantly use procedures display less inclination to filter out information (Gray & Pitta, 1997). Relational thinkers appear to reject information or, to put it another way, are more able to select the information that is more relevant to a particular situation. This would suggest that the different images identified amongst children at extremes of numerical achievement have their roots in a qualitative abstraction governing the individuals active mental process of making sense of data through personal and/or impersonal involvement.

These forms of involvement have featured as some of the attributes which guide the classification of different kinds of imagery explored by Cornoldi, De Beni and Pra Baldi (1988) and De Beni & Pazzagalia (1995). The former suggest that images spontaneously evoked from a single verbal cue may be identified as *general, specific* and *autobiographical* in decreasing proportions. General images represent a concept

without any reference to a particular example or to specific characteristics of the item. For example, the cue 'table' may evoke the response "I can see a table". Reference to a single well-defined example of the concept without reference to a specific episode characterised specific images. Autobiographic images, seen to be special cases of the 'specific' category enlarged to include the involvement of the self-schema, were those which involved either the subject without a precise episodic reference or objects belonging to the subject.

De Beni & Pazzagalia questioned the meaning that may be given to the autobiographic image category. They suggested that there is a distinction between images referring to a single episode in the subject's life (*episodic–autobiographic*) and those that actually involve the subject without a precise episodic reference (*autobiographic images*).

METHOD

Within this study images are inferred from the words of subjects. Thus, two features governed the framework for the development of cues that formed the basis for an interviewee's response. The first is embedded in psychological approaches which evoke imagery through a verbal and visual stimulus (see, for example, Stillman & Kemp, 1996). The second is that the relationship between imagery and numerical achievement should focus on two issues:

- the existence of different kinds of image identified through distinct generation processes, and the likelihood that these can be grouped into categories.
- the relationship between an emphasis on one or more of these categories and the level of numerical achievement.

Visual and verbal cues were presented to a sample of 16 children representing the extremes of numerical achievement within each of four year groups of a primary school within the UK. Numerical achievement was measured by criterion based test results available in the school and a numerical component which formed part of a larger study of which this paper is a part. The final sample had 8 'high achievers' and 8 'low achievers', 2 of each drawn from children aged 8 to 11.

A modified version of the defining feature approach (see, for example, Roth & Bruce, 1995) was used to gain a sense of what it is children feel is important to communicate when faced with cues in verbal form. These included concrete words and conceptual labels that had more abstract meaning. The former, seven items which denoted things that could be perceived by one of the sense modalities and had shown they could evoke images more readily than other words (see Pavio, 1969) included the cues 'dog', 'table', 'dots', 'football'. The latter, more clearly associated with elementary arithmetic, had eleven items including 'five , 'thirty-three', 'half', 'three-quarters', 'three-eighths', 'naught point seven five', 'number' and 'fraction'.

Sixteen cues were presented visually, nine being visual representations of verbal cues The item bank was subdivided into two sections, pictures and icons, for example, a 'football', 'dots', a 'table', and symbols for example, 5, 99, 3+4, 0.75.

Each verbal and visual cue was presented with the following instructions:

Verbal/visual: What is the first thing that comes to mind when you hear the word (or see)...?

Verbal: Talk for 30 seconds about what comes in your mind when you hear the word...

Visual: Look at this, when I tell you close your eyes and put this in your mind. Talk to me for 30 seconds. Do it now.".

Children were interviewed over two separate occasions approximately 8 weeks apart. All interviews were video-recorded, linked to field notes and transcribed.

RESULTS

Classifying Responses

Children images were classified as *general* when responses indicated that they were not talking about a specific item. For example:

"It's a surface on metal or wooden sticks" (Y4+, verbal, 'table')[1]

"Part of" (Y6+, verbal, 'fraction')

The criteria for responses identified as *specific* were extended to allow for multiple examples which were qualitatively similar. For example:

"... a cheetah is one, a rabbit is one, a dog is one a cat, a Labrador, Dalmatian, owl, eagle, buzzard, etc." (Y3–, verbal, 'animal')

"Like one, two, three, four, five, six, and ten are numbers". (Y4–, verbal, 'number')

De Beni and Pazzaglia suggested that some images could be seen to be 'contextualised' since they had distinctive and relational characteristics. However, the way in which contextualised mental representation were identified as 'item specific' and 'relational', did not satisfy the clear distinctions observed in the responses of the subjects within the current study. They could be descriptive through association with a scene or a sequence of scenes or they could have a higher order quality more in tune with Skemp's (1976) notion of relational. After detailed analysis of responses it was decided that the notion of a contextual image would be better served if there were a distinction made between *episodic* and *generic* images.

Episodic kinds of image were associated with some scene or sequence of scenes and were most often narrated in continuous speech:

"Boys can kick it around and sometimes it can get lost over the field." (8–, verbal, 'ball')

"Number five. I think of a row of numbers and light shines on number five. A light goes along and stops over the number five." (Y5–, verbal, 'number')

---

[1] The indicators at the end of each example provides the age of the child and their level of achievement, the phase of items and the item itself. Thus (Y4+, verbal, 'table') indicates a 'High achieving' nine-year-old responding to the verbally presented item 'table'. Low achievers are denoted by the symbol –.

Other responses that implied the existence of a context were more fragmentary; more a collection of disconnected, seemingly arbitrary, *generic* statements. These originated from the same general concept that served as the basis for explicit relational connections. They were not descriptions of a sequential event with a clear beginning and end but more often a collection of statements that seem to have the potential to produce new ideas. Though they had a 'general' quality, the statements diverged to produce different ideas related to the iten . For example:

> "Keeps you fit. An exciting game. Millions of fans. Important in every nation. Children and adults play it. Different types of football and balls." (Y4+, verbal, 'football')

> "... maths and writing. Seven... you could be doing some adding or times and the number seven might come up. Seven is also played in sport... seen on the back or shirt... has one digit... in a phone number." (Y5+, verbal, '7').

The 'autobiographic-episodic' category, which allowed for the "occurrence of a single episode in the subject's life connected to the concept" (De Beni and Pazzaglia, 1995 p. 1361), was noted infrequently but identified as follows:

> "My friend wasn't good at fractions and she had to take extra work home." (Y4+, verbal, 'fraction')

> "We have recently done reflections and they had lots of halves in them. We had to put our mirror down the side and see the rest of it. I saw lots of those." (Y4+, visual, 'half')

Though De Beni and Pazzaglia's approach requested subjects to construct 'good and vivid images' of 'high value nouns' given as cues, the current study involved reporting images of abstract nouns and of symbols or icons representing them. Such stimuli could evoke mental representations of a proceptual nature (Gray & Tall, 1994), for example:

> "It's divisible by nine" (Y6+, verbal, '99'),

> "3 parts out of 4, fraction, 0.75, more than half." (Y6+, visual '3/4')

Analysis of Results

Here we present results relating to the 30-second response that allowed children to contribute as much as they felt able to. Consequently, from each child, there may be a sequence of responses that embrace different kinds of image. All responses from each child were classified. Figures 1 and 2 display the different kinds of representations recorded as a proportion of the total number of child responses given (N). To provide a clearer sense of the more dominant mental representations classifications identified in less than 8% of instances are collated in the category 'Other'. This figure may be regarded as quite arbitrary, but careful consideration of the summarised results suggested that percentages up to this level frequently indicate more idiosyncratic and less common behaviour.

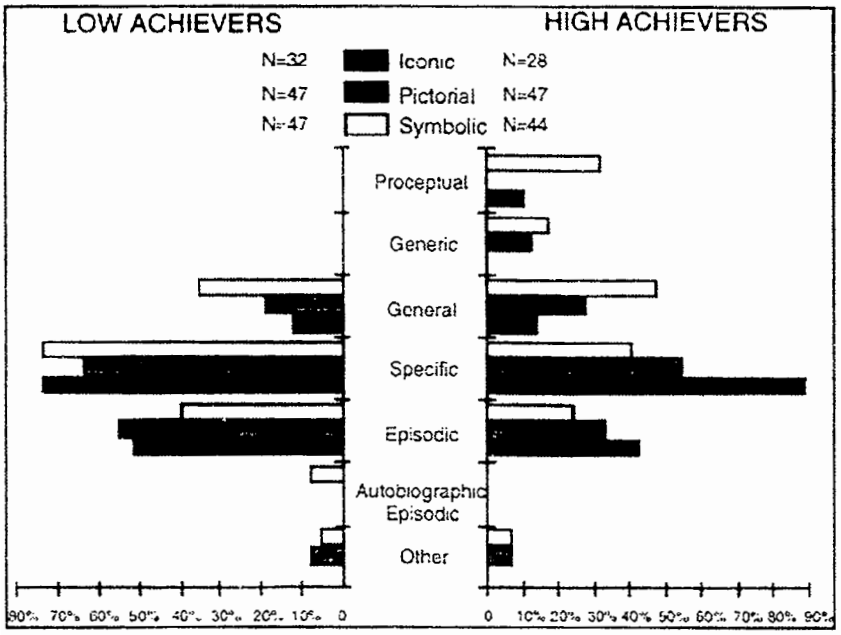

Figure 1: Occurrence of the different kinds of mental representation as a proportion of the number of items considered in the second response of the visual phase

Figure 1 provides a summary of responses to the visual items. The dominance of specific images may be clearly seen amongst the low achievers. These, together with the episodic form, are clearly dominant in reactions to each set of cues: the pictorial, iconic and symbolic.

Images from the numerical cues by high achiever's covered a wide spectrum of the different kinds. However, like the low achievers, high achievers appeared to have had difficulty detaching themselves from mental representations associated with specific and episodic content when cued by icons. These had easily distinguishable surface features but were less easy to name and connect with different experiences. It is suggested that these features militated against the abstraction of the intrinsic qualities that would have lead to the projection of generic and proceptual kinds of image.

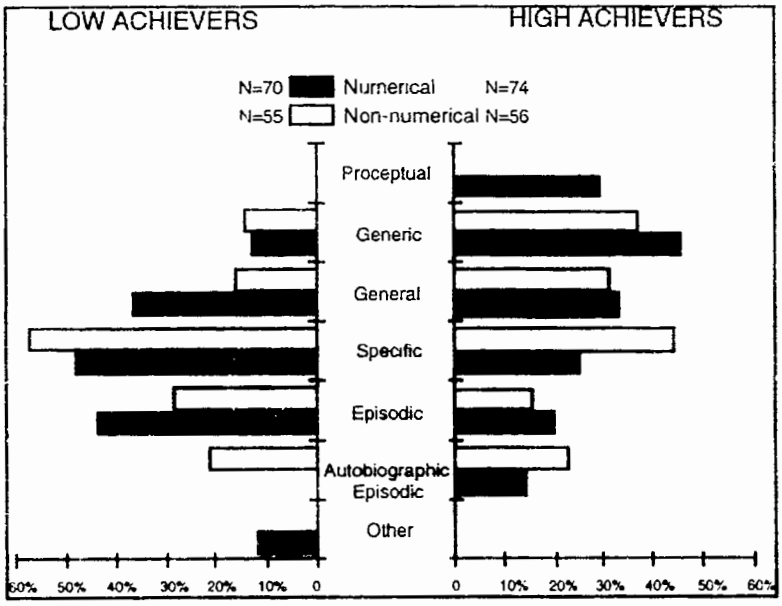

Figure 2: Occurrence of different kinds of mental representation as a percentage of the number of verbal items in the second response of the verbal phase.

Figure 2 summarises images associated with the verbal cues. The proceptual and generic images identified from high achievers when responding to these items suggest they have an ability to link the cues to different experiences so that intrinsic similarities may be abstracted. In contrast low achievers continue to project specific and episodic images but the symbols evoke a relatively high proportion of general ones.

DISCUSSION

This study supports the notion that different kinds of imagery may be identified amongst children of elementary school age. Additionally, it suggests that these may be identified through responses to both verbal and visual cues of either concrete or abstract nature and the evidence points to qualitative differences in the kinds of imagery projected by children at extremes of numerical achievement. Both groups projected imagery underpinned by descriptive qualities in that they are specific and/or episodic. However, whilst low achievers consistently project features embedded in such images, high achievers projected more relational imagery to display a spectrum of quality which, it is conjectured, has a more generic core.

Such differences, pivoting as they do around tendencies to project descriptive and/or relational images, are made apparent by the inclusion of generic and proceptual kinds of image. Perhaps it is no surprise to see that children who are selected on the basis of achievement, with the implications this may have for their proceptual/procedural interpretation of symbolism at an operational level (Gray & Tall, 1994), reflect such differences. However, the paper goes further than this. Not only do children at different levels of arithmetical achievement project qualitatively different images when prompted by numerical cues, they also project qualitatively different images of other conceptual ideas that are presented free of context through verbal and the visual cues.

It is hypothesised that the high achiever's reactions to the different phases may be accounted for by the processing differences that apply between the presentation of a visual stimulus and the presentation of a verbal stimulus. Though the invitation to consider the 'first thing that comes to mind' has not been considered in this paper, its analysis suggests that high achievers initially provide a general mental representation, often through naming or by giving a general comment about the item without any reference to other characteristics. It is conjectured that this needs to be done before a mental search to retrieve generic or proceptual qualities is carried out. When it was too difficult to project a general mental representation high achievers did not give a response but low achievers supplied a specific image associated with the surface characteristics or a specific example of the item.

Age differences have not featured in the analysis as presented. However, it does not appear to have much influence upon the quality of mental representations projected by low achievers. However, those of high achievers, being of a more generic nature, operate at a more relational level that seems to grow in complexity.

CONCLUSION

The results would seem to have important implications for our understanding of the way in which children view the development and use of numerical activity in the context of repeated process-to-concept encapsulations. The limited spectrum of mental representations projected by low achievers suggest they are either unable to, or simply choose not to, see through actions and objects to embrace more abstract qualities. It may even be that early teaching has influenced their focus of attention.

The development of elementary number requires an ability to concentrate the mind and give careful thought to an act or idea — to filter out irrelevancies and separate notions from their context. It involves the construction of relationships between and amongst objects and of the actions on them. It would seem that such a process might work to the advantage of the high achievers. Their disposition towards the formation of images that integrates descriptive and relational characteristics seems to ensure the construction of number concepts through the synthesis of pseudo-empirical and reflective abstraction Tall (1995). It is conjectured that this follows a very different cognitive development from that of children whose disposition towards descriptive images arises from their concentration upon empirical abstractions and direction, through teaching, towards the pseudo empirical.

THE ROLE OF UNCERTAINTY IN CONSTRUCTING AND PROVING IN COMPUTERIZED ENVIRONMENT

Nurit Hadas & Rina Hershkowitz

The Weizmann Institute, Rehovot, Israel

The role of uncertainty in promoting the need to prove, in the sense of explaining and convincing in geometry, has been discussed by many researchers (e.f., Chazan, 1993; Dreyfus & Hadas, 1996; Goldenberg, Cuoco, & Mc [illegible], 1998). We demonstrated (Hadas & Hershkowitz, 1998) that uncertainty stems from a geometrical situation in which students cannot find any example confirming their intuitive conjecture, because such an example does not exist. In the present article we describe a case in which students are engaged in a construction task in a situation of uncertainty: the construction was possible, but was opposed to students' intuitive conjectures.

Background

Yerushalmy, Gordon & Chazan (1993) distinguish two kinds of geometrical problems in computerized learning environments: construction problems and conjecture problems. In both, one has also to consider the different roles of proof; i.e., as a tool to show the universality of a statement and as a tool to explain (Hanna, 1990). In many conjecture problems students feel that the universality of the conjectured attribute of the geometrical object is confirmed by the computerized environment. The dragging operation on a geometrical object enables students to apprehend a whole class of objects in which the conjectured attribute is invariant, and hence they are convinced that their conjecture will be always true (De Villiers, 1998). Therefore the only motivation driving students to prove is to explain. We have already described (Hadas & Hershkowitz, 1998) an example of a conjecture problem, in which the conjectured attribute does not exist, hence the dynamic tool does not play a convincing role. Such a problem is a good didactic opportunity to make the student aware of the role of explaining by proving, as a convincing tool.

In construction problems the universality and the explanation are interwoven. Schoenfeld (1986) has described two construction problems to support his claim that "empiricism is an essential component of the machinery of deduction, conversely, however deduction makes possible a discovery that is inaccessible to insight or empiricism" (p. 249). In common construction problems in computerized environments, students are asked to construct a figure whose existence is obvious. In the following, we will show students working on a problem in which they are asked to investigate by construction, the existence of a figure satisfying given conditions.

The problem - Congruent Triangles

*In this activity, we will investigate **if** and **when**, two triangles having several equal elements, are congruent.*

Task 1. Given a dynamic triangle ABC, build another triangle having two angles and the included side equal to two angles and the included side of ΔABC.

*Task 2. Is it possible to build a triangle with one side and two angles equal to those of a dynamic triangle ABC, but **not** congruent to ΔABC? If it is possible, build such a triangle; otherwise explain why .*

*Task 3. Is it possible to build two non-congruent triangles, with **five** equal elements? Create a hypothesis.*

*Task 4. Is it possible to build two non-congruent triangles with **six** equal elements? If yes construct two such triangles, otherwise explain why .*

*Task 5. Is it possible to build two non-congruent triangles, with **five** equal elements ? If yes construct two such triangles, otherwise explain why .*

Problem analysis: a. Task 1 prepares students for Task 2: they realize that congruence is an invariant attribute under the dragging operation. This means that when one changes the original ΔABC by dragging, the second congruent triangle changes accordingly. But, the second triangle cannot change when it is itself dragged by one of its vertices.

b. When students complete Task 2, they are asked to identify the equal elements, and to their surprise, discover 4 equal elements in the two non-congruent triangles.

c. The task of constructing a triangle non-congruent to ΔABC, with 5 elements equal to elements in ΔABC, is quite complex. We consequently decided to decompose it into three stages: a conjecture stage (Task 3), a discussion of the case of 6 equal elements (Task 4), and finally the construction of a triangle with 5 elements equal to elements of ΔABC, although non-congruent to it.

Problem Characteristics: (i) As in all other construction problems in such an environment, the computerized tool elicits empirical actions followed by a prompt feedback from the tool. But, for complete success, deductive considerations are needed. (ii) The problem provokes surprise followed by uncertainty. (iii) Students' construction processes depend on their ability to analyze the problem deductively, leading to the elaboration of an existence proof. The last two characteristics are discussed in detail in our analysis of some students engaged in this activity.

The Interviews

Pairs of Grade 10 students with ability in the upper half of the population, were interviewed while working on the problem. The interviews were videotaped and analyzed. The students were towards the end of a two year geometry course, and were familiar with ways to prove. In the following, we describe two representative pairs of students.

The first pair

In Task 1 a girl and a boy, Gili and Nadav, constructed a triangle non-congruent to ΔABC with two angles and the included side equal to the same elements in ΔABC. They discovered that the new triangle can be modified only by dragging the vertices of ΔABC, and explained this modification by invoking the relevant congruence theorem. They then struggled with Task 2 for 15 minutes. First they constructed the second triangle (see Figure 1) where: DE=AC; <D=<A; and <F=<B.

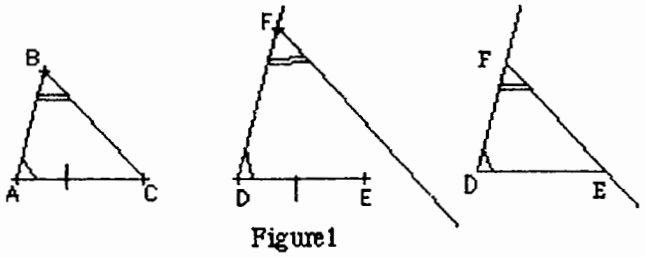

Figure1

The following excerpt expresses the dialectic process the pair underwent.

Nadav: *They were supposed to be non-congruent but they are* [congruent].

[F is a random point on the line DF, They drag F in such a way that FE remains the triangle side. When they change ΔABC, they had to adjust F again by dragging.]

Gili: *It's the same again.*

Nadav *Ah! It is like that because if this one* [pointing at <D and <A] *and that one* [pointing at <B and <F] *are equal, the third must be equal as well...If two angles are equal even if they are not at the two ends of the side, the third is equal too.*

I: *So what is your conclusion?*

Nadav: When *we have two* (equal) *angles and side, and they* [the triangles] *are not congruent, it is impossible.*

[Gili starts looking for a way to show that the construction is possible. The interviewer suggests analyzing all possibilities for locating the "second angle".]

Nadav: If *we copy it* [pointing at <B] *here* [pointing at a point on DF] *we get stuck!*

Gili: *If we copy <C here* [she points at a point on DF, and starts to construct].

[Nadav who was hesitating so far, starts watching Gili, and after she copies the second angle, exclaims:]

Nadav: *Ahh! you did it the opposite* [meaning not correspondingly].

[The pair complete the construction and check it by dragging. Nadav explains what they did explicitly. The discussion continues.]

Gili: *So, we succeeded?*

I: *Did you discuss the idea of correspondence between two triangles in the context of congruence in the class?*

Nadav: *No, we didn't. The teacher did and now I understand why.*

[To their surprise, the students find that the two non-congruent triangles have even 4 equal elements.]

In Task 3, the pair hypothesize that a triangle with 5 elements equal to elements of ΔABC, but not congruent to ΔABC, can be constructed in a way similar to that in Task 2. The interviewer does not let them try to construct such a triangle and asks them to move to Task 4. They discuss the issue of 6 equal elements in non-congruent triangles. Gili claims that it is impossible to construct such a triangle, but did not justify her answer. In contrast Nadav argues that it is possible and applies the strategy used successfully in Task 2, on a piece of paper (see Figure 2).

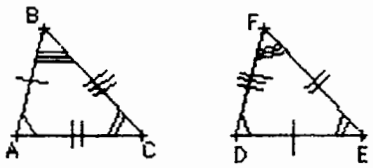

Figure 2

The interviewer asks them to analyze their drawing using their geometrical knowledge. Nadav answers immediately: *In fact there are 3 equal sides so the triangles are congruent, hence it is impossible with 6 equal elements.*

Their investigations on Task 5 are based on: (i) considerations they raised in the previous task, (ii) their hypothesis in Task 3 that it is possible to construct a triangle with 5 elements equal to elements of ΔABC, but not congruent to ΔABC. They try to apply similar methods to those they used in Task 2. First they plan the construction by erasing the "equal signs" of one pair of corresponding sides, on their drawing in Task 4 (Figure 2). They then try to construct ΔDEF according to this drawing. They succeed in this endeavor, but with 3 equal elements only. They use measuring and dragging operations to try to obtain all the 5 equal elements, but without success.

The students then discuss what they have done with the interviewer and conclude that it is difficult or even impossible to obtain the 5 equal elements in the two triangles by dragging, even if such a triangle exists. They initiate deductive

considerations as following: the triangles can have only two equal sides, so they must have 3 equal angles. This means that the triangles are similar, and therefore the ratio between corresponding sides in the two triangles must be constant. Following a suggestion by the interviewer, the students construct an example of two such triangles by choosing (with the help of the interviewer) particular lengths for two of the sides in each triangle (see Figure 3). They deduce that the invariant ratio between the corresponding sides in ΔABC and ΔDEF must be 1.5, and hence that AB must be 4 and DE, 13.5.

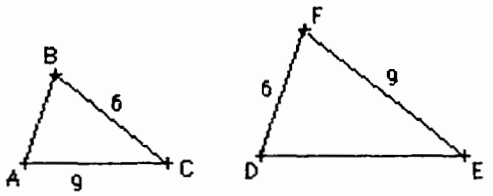

Figure 3

The pair then constructed the two triangles with the software. The following discussion took place.

Nadav: *But the angles should be equal as well.* [He thought for a while and added:] *but it is O.K.*

I: *Why are you sure that the angles should be equal?*

Nadav: *Because they* [the triangles] *are similar.*

The second pair

Two boys, Asaf and Asher answer Task 1 in the same way as the first pair. They also start Task 2 by constructing a second triangle (see Figure 1), in which DE=AC, <D=<A, and <F=<B. Once they realize that they obtain congruent triangles, they immediately conclude that they did it wrong, and replace the third equality by <F=<C. They then succeed in constructing the two non-congruent triangles. The following excerpt **came at** the end of their discussion concerning 4 equal elements:

I: *So, how many equal elements do you have in the two triangles?*

Asaf: *Three*

I: *No more?*

Asaf: *The third* [pair of] *angles cannot be equal because then they* [the two triangles] *will be congruent.*

Asher: *No because if the third* [pair of] *angles* [are equal] *they will be similar and not congruent.*

I: *Can you construct two triangles with two pairs of equal angles in which the third pair is not equal?*

Asaf: *Yes!*

Asher: *No!*

Asaf: *Wow! It's impossible!...Only the sides are not equal, because the sum of the angles in a triangle is 180°. Wow! four equal elements and the triangles are not congruent.*

In Task 3, they hypothesize that triangles with 5 equal elements are always congruent. This assumption is elaborated in Task 4, for 6 equal elements. The interviewer does not let them leave this issue too quickly, and brings the idea raised by the previous pair of students at this point by asking: *Maybe one can construct equal angles not opposite to the equal sides?* The students seem intrigued by this idea and draw a sketch similar to Figure 2, discuss it for a while, and conclude that because the triangles have 3 equal sides they must be congruent.

They come back to the issue of 5 equal elements in Task 5, and conclude that if such triangles do exist they must be similar, because the three angles are equal, and thus the ratio between corresponding sides must be constant. After a long dialogue between the two students, in which the interviewer suggests they focus on one special pair of triangles, they succeed in sketching one example, by calculating the ratio between the sides and applying it to calculate the third side in each triangle, - in the same way as the first pair (see Figure 3).

The interviewer checks their awareness of their own actions by asking: *What do you think about the angles, must they be equal as well?* This pair of students is unable at this point, to refer back to the similarity of the triangles in order to justify the equality of the angles, in spite of their intuitive feelings that this is true. So, they construct the two triangles with help of the software, measure the first pair of angles and find them equal. In the process, the similarity of the constructed triangles becomes visually obvious (see Figure 4).

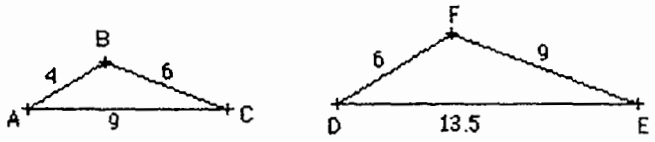

Figure 4

This visual clue leads the pair, after a while, to deduce the triangles' similarity,as we can see from Asaf's concluding remark: *If the ratio between the sides is fixed, then they* [the triangles] *are similar and then the angles are equal. But, they* [the triangles] *are not congruent. So, we did it!*

Discussion

The dialectic feeling of uncertainty.

As we mentioned above, one of the characteristics of this activity is the feeling of uncertainty concerning the existence of examples fulfilling the constraints. In Task 2, in contradiction to their conjecture, both pairs were surprised to find a way to construct the non-congruent triangle with the 2 angles and one side equal to those given, and even more, to discover that the two triangles have 4 equal elements. This way of copying an equal angle into ΔDEF in a non-corresponding position, is based on deductive geometrical reasoning. By using it to construct the required triangle and watching the result on the screen, students became confident that their construction was correct. This confidence led them to hypothesize that non-congruent triangles with 5 equal elements can be constructed. The students went even further to claim that when two triangles have 6 equal elements, they are not necessarily congruent, and they even tried to sketch such triangles. However, when they used a congruence theorem, they were confident that 6 equal elements always implies congruent triangles. This raised their suspicion in Task 5, and uncertainty characterized their first steps in this task. Only after they succeeded in designing their construction deductively did they become confident again that such triangles do exist, and insist on constructing them on the computer.

The deductive explanations.

Different kinds of deductive reasoning occurred in the various tasks. In Task 2, students constructed the ΔDEF by copying the two angles to two vertices which are not both on the given side, yet obtained a congruent triangle (see Figure 1). This action led them to a different construction, based on deductive considerations. This construction by itself is the deductive solution (an existence proof) to Task 2. The situation in Task 4 is similar to the one we have already described (Hadas & Hershkowitz, 1998), where students could not find any example confirming their intuitive conjecture, because such an example does not exist. Here a non-congruent triangle with 6 equal elements does not exist, so the only way to be convinced is to give deductive explanations. Task 5 has the same characteristics as Task 2; the construction is based on deductive considerations. And yet we saw that these deductive considerations are very fragile. Students needed to reflect on the whole process they underwent, before they became aware of the logical chain they themselves elaborated.

Deductive explanations were not the first weapon used by students in justifying their actions or their planned actions. This finding has been noticed by many researchers (e.f., Schoenfeld, 1986; Hoyles and Jones, 1998) Examples: (i) When asked, after accomplishing Task 2, how many equal elements the two non-congruent triangles have, the second pair spent a long time at arguing before being able to use deductive considerations, based on the sum of angles in a triangle. (ii) The two pairs had difficulties in seeing the logic chain on which the construction of the triangles in

Task 5 was based. It was even more difficult to recreate the opposite chain from the constructed triangles to conclude that the triangles must be similar, and hence the angles must be equal.

As described above, students gave deductive explanations of their actions, a fact that made them confident in what they did and in the ways they justified why certain constructions are impossible.

Mathematics Education Research Project: Researching Teacher Development Through Action Research

Anjum Halai[1], University of Oxford, UK.

The report is on a one-year action research project where university-based researchers facilitated and studied the action research being conducted by a group of mathematics teachers from schools in Karachi Pakistan. The research design was qualitative in nature and used participant observation, field notes from meetings, and reflective journals maintained by all participants as tools for data collection.The study claims that action research promotes teachers' learning and professional growth by enabling them to take a critical look at their practice. However, also significant is the growth and learning of the university-researchers, as helping teachers to inquire itself requires critical reflection. The study has immense implications for inservice and preservice teacher education initiatives and raises some important questions regarding the structural changes that might be required in schools to allow them to become communities of inquiring practitioners

The mathematics research project looked at teacher development through action research. The research group comprised a team of eleven. Of this, six were teacher- researchers who taught mathematics in schools from the public and private sector in Karachi Pakistan. The remaining five were university-researchers who both researched and facilitated the inquiry that the teacher-researchers conducted into their practice. One of the five from the university coordinated the project. I worked as university- researcher with one mathematics teacher.

Action Research. The term 'action research' means different things to different people. Smith & Lytle (1993) defined teacher research as systematic, intentional inquiry by teachers. Carr & Kemmis (1986) saw action research as undertaken by participants in social situations to improve the rationality and justice of their practices, their understanding of these practices and the situation in which these practices are carried out. The concept of a reflective practitioner as defined by Schon (1983) and Stenhouse (1975) is consistent with the idea of teacher as researcher. Action research is seen as a vehicle to promote reflection and growth of the reflective practitioner entailing cycles of planning, implementing, observing and reflecting on ones own practice. Grundy (1987), describes three modes of action research i.e. technical action research which is effective but product directed. Practical action research which emphasizes the role of personal judgement in decisions to promote change and emancipatory action research which promotes critical consciousness towards change

[1] Anjum Halai is currently on secondment from the Aga Khan University, Karachi (Pakistan), pursuing her D.Phil in mathematics education from the University of Oxford, UK.

initiatives. Hence if the project is directed by the university-researcher and ownership of ideas is not taken up by the practitioner the research project will remain in technical mode. However, if the participants take over ownership,the project could become critical or emancipatory.

Similar to the project in Jaworski (1998), a central issue in this case was the interrelationship and interdependence between teachers' research and the study of the research. The university researchers provided a major support to the teacher-researcher in conducting the research and worked in dual roles of researcher and mentor. Given the nature of the project I see action research as defined by Pedretti (1996) as a form of professional development which encourages teachers to participate in cycles of planning, acting, observing and reflecting thereby creating possibilities for change and transformation and in which equally important are the transformations and growth experienced by the facilitator (mentor) in an action research context.

The Context. The school was a private school for girls in Karachi with a staff of about eighty teaching 1300 girls. The overall administration is in the hands of the principal. All the class room activity in this project was based in one particular section of Class Six (10-11yrs.) chosen because both the teacher-researcher and I were jointly responsible for teaching mathematics to it. By agreement I initially did most of the teaching and Zarina observed me. About two months later she indicated her wish to teach and be observed. Each provided feed back to the other.

The universiy-researcher. After teaching at this school for eight years, I participated in a degree course in teacher education at a local university. The programme selects and trains teacher educators, who then return to their schools to work jointly with the university and the home school that sponsored them: in university 6 months running courses for the visiting teachers, and in school for 6 months. In the school I taught mathematics to one class which was 1/3 of the total teaching load that teachers in school had. For continuity to the pupils, one other teacher (Zarina) was assigned to work with me in the same class so that when I left for my university work the second teacher could take over and continue smoothly.

The teacher - researcher. From all the mathematics teachers in school Zarina accepted my invitation to join the project. She had been teaching mathematics in the school for four years and 11 years elsewhere. She has a first degree in biology but no professional qualification. I got to know, Zarina better when she came to the university to attend the visiting teachers programme, which I was conducting along with a group of other colleagues.

The project team. The project team including the teacher-researchers, university-researchers and the coordinator met once a quarter over a period of one year to find out where each one was at, sharing learning, and raising issues. These meetings provided opportunities of on-going cross analysis of emerging data.

The Research Process. Over a period of one year Zarina and I met once a week for 90 minutes to plan lessons, share ideas and expertise including doing the mathematical activities that we wanted to carry out in the class. A regular feature of these meetings was to reflect on the previous week's happenings and discuss issues that had arisen.

Observation & post-observation conferences: After each classroom session a post-observation conference took place between Zarina and myself to promote reflection on key issues arising in the classroom.

Reflective journals: Writing and sharing journals raised an issue. If the journal was written for an audience then the entries might be coloured by considerations of what the reader might want to see in them. In order to let journal writing be an exercise in genuine reflection and yet allow others to learn from them Zarina and I decided to read, talk about and analyse portions of our journals that we wanted to share with each other in our pre- and post - observation conferences.

Analysis. For discussion of results, critical incidents have been selected from our work together because they throw light on how Zarina was thinking about planning for teaching, learning, mathematics and other emerging issues and how my own understanding developed of teacher learning and action research. To give a sense of progression these incidents have been described in sequence.

Action Research Focus. When I look at Zarina's initial journal entry I find her thinking about lesson planning in conjunction with planning in-groups.

> Planning lesson in-groups provides opportunities to learn from others and we learn many things, which we did not know before.
> Journal entry: 2-9-96

Later In a conversation she identified the focus of her action research by saying:

> Z_1: I want to know what a lesson plan is like.What should be in it. I want to plan using the ways shown in the VT programme.
> field notes: 28-9-96

I interpret from above that her action research focus is embedded in her recent experiences of professional development in the VT programme. Her journal entries indicate that she had realized the value of group work during her

experiences in the programme where working in groups provided opportunities to exchange ideas, work out meaning of new ideas or take an in-depth look at familiar concepts. So she links up the idea of planning with group work. The VT programme may have inititated the process of critical reflection on her practice but in action research that by engaging in cycles of planning, action and reflection that she takes overt and systematic action on that critical reflection. Does it mean that a springboard is needed to facilitate the action research process? Rudduck (1991) suggests that a pre-condition for teacher research may be that the teacher temporarily becomes a stranger in his or her own classroom. Becoming a stranger would allow them to look at 'ordinary' interactions and events with new eyes. My interpretation is that Zarina's experience of participating in the VT programme allowed her this opportunity to step back and look at her own practice with anew.

However, over the life of the project her question did not remain the same. I saw that the questioning stance enabled by the research process got her to look critically at other aspects of her practice. For example, she questioned the traditional examination which usually assesses pupils' procedural knowledge of mathematics but does not necessarily indicate pupil understanding of those procedures. Hence the examination paper was modified so that questions were not asked according to the set pattern.

An Example of Zarina's Learning.

The fraction lesson: This lesson on fractions had been planned together by Zarina and myself. However, I taught while Zarina observed. I asked the pupils to work in pairs on the problem given below and left them to choose their own ways of interpreting the problem and recording its solution. Squared paper and other manipulatives were made available to them.

Saima wants to divide three fourths of a cake into fifths so that she may send it to five of her friends who could not attend her birthday party. How much will each friend get?

A number of issues arose from this lesson. It was apparent that students were not sure which strategy to use and why. Some had got the solution through the routine rule 1/5 of 3/4=3/20 but could not explain the reasoning behind it. Naima had used 3/4÷1/5=15/4 and could also not explain the use of the strategy or what the answer 15/4 signified.

In a subsequent conference talking about her action research Zarina referred to this lesson and the following conversation took place:

I_5: Then what do you want to do?

Z_6: Show it (lesson plan) to you so that my lesson plan is not such that when I go to the class I get confused myself

I_7: i.e. you then want to teach yourself?

Z_8: and you then tell me

I_9: Tell what?

Z_{10}: feed back-what was right what was wrong-my language my questioning-

I_{11}: Explain confusion some more

Z_{12}: Like Naima's question today. Which I had also asked you yesterday (refers to the planning meeting)-whatever I am taking in the plan that I should also know and then what questions come out of it I should know the expected answers.

I_{13}: This confusion that Naima had what do you think about it?

Z_{14}: When you explained then I understood otherwise I also used to think like Naima---lesson plan should not be such that I do not know what answer to give the child-child will get confused but we should satisfy her-this question that Naima asked many should have asked-if children ask a question and we cannot satisfy them we are putting them in greater difficulty. Field notes: 1-10-96, Translated from Urdu

Her journal entry regarding her action research question read:

> In action research I want to learn to make a lesson plan which is correct i.e. its application is not difficult and neither is my plan such that the pupils are confused by it. Instead it should be clear and it should not require too much time to apply neither should it confuse pupil thinking. Zarina's journal: 3-10-96 Translated from Urdu

A number of questions arise as a result of the above conversation & journal entry. My interpretation is that Zarina is struggling with the question 'how does learning take place?' Hence when she says 'the child will get confused' she is talking about 'cognitive conflict'. She is saying that in the process of learning some confusion does arise and sees the teacher's role in facilitating learning by alleviating confusion. But she also regards confusion as a sign of weakness and so something to be avoided by the teachers. Hence, she insists on a perfect plan which would somehow help her avoid confusion. The question arises how does

Zarina anticipate creating cognitive conflict if she does not see a place for confusion in her teaching. Is she holding conflicting beliefs that confusion is necessary for learning and that confusion is something wrong and to be avoided. The above conversation with Zarina also raised questions regarding her perception of a teacher. Perhaps, it is her perception of the teacher's role as a source of all knowledge and authority, which makes her shy away from confusion. It could also be due to her feeling of inadequacy in dealing with the confusion that she tried to avoid it in her classroom.

In the above conversation, it was not clear what it was that Zarina did not know but had understood after our planning meeting. On asking, she said that like Naima (in the lesson above) she was also not clear about the rule of division of fractions. It was when we had worked through some of the mathematical activities in our planning meeting and discussed the reasons behind the rule that she became clear about the division rule in fractions. I found like Shulman(1987), that teachers' subject matter understanding plays a significant role in teaching mathematics. I was also convinced like Feiman Nemeser & Parker (1990) that doing mathematics with the mentee is a way of making subject matter a part of the conversation in learning to teach

My learning: I see that action research is suited to the purpose of helping teachers question their practice, understand it better and take steps to improve it. The reason as claimed by Smith & Lytle (1993) is that in teacher research the questions asked and the interpretive frames used to understand and improve the practice are owned by the teacher. For example, I saw Zarina identify lesson planning as an area of concern for her. Perhaps, she felt that a perfect plan is one that would help her improve her practice so that she could teach mathematics for understanding. However, during the course of her research I found her asking questions about her own understanding of mathematics. In the fractions lesson she learns the rule of division of fractions. I saw her questioning the process of pupils learning so that she thinks critically about the role of confusion in aiding or inhibiting learning. Assessment and its related issues and concerns also became part of her deliberations at the time of term examinations. Action research takes the teacher beyond the immediate focus of the research question so that the teacher focuses on almost all aspects of her practice. Carr & Kemmis (1986) claim that the questioning stance enabled by the action research made problematic the taken for granted aspects of the teacher's practice. To this end action research seems to be a tool which enables the teacher to look at her practice in a holistic way.

By breaking teacher isolation through creating opportunities of sharing ideas, issues concerns and celebrating success it helped build morale and self confidence of the teachers. For example, Zarina as I knew her in the VT programme and what I heard of her from other colleagues had always been a

retiring kind of an individual. But, during the course of the project Zarina participated in almost all the group meetings. She increasingly contributed her ideas whereas in the initial stage she had expressed her worry about speaking out in-group meetings.

The opportunity to work as a mentor allowed me to deepen my own understanding of the skills and attitudes required to be an effective mentor. I realized that there were certain behaviours, for example, being non-judgmental, encouraging, valuing ideas and respecting confidentiality. I also became sensitive to the impact my actions might or might not have for the teacher. For example, a constant question in my mind was will I create dependency if I do all that she wants in terms of providing new ideas, support, and resources. Grundy (1987) and Showers (1985) also indicate that issues of dependence and autonomy are central to the role of the facilitator or critical friend in teacher research. It would thwart the emancipatory spirit of action research if new forms of dependency are created by the facilitators in their concern for directing rather than facilitating action and reflection. This meant that I had to be very sensitive when deciding when and how to act on judgment formed. Research by Pedretti (1996), Carr & Kemmis (1986), and Jaworski (1998) also recognizes the need for the mentor to use among other things sound professional judgment to enhance the teacher inquiry.

Concluding reflections: For action research to be taken as model of teacher development for the whole school would require greater and more visible support from the principal including the building of a supportive infra-structure, with time for teachers to meet and work collaboratively with other teachers. In this case, the principal agreed to let us conduct action research but did not provide any release time to the teacher to meet and work with me. Smith & Lytle (1993) have indicated that participation in teacher research requires considerable effort for teachers to carve out opportunities to inquire and reflect on their own practice while fulfilling their other responsibilities in school. Zarina gave her own time during lunch breaks or after school. In informal conversations she indicated that she was learning so much that she felt it was time well spent. But this does not mean that other teachers would be in a position to give the kind of time that Zarina or I could.

An implication might be to introduce action research in all teacher education programmes whether pre- service or in- service. This would have the advantage of creating awareness regarding the procedure, value and implications of action research as tool for teacher development. Involving head teachers in action research projects would be one way to ensure support from them and bring about awareness about the kind of time and other resources required. Another implication would be greater involvement of head teachers in what goes on in class rooms and reduced status differential between head teachers and teachers.

Using arguments from physics to promote understanding of mathematical proofs

Gila Hanna

of the University of Toronto, Canada

Hans Niels Jahnke
Institut f? r Didaktik der Mathematik
Bielefeld, Germany

Abstract: *An important challenge faced by mathematics educators is to find effective ways of using proof in the classroom to promote mathematical understanding. We advocate the investigation of one very promising approach that has been insufficiently explored: The use of arguments from physics within mathematical proofs.*

The first premise of this paper is that proof must be part of any mathematics curriculum that aims, as it should, to reflect mathematics itself and the important role of proof within it. The second is that the most significant potential contribution of proof in the classroom is in the promotion of mathematical understanding, a role that it plays in mathematical practice as well (Thurston, 1994). Some educators, proceeding from these premises, have considered ways to make effective use of proof in teaching, and especially in the last twenty years there has been a significant reorientation towards intuition in the teaching of proof (D3rfler and Fischer, 1979). Wittmann and M? ller (1988) speak of "intuitive proof" ("inhaltlich-anschaulicher Beweis"), and Hanna (1990) and Dreyfus and Hadas (1996) draw on the distinction between explanatory and non-explanatory proofs.

These educators, however, have concentrated on the internal aspect of proof, focussing in the main on its function within mathematics (Hanna and Jahnke, 1993; 1996). This paper seeks to redress this imbalance somewhat by investigating proof primarily from the external viewpoint, with a focus on one of its important external aspects: the relationship between physics and mathematical proof. Jahnke (1978) and Winter (1983) have already argued that the usual opposition between "intuitive" and "deductive" is unacceptable, and that mathematical proof should not be seen as a turning away from observation and measurement, but rather as a guide to an intelligent exploration of phenomena. The specific question the paper poses is

twofold: What is the possible role of arguments from physics within mathematical proof, and how should this role be reflected in the classroom?

Previous scholarly work

The first part of this question has to do with mathematics itself. The close cooperation between mathematicians and theoretical physicists has led to a heightened awareness of the many benefits that mathematics derives from physics (Jaffe and Quinn, 1993). Jaffe (1997) points out that physics has traditionally been a source of important problems for mathematics, contributing in this way to its progress, and that in turn mathematical results have helped in the solution of difficult problems in physics.

In a paper on the phenomenology of proof, Rota (1997) maintains that the benefits of this close association are to be seen in mathematical proof in particular. Mathematicians often remain dissatisfied with proofs that, though they establish without a doubt that a theorem is true, provide no insight as to why it is true. Physical concepts and models can make an important contribution to understanding in such cases, and can even help mathematicians devise purely mathematical proofs of a more explanatory nature. In addition, however, an argument from physics may form an integral part of a mathematical proof.

The second part of our question relates to mathematics education. In approaching this issue, we have taken our cue in large part from two publications that deal directly with the role of arguments from physics in the classroom: Winter (1978) and Polya (1981). The ideas contained in these works would be a good point of departure for the suggested investigation. References to physical laws do appear in other educational publications, but only as remarks in passing. Castelnuovo (1971), for example, introduces projections and shadows when treating the notion of similarity. From a theoretical viewpoint, Struve (1990) discusses geometry as an empirical science in contrast to geometry as a theoretical system. In Bender and Schreiber (1985) one finds a different conception of the relation of empirical and theoretical geometry, based on the ideas of H. Dingler. The following paragraphs discuss work published on closely related issues.

Some recent publications describe various approaches to making proof meaningful in

the classroom with the help of empirical arguments. Dreyfus and Hadas (1996) showed that an empirical approach to teaching geometry with dynamic software can bring students to see that proof is required to explain results that are unexpected or counterintuitive. De Villiers (1995), Mariotti (1995), and Mason (1993) discuss several dynamic geometry constructions, illustrate problem-solving methods not possible with pencil and paper and advocate the use of dynamic software for fostering new insights into traditional geometry theorems. Greer (1996), as well, describes the use of empirical arguments for proving.

Among mathematics educators there are also those who advocate basing the teaching of mathematics upon its various applications. This movement includes suggestions for a closer relationship between mathematics and the other sciences (OECD, 1991), a theoretical framework for what is called Realistic Mathematics Education (RME), which advocates using reality as a source for mathematization (Freudenthal, 1983; Streefland, 1991), and other projects that in various ways seek to strengthen the role of applications in mathematics teaching. For the higher grades of school teaching, one must also take into consideration the publications of the ISTRON group (Blum, 1993). None of these proposals deals explicitly with the teaching of proof, however.

What is meant by "arguments from physics within mathematical proofs"?

To explain better the concept behind the proposed investigation, we would like to draw a clear dividing line between using arguments from physics within mathematical proofs and merely using physical representations or illustrations of mathematical concepts or theorems. An example of the latter is the representation of the laws for natural numbers by geometrical configurations of pebbles. The underlying idea we suggest, on the other hand, is to apply in a mathematical proof a complex law of physics as if it were a mathematical theorem. For this there are historical as well as educational examples.

To begin with the former, the application of physics to mathematics has a long history. When a purely mathematical proof of a theorem proves elusive or awkward, mathematicians have often found that the introduction of concepts and arguments from physics yields a straightforward proof. A famous example is Archimedes' use of the law of the

lever for determining volumes and areas (compare his work on "the method"). Another equally famous example, from the calculus of variations, is the so-called Dirichlet principle, which asserts the existence of certain minimal surfaces as solutions of certain boundary value problems. In the 19th century, Dirichlet and Riemann took this theorem as obvious for physical reasons. Weierstra? later criticized its use, however, forcing mathematicians to look for a purely mathematical proof of the principle. This was quite hard to achieve, but in the end the effort led to considerable progress in the calculus of variations (Monna, 1975).

As an example of the application of laws of physics to mathematical proofs in education, we might first mention the construction of the Fermat point of a triangle, where the most elegant method is to model the triangle by a physical system consisting of a perforated plate and weighted ropes (Polya, 1981). Some theorems of elementary geometry, such as the Varignon theorem that the midpoints of the sides of a quadrangle are the vertices of a parallelogram, can be proved most easily by applying the laws of the lever or the notion of centre of gravity. For these and numerous other examples see Winter (1978). A final example is the mean value theorem of differential calculus. If we interpret the derivative of a function as the velocity at a given instant, then the mean value theorem follows directly from the observation that a car going from A to B must have had, at least at one point, the mean velocity as its actual velocity.

Such applications of physics do much more than illustrate a theorem. By introducing productive concepts, they make possible a more satisfactory proof of the theorem, and one that, on the basis of an isomorphism between the mathematical and the physical constructs, is no less rigorous. (In this they differ from much of what has come to be referred to as "experimental mathematics," which in its essence consists of generalizations from instances.)

For the mathematician, indeed, the use of concepts and arguments from physics is primarily a way to achieve a more elegant proof. But such a proof may also be illuminating, in different ways. It may reveal the essential features of a complex mathematical structure, provide a proof that can be grasped in its entirety (we call this the holistic version), as opposed to an elaborate and almost incomprehensible mathematical argument, or point out more clearly the relevance of a theorem to other areas of mathematics or to other scientific disciplines.

These broader benefits are invaluable even to the practising mathematician, so they clearly have great potential for promoting understanding among students. Unfortunately this potential is not being exploited, however, because concepts and arguments from physics have not been integrated into the classroom teaching of proof to any great extent and certainly not in any organized way. This is not surprising, since there is no body of research work on this topic that might provide guidance and tools for teachers and curriculum developers.

Prerequisites for success in using arguments from physics

The educational aspect of our question actually comprises two tightly linked issues: How can the actual role of arguments from physics in mathematical practice best be reflected in the curriculum, and how can such arguments best be used to promote understanding?

To address the first issue, one would have to examine the epistemology of mathematics implied by much of present classroom practice and compare it with accounts of the nature of mathematics implied by the practice of mathematics itself or espoused by mathematicians and philosophers of mathematics.

Implicit differences of epistemology are important. For example, students are often taught that the angle sum theorem for triangles is true in general just because it has been proven mathematically. Ignoring the fact that measurements have shown this relationship to hold true for real triangles as well, this practice implies a very specific and limited view of the nature of mathematics and its relationship to the outside world. Students do not share this view, however, bringing to the classroom the belief that geometry has something to say about the triangles they find around them. In this they may unwittingly be closer than the curriculum to the broader view of the nature of mathematics held by most practising mathematicians. For this reason it should come as no surprise to educators when students are taken aback, misinterpreting the assertion that mathematical proof is sufficient in geometry to mean that empirical truth can be arrived at by pure deduction.

It would seem that educators themselves need to come to the classroom with a more satisfactory understanding of the nature of mathematics, one that encompasses its

relationship with the empirical sciences and everyday human experience. Of course the curriculum itself should be informed by the same understanding.

The second issue is the use of proof for the promotion of understanding. Students being introduced to mathematical proof come to the classroom with preconceived notions and complex epistemological uncertainty. Educators need to understand both much better than they do today. When confronted with the proof of a theorem, for example, students quite often say that they have understood the proof, but still ask for additional empirical testing. From a purely mathematical viewpoint such a request seems quite unreasonable, and teachers usually take it as an indication that the students did not really understand what a mathematical proof is. From the viewpoint of a theoretical physicist, however, the same request would seem quite natural; no physicist would accept a fact as true simply on the basis of a theoretical deduction. Thus a consideration of the role of mathematical proof in theoretical physics may well shed light on the way in which students view proof.

Keeping in mind the viewpoint of the theoretical physicist is useful when analysing how students approach proof when using dynamic geometry software such Cabri Geometry or the Sketchpad, which allow explorative work similar to experimental physics. Comparing students with theoretical physicists also promises to be of help in understanding how teachers might best cope with the questions that may be created in students' minds by the use of concepts and arguments from physics in mathematical proofs.

Broader educational aims

There are also broader educational reasons for studying the use of arguments from physics within mathematical proofs. We will sum up these up in four statements.

- As already mentioned, there is a trend in all Western countries away from using proof in the classroom. In our view this development will undercut the educational value of mathematics teaching and should be countered by fresh approaches to the teaching of proof.
- Of course the growing trend to experimental mathematics should be reflected by an

increased emphasis on experimental mathematics in the schools. But experimental mathematics in the schools should not be just "mathematics with computers." From an educational point of view, this would be a dangerous development. Rather, one should be guided in the use of experimental mathematics by the question of how it contributes to our understanding of the world around us.

- The holistic aspect which many arguments from physics can bring to mathematical proofs (see above) is an important part of mathematical competence that is frequently underestimated. Instead, there is a predominance of step-by-step procedures. Seeking good examples of instances where arguments from physics are useful to mathematics proofs will contribute to developing a way of teaching and learning mathematics which is more balanced in this regard.

- In Western countries physics is less and less a required subject. Physics is the discipline nearest to mathematics, however, and to maintain meaningful and inter-disciplinary mathematics teaching it will therefore become necessary to include some elementary physics in the mathematics curriculum. In Germany there are already proposals in this direction, as a consequence of the country's poor results in the Third International Mathematics and Science Study (TIMSS), and the "Konferenz der Kultusminister" intends to decide upon a large scale project exploring new types of interdisciplinary teaching.

GENERATING ADEQUATE MATHEMATICAL QUESTIONS ACCORDING TO TYPE OF PROBLEMS

Shirley H. Har-Zvi, Bar-Ilan University
Zemira R. Mevarech. Bar-Ilan University
Levi Rahmani, Tel-Aviv University

In recent years, mathematics educators, researchers, and philosophers have convincingly argued that students have to learn how to "do mathematics" and communicate their mathematical ideas to others, rather than memorizing formulas and applying procedures. It leads students to a deeper understanding of the mathematical processes. For this propose The students have to learn how to formulate and solve problems, look for patterns, make conjectures, examine constraints, make inferences from data, abstract, invent, explain, justify and so on (Stein, Grover & Henningsen, 1996).

The constructive theories of learning and teaching emphasize the importance of student-generated problems as a tool of developing deeper understanding. According to these theories, learning occurs when students construct connections between exiting knowledge and new knowledge (Witrock, 1976).

Generating problems is assumed to lead students to look for additional information, which in turn facilitates the constructions of these connections (King, 1989, 1991, 1994; Mevarech & Kramarski, 1997).

Mathematical problem generating refers to creating new problems, reformulating given problems (Polya, 1973), and generating questions based on a given set of quantitative information. It is usually part of inquiry processes.

Silver (1994) argues that problem generating (posing) is a feature of (a) Creative activity or exceptional talent (e.g., in mathematics- Kruteski, 1976; Ellerton, 1986; in others areas- Getzels & Csikkszentmihalyi, 1976; Mansfield & Buss, 1981;). (b) Inquiry oriented instruction (e.g., Brown & Walter, 1983 ; Schoenfeld, 1985). (c) Mathematical activity (e.g., Polya, 1973; Schoenfeld, 1985; Mevarech & Kramarski, 1977; Simon, 1973). (d) A window into students' mathematical understand ng (e.g., Ellerton, 1986; Silver& cai, 1993). (e) Mathematics learning activity (Healy, 1993; Streeflend, 1991; Yerushalmi, Chazan, Gordon. 1993). (f) A Means of improving problem solving (e.g., Owen & Sweller, 1985; Silver &cai, 1993). (g) A Means of improving student disposition toward mathematics (Brown & Walter, 1983). (h) A Means for improving information processing and metacognition (e.g., in mathematics- Mevarech & Kramarski, 1997 ; Schoenfeld, 1985,1987; in other areas- Grasser & Person, 1994; King, 1989, 1991, 1994; Pressley & Pressley, 1985; Wong, 1985).

What is generating adequate mathematical questions?

Students are given a mathematical word "problem" in which the question sentence is missing and they have to generate questions that relate to the entire story "problem". Generating questions in this case may vary in the degree of their complexity as a function of the "problem" complexity: one question fits one-step "problems", a series of two or three questions fits two- or three-step "problems", respectively.

Rahmani (1994) developed software called "Pithagoras" (in Hebrew, English and Italian versions), in which students are taught how to generate adequate mathematical questions that are appropriate for various kinds of "problems". It was designed for pupils from 4^{th}-5^{th} grade to the level of elementary algebra problems.

The "Problems" were organized hierarchically, from one-step to multiple-step problems. Students could not move to a higher level on the hierarchy before they mastered the lower level.

The purpose of the software is to develop the ability of students to understand and solve mathematical problems, which are part of their school tasks and beyond

The goals of the software

1. To develop the comprehension of a mathematical problem and mathematical reasoning.

This software follows closely the topics taught in elementary schools regular classes. The problems concerned with the underlying mathematical concepts such as the four basic arithmetic proportions.

The software emphasizes the comprehension of the linkage, similarities and differences, between the problems. The requirement for calculation is secondary to that of posing the adequate question according to type of problem.

The program leads the student to grasp the relationships between given items of information and ask questions about unknown items of information and arithmetic operations. This implies the ability to extract the substance from the story, the relations between quantitative values – numbers, fractions, etc. – and distinguish between unknown yet reachable information, and unknown and unreachable information.

2. To go beyond cognitive goals.

The software endeavors to increase students' motivation to confront with word-problems. A learner who experienced repeated failures to handle mathematical problems is encouraged to comprehend the problems while working at the computer. The learner is prone to run more "cognitive risks"

3. To develop the ability to categorize problems.

The program leads the student to categorize mathematical problems according to given information about quantitative relations and to the additional information that can be derived from it.

4. To lead the students from concrete to abstract.

The program progresses from rather concrete problems involving information on definite quantitative values, to more abstract problems, involving exclusive information on relations among quantities. Thus, the software advances from numerically presented problems to encourage computation to problems that require the student to determine whether two sets of data are quantitatively equal or not, while the quantities as such cannot be determined. Quite frequently students initially claim that such problems cannot be solved.

5. To distinguish between definite and possible solutions.

Students are trained to discover the framework in which solutions are possible and to understand which solutions are not possible.

6. To develop the ability to grasp an entire problem.

Frequently, students tend to grab a certain piece of information that happened to catch their attention, and embark on the wrong track to the solution, typically a series of casual trials and errors. The software promotes the habit of seeking for the whole available relevant information before taking the first step in the right direction and proceeding straight toward the solution.

7. To upgrade the comprehension of the text of a problem.

Students may fail to solve a problem because of misunderstanding a text, a word or a sentence or because of linguistic poverty and words with inappropriate and inaccurate meanings. The tendency of the software is not to avoid these items. On the contrary, such lexical items are incorporated into the problem story. Indeed, mathematical word problems are useful to enrich the student's vocabulary.

The Bar-Ilans' study

A study was conducted at Bar-Ilan University with 6th grade Israeli students. The hypothesis of the research was that training students to generate adequate question on the basis of given word "problems" in which the question sentence is missing would exert positive effects on students' ability to generate problems, solve problems, and on their attitudes toward the learning of mathematics. Moreover, there is reason to suppose that training students to generate questions in cooperative setting will be more effective than training them to generate questions individually

Method

Participants were 122 sixth-grade students (63 boys and 59 girls) who studied in two Israeli public schools. Both schools are located in the center of the country and the students come from a similar background.

Treatments

The research was based on a 2X2 factorial design, as follows: about half of the participants were trained to generate mathematical questions based on "word problems" with missing questions, and then solve the problems. The other half was trained to solve the same problems in which the questions were provided. Under each treatment, about one third of the participants studied individually, and the others in pairs. Students did not receive any special training for enhancing cooperative behaviors.

The computer presented the problems under both conditions. The "Question Generation" condition: under this condition the students used the computer software- "Pithagoras", which was introduced before. Students were asked either to select a question (or a series of questions) from a set of questions or to generate a question (or a series of questions) based on all the quantitative information or the relational terms that were presented in the "problem" text. Students received immediate feedback from the computer telling them the extent in which their responses were correct. Then, students were asked to solve the problems.

The "Problem Solving" condition: Under this condition students were presented the same problems, organized in the same way as under the "Question Generation" condition. The two programs were identical except that in the "Question Generation" software the questions for each "problem" were missing Thus, under the "Problem Solving" condition instead of generating questions, students were administered a "complete problem" in which the question sentence was included and were asked to solve the problems. The computer provided immediate feedback referring to the correctness of responses.

Measurement and Procedure

The battery of examinations and questionnaire included three measurements: Mathematical Word Problem Examination (MWPE), Mathematical Question Generation (MQG) Examination, and Mathematics Attitude Questionnaire (MAQ).

To get further information on the experiment, at the end of the study eighteen students were interviewed Prior to the beginning of the study, all four groups were administered a battery of pretest. Then, each classroom was assigned to study as planned· about third of the students worked individually and the others cooperatively (in pairs). At the end of the study, all students were

re-administered the battery of examinations and questionnaire. The duration of the study was about three months.

Results and discussion

The findings of the present study showed that students' ability to generate problems prior to being exposed to the training was rather low. In particular, students faced difficulties in generating questions on the basis of two – and three-step problems. These findings are in line with previous studies that focused on questioning skills in non-mathematics classrooms (e.g., Mevarech & Susak, 1994). The findings further showed that training children to generate questions improved their questioning skills, specifically on higher cognitive questions that relate to two- and multiple-step problems. More information about the findings will be introduced in the conference.

These results are appropriate the constructivist theories of learning and instruction. Generating a series of questions on the basis of a given complex problem may lead students to focus on all the quantitative information provided in the "story problem", which in turn may facilitate the solution of such problems. An indirect support for this hypothesis comes from children's interviews.

Several students emphasized the facilitative roles of generating problems compared to solving problems. The following excerpt describes students' responses:

"Selecting and generating the most appropriate questions and thinking why a question is not appropriate increased the probability of solving the problem correctly". "Generating questions helped me to focus and take into consideration all the (quantitative) information mentioned in the story problem". "Generating questions helped me to understand the problem better. It helped me to understand complex problems".

Other students referred to the double roles of generating and solving problems:

"In generating problems I have to think more, because I have to think on both the questions and the answers (solutions)". "Being asked to find both the questions and the solutions facilitates understanding more than being asked only to write the solutions".

Some students mentioned the effects of the very nature of being exposed to a new way of learning mathematics:

"In the past we repeated again and again problem solving. That did not help. In generating questions, I succeeded better in understanding the problems".

Finally, several children had their own suggestions regarding question generation training: "Moving systematically from easy to complex problem (i.e.,

from one-step to multiple-step problems) facilitates learning". "Separating the "problem" and the "question" helped a lot".

The finding further showed that students' positive dispositions toward mathematics were rather stable for those who were trained to generate questions, but decreased for those who were not exposed to the training. This finding supports our hypothesis that being trained to generate questions enhances students' disposition toward mathematics, as seen in following excerpts: "Pithagoras can help children who are anxious in math classes because it teaches them how to generate questions, and that helps them to understand the problems. " Learning with Pithagoras made me like mathematics more because it helped me to understand mathematics". "Pithagoras strengthened my self-confidence because it taught me how to solve problems. I had to select and generate questions and that's easier (than solving problems). Also, the teacher sometimes loses her temper. Pithagoras never gets angry on me and therefore I am not anxious when I study with computer".

Comparing the responses of children who were or were not exposed to problem generation training indicated that "Pithagoras" helped them to (a) better understand mathematics (71% vs. 64% respectively); (b) overcome mathematics anxiety (100% vs. 70% respectively); and (c) strengthen their attitudes toward mathematics (29% vs. 22% respectively).

Contrary to our hypothesis, overall no significant differences were found between children who learned cooperatively versus those who learned individually. Also, none of the interactions between question generation training and learning environment (cooperative vs. individualized) were significant. This finding may be explained by Slavin (1996) as well as other researchers (e.g., Cohen & Lotan, 1995; Johnson & Johnson, 1994). Cooperative learning is effective under certain conditions, such as group reward, special training that focuses on cooperative behaviors, or special training regarding social cohesiveness of the small groups. Such training was not provided in the present research.

The effects of such training on the effectiveness of question generation and solving merits future research. It is also possible that, student with different learning styles and entry behaviors benefit differently from cooperative vs individualized settings.

Summary and conclusions

The findings of the present research offer practical evidence that we can successfully promote higher cognitive processes regarding adequate mathematical question generation, word problem solving, and strengthening students' positive attitudes toward mathematics

There is a need to continue this research for a longer period of time and with more students in order to be able to generalize the findings. Examine the effects of generative questions on the development of understanding of mathematical problems merits future research.

CHILDREN'S MENTAL MULTIPLICATION AND DIVISION STRATEGIES

Ann M. Heirdsfield, Tom J. Cooper, Joanne Mulligan* and Calvin J. Irons

Centre for Mathematics and Science Education, QUT, Brisbane, Australia

*School of Education, Macquarie University, Sydney, Australia

This paper reports changes in children's mental computation solution strategies for multiplication and division applied word problems (involving 1, 2 and 3-digit numbers combinations). The study followed 95 Queensland children from Year 4 through to the end of Year 6. The children's responses showed a development from simple counting to use of derived or known facts for small number combinations, and from counting to quite complex and creative strategies to algorithmic procedures for large number combinations. There was some evidence of instructional effects in the increased use of the taught algorithms, the continued use of counting strategies. There was, at times, sustained use of wholistic.

Interest in mental computation as an important computational method for numbers of two or more digits is not new. However, its significance is now seen in terms of its contribution to number sense as a whole; for example, as a "*vehicle* for promoting thinking, conjecturing, and generalizing based on conceptual understanding rather than as a set of skills that serve as an *end* of instruction" (Reys & Barger, 1994, p. 31). To achieve this contribution, it appears necessary to develop proficiency in mental computation through the acquisition of self-developed or spontaneous strategies rather than memorisation of procedures (Kamii, Lewis, & Livingston, 1993; Reys & Barger, 1994). Mental computation in this form features in various models of computation (e.g., National Council of Teachers of Mathematics, 1989; Trafton, 1994), although usually in combination with written, and calculator methods.

There is research evidence that children can use self-developed strategies to efficiently and effectively solve mental multiplication and division problems of two or more digits, even before instruction (e.g., Anghileri, 1989; Carpenter, Ansell, Franke, Fennema, & Weisbeck, 1993; Kouba, 1989; Mulligan & Mitchelmore, 1997). Even in studies of children's solution strategies for more difficult multiplication and division word problems (Murray, Olivier, & Human, 1994), some self-developed strategies have been used (e.g., repeated addition, decomposition and compensation for multiplication; and repeated subtraction, use of multiplication and partitioning for division). There is also evidence for the negative effect of traditional algorithm instruction on efficient mental strategies for multiplication and division examples. For example, Kamii et al. (1993) reported that 60% of third graders who had not been taught the traditional multiplication algorithm were able to mentally solve 13 x 11 (by thinking 13x10=130, 130+13=143); a problem which, in contrast, was only successfully mentally solved by 15% of fourth graders who had been taught the algorithm.

Research has also indicated that performance in mental multiplication and division problems is influenced by the semantic structure of the word problem, with some problems being more difficult than others (e.g., cartesian product multiplication was found to be poorly attempted compared with other types of multiplication - Mulligan, 1992). However, the solution strategy used did not always reflect the semantic structure, particularly as children progressed (Mulligan, 1992; Mulligan &

Mitchelmore, 1997; Murray et al., 1994); for instance, children rarely used sharing for partition division (Mulligan, 1992). Similar results have been found for subtraction (Heirdsfield & Cooper, 1996).

Many researchers have categorised children's solution strategies for multiplication and division word problems (e.g., Anghileri, 1989; Boero, Ferrari, & Ferroro, 1989; Bryant, Morgado, & Nunes, 1993; Carpenter et al., 1993; Clark & Kamii, 1996; Kouba, 1989; Mulligan, 1992; Mulligan & Mitchelmore, 1997). Most of this research has been limited to small number combinations and, therefore, has categorised strategies as counting types (Mulligan & Mitchelmore, 1996). Some research has focused on more complex number combinations, describing strategies in detail (Murray et al., 1994). However, little research has looked across all number combinations.

This paper reports on Years 4 to 6 children's responses to six multiplication and division word-problem tasks which formed part of an Australian Research Council funded five-year longitudinal study of Years 2 to 6 Queensland children's mental strategies for the four operations. Students were tracked over the three years from simple 1 by 1-digit to more difficult 2 by 2-digit multiplication and 1 by 1-digit to 3 by 2-digit division word problems. Further, the study traced strategy changes from pre-instruction in multiplication and division terminology and notation (for some children), through a period of number-fact instruction, and finally until children were taught the written standard algorithms for 2-digit by 2-digit multiplication and 2 and 3-digit by 1-digit division. It also differed from previous research in that the emphasis was not on the semantic structure of the problems; rather, the emphasis was on identifying strategy choice for simple semantic structure and increasingly difficult number combinations.

Method

Subjects. The subjects were 95 children from 14 schools (Independent, Catholic and State). The schools were representative of differing socioeconomic backgrounds. The children had been chosen, when in Year 2, by their teachers to comprise one third of each of above average, average, and below average ability. During the study on which this paper reports, the children progressed through Years 4, 5 and 6.

The Queensland mathematics syllabus advocates that children be introduced to the concepts of multiplication and division in Year 2, the multiplication symbol (up to 9x9=81) in Year 3, the standard written multiplication algorithm (2 by 1-digit) and the division symbol (up to 81÷9=9) in Year 4, and the standard written multiplication algorithm (2 by 2-digits) and the standard partition written division algorithm (2 by 1-digit) in Year 5. Although schools generally followed the Queensland syllabus, there were classes that had not been formally introduced to the concepts of multiplication and division by Year 4.

Instrument. The instrument used was Piaget's clinical interview technique. The tasks, reported in this paper, comprised three equal grouping multiplication word problems (5x8, 5x19, 25x19) and two partition (24÷4, 100÷5) and one quotition division (168÷21) word problems. The six tasks represented a cross section of the possible multiplication and division problems and were the most frequently attempted problems in the larger study. They involved contexts common to children (money, lollies, and children in classes). They were given in picture form (the child listened as the interviewer said the problem); no algorithmic exercises were presented. The numbers were chosen

and the pictures used in the hope that it would maximise the use of children's own invented strategies, and minimise the use of the traditional written algorithm.

Procedure. The students were interviewed in the second and fourth terms of Years 4, 5 and 6. They were withdrawn from the classroom and interviewed individually in a separate room. The interviews lasted for a maximum of 20 minutes and were videotaped. The word problems were presented visually in the form of pictures, and orally as the interviewer verbalised the task. Although all tasks were presented to all children, not all children were able to attempt every task. If the children attempted a task, further questions were asked to probe for the strategy they used.

Results

Strategy categories. The videotapes were viewed, children's responses were analysed for commonalities in relation to the procedures identified in the literature; and a list of initial strategies developed. Then, the responses of each child for each task in each interview were classified in terms of these strategies and recorded for each interview. Finally, the calculation strategies were considered carefully, and after discussion among the researchers, five strategy categories were identified for each of multiplication and division (see Table 1). All responses were then coded using these strategy categories, and the results were analysed for trends across the three years.

Table 1. *Mental multiplication and division strategy categories*

Category	Description	Examples
Multiplication	Any form of counting strategy, skip counting forwards and backwards, repeated addition and subtraction, and halving and doubling strategies.	5x8: 5, 10, 15, … 5x8: double 5, double 16, +8.
Basic fact (BF)	Using a known multiplication or division fact or a derived fact.	5x8: 10x8=80, so 5x8=40.
RL separated (RLS)	Numbers are separated into place values, then proceed right to left.	5x19: 5x9=45=40+5, 5x10=50, 50+40=90, 95.
LR separated (LRS)	Numbers are separated into place values, then proceed left to right.	5x19: 5x10=50, 5x9=45, 50+45=95.
Wholistic (WH)	Numbers are treated as wholes.	5x19: 5x20-5=100-5=95. 25x19: 4x25=100, 4x4=16, 4x100=400, add 3x25(75), so 475.
Division	Any form of counting strategy, skip counting forwards and backwards, repeated addition and subtraction, and halving and doubling strategies.	24÷4: 4, 8, 12,… 24÷4: half of 24, half of 12.
Basic fact (BF)	Using a known division fact or a derived fact.	24÷4: 4x?=24. 6 24÷4: 5x4=20, so 6x4=24.
LR separated (LRS)	Numbers are separated into place values, then proceed left to right.	100÷5: 10÷5=2, 0÷5=0, 20.
RL separated (RLS)	Numbers are separated into place values, then proceed right to left.	100÷5:, 0÷5=0, 10÷5=2, 20.
Wholistic (WH)	Numbers are treated as wholes.	100÷5: 100÷10=10, 10x2=20. 168÷21: 5x21=100 ∴ 5x21=105, about 60 left, 3x20=60 ∴ 3x21=63, 63+105=168, ans. 5+3=8.

General trends within each task

The results for multiplication are presented in Table 2 and, for division, in Table 3. As would be expected, the percent of children attempting and correctly attempting the tasks increased across the six

BEST COPY AVAILABLE

interviews. Further, the multiplication tasks were easier for the children as evidenced by the higher percentage attempted, and attempted correctly, than the division tasks.

Table 2. *Multiplication responses for Interviews 1 to 6 (n=95)*

Question	Interview	% attempting (% correct)	% attempting (% correct)				
			CO	BF	RLS	LRS	WH
5x8	1 (Year 4)	92 (71)	54 (34)	38 (37)			
	2 (Year 4)	97 (87)	23 (17)	74 (71)			
	3 (Year 5)	99 (87)	22 (13)	77(75)			
	4 (Year 5)	99 (93)	17 (15)	82 (78)			
	5 (Year 6)	100 (96)	6 (5)	94 (91)			
	6 (Year 6)	100 (97)	3 (1)	97 (96)			
5x19	1	26 (18)	1 (0)		11 (7)	4 (2)	10 (8)
	2	68 (51)	6 (2)		37 (30)	12 (7)	14 (12)
	3	72 (51)	4 (1)		33 (26)	17 (7)	18 (16)
	4	86 (73)	16 (7)		44 (42)	6 (5)	20 (18)
	5	96 (85)	7 (4)		58 (51)	7 (7)	23 (23)
	6	98 (85)	4 (0)		56 (51)	11 (8)	27 (26)
19x25	1	2 (2)	1 (1)				1 (1)
	2	16 (5)	2 (0)		7 (0)		6 (5)
	3	28 (12)	7 (1)		8 (1)	2 (1)	11 (8)
	4	78 (32)	9 (3)		37 (8)	5 (1)	26 (19)
	5	79 (35)	9 (2)		28 (7)	4 (1)	37 (24)
	6	85 (45)	8 (2)		34 (13)	4 (1)	38 (29)

For task 5x8, *Counting* was the initial dominant strategy (included skip counting in fives and near doubles, e.g., double 8, double 16, add 8). However, by Interview 2, the *Basic fact* strategy was dominant and reasonably accurate.

A low of 26% attempted task 5x19 in Year 4, while 98% attempted it by the end of Year 6. From the end of Year 4 to the end of Year 6, the *RL separation* strategy was dominant, with the *Wholistic* strategy being used half as much (surprisingly due to the ease by which it applies to 5x19 (5x20-5). The *LR separation* strategy was used by a significant minority and some children persisted in using the *Counting* strategy into the last interview.

Task 19x25 was attempted by only two children in Interview 1. One child counted in 25s, the other used a *wholistic* strategy ("10x25=250, another 250, take 25"). Both solutions resulted in correct answers. From there, the number of children attempting a solution increased across the interviews, until 85% attempted the problem in the last interview. However, only about half the solutions were correct. Most errors resulted from the application of the *RL separation* strategy (which is not surprising considering the memory load needed to remember all the interim calculations). Strategies that were more successful in giving correct answers included *Counting* (counting in 25's and grouping in 100's), *Wholistic* (20x25=500, 500-25=475), and even *LR separation* (10x25=250, 9x25=225, using 8x25=200 as known, 250+225=475).

For task 24÷4, the dominant strategy for all interviews was *Basic fact*. Most children reported knowing, "twenty-four divided by four is six, because four sixes are twenty-four." The other strategy used was *Counting* (halving, doubling, repeated addition, skip counting and sharing). A very small minority of children solved the problem by sharing one at a time (reflecting the semantic structure of the problem), while another minority used halving accurately.

Table 3 *Division responses for Interviews 1 to 6 (n=95)*

Question	Interview	% attempting (% correct)	% attempting (% correct)				
			CO	BF	LRS	RLS	WH
24÷4	1	68 (57)	12 (5)	57 (52)			
	2	84 (77)	10 (7)	75 (70)			
	3	88 (82)	8 (6)	80 (76)			
	4	97 (91)	13 (11)	84 (80)			
	5	96 (95)	3 (2)	93 (93)			
	6	97 (96)	4 (4)	93 (92)			
100÷5	1	56 (48)	11 (18)	18 (18)	2 (2)		25 (23)
	2	72 (60)	8 (2)	26 (25)	6 (5)		31 (27)
	3	79 (73)	6 (5)	34 (32)	2 (2)		37 (34)
	4	90 (76)	12 (6)	40 (38)	2 (2)		36 (30)
	5	85 (81)	4 (4)	44 (42)	2 (2)		35 (33)
	6	94 (90)	1 (1)	56 (54)	5 (5)		33 (31)
168÷21	1	1 (1)	1 (1)				
	2	6 (3)	2 (0)		2 (1)	1 (1)	1 (1)
	3	11 (8)	5 (5)			1 (0)	4 (3)
	4	38 (26)	23 (13)		5 (5)	1 (1)	7 (6)
	5	47 (36)	21 (13)		4 (2)	5 (5)	17 (16)
	6	61 (51)	27 (21)	1 (1)	2 (1)	2 (2)	28 (25)

For task 100÷5, accuracy levels were generally high, with *Wholistic* (ignoring the final zero, or using 4x25=100 or 10x10=100) and *Basic fact* strategies (knowing that 5x20=100 or 100÷5=20) popular throughout.

Like 19x25, task 168÷21 was attempted by a lower number of children, with less accuracy, throughout the interviews (one child in Interview 1 through to 61% by Interview 6) and elicited a greater variety of strategies than the other four tasks. The *Counting* strategies included skip counting, repeated addition and doubling, and persisted across all interviews (only one child used repeated subtraction). The *Wholistic* strategies included trial and error for multiplication (e.g., "21 times something is 168. 7? No. I'll try 8. Yes.", "1 times something is 8, 8 times 2 is 16, so it's 8."), trial and error for division (e.g., "Something goes into 16, 2 times, and into 8 once. That's 8."), and partitioning (e.g., "about 100 and the rest, because I know 5 x 20 = 100"). By Interview 4 (end of Year 5), some children attempted to solve the problem using *LR separation*. Interestingly, a handful of these children said that they wouldn't be able to attempt 168÷21, because they had not been taught how to divide with _-digit divisors; yet prior to this interview, no such excuse was made for the inability to solve the problem.

Discussion

Strategy use and preferences. Strategy use across the six interviews was influenced by number combinations and students' available strategies. Tasks that were basic facts (5x8 and 24÷4) tended to be solved initially by the *Count* strategy and, then, later by the *Basic fact* strategy. Tasks that involved more complex numbers were initially solved by a greater variety of strategies. Across the interviews, the strategy category preferences of the children moved increasingly to the more efficient strategies, specifically the *Separation* and *Wholistic* categories, except when the task was related to a basic fact (e.g., 100÷5). For multiplication with ?-digit numbers, the tasks were solved increasingly by *RL*

separation after Interview 2. For the division task with a 2-digit divisor (168÷21), *LR separation* began to be used, without success, in Interview 4.

There was little or no use of repeated subtraction or sharing one to one (contrary to recommendations for teaching division in Queensland). A sharing strategy was used by weaker students, generally unsuccessfully, seemingly because of the heavy load on working memory. The trial and error strategy (e.g., 4x?=24. 5?, check by skip count or doubles or basic fact; no, try 6.) was found to be more reliable and efficient (similar to Mulligan, 1992).

Instructional effects. During Years 4 and 5, the traditional written multiplication and division algorithms are introduced to children. Their procedures are similar to the *RL separation multiplication* and *LR separation division* strategy and, hence, should reinforce and reduce working memory load for these strategies. *Wholistic* strategies appear to be less complex mentally than separation strategies (requiring less working memory) because they do not require numbers in the different place-value positions to be remembered and operated on separately, as is required by separation strategies. The four tasks where numbers were 2-digits or more had numbers chosen so that the *Wholistic* strategies were applicable. For example, 5x19 is close to 5x20, as is 100÷5, while 19x25 is close to 20x25 (and involves 25 which is one-quarter of 100), and 168÷21 is close to 160÷20. Therefore, it seemed reasonable to predict that *Wholistic* should have been the most efficient mental strategy for these four tasks, that separation strategies should have been little used, and that the use of the *RL separation* strategy involved some component of instructional effect.

There is some evidence that there may be an instructional effect, at least for multiplication (similar to the findings of Cooper, Heirdsfield, & Irons, 1996, for addition and subtraction). There was a trend to the *RL separation* category in tasks 5x19 and 19x25, yet the use of the *Wholistic* strategy was a little more accurate (particularly for 19x25). For division, there was not the same strength of support for an instructional effect in the strategy trends. However, there was some extra support for an instructional effect in division in the comments of the children. In Interview 4 and with task 168÷21, some children would not attempt the task because they "had not been taught to do long division with two digit divisors". Previous to this, the children had been willing to "have a go" at many tasks they had not covered in their mathematics classes. It seemed that the teaching of the division algorithm had "coloured" their approach to arithmetic.

Conclusions

The findings of this study show children's changing accuracy and strategy preference for mental multiplication and division across three years during which they were introduced to written algorithms for these operations. The children improved in percentage attempting the tasks and accuracy. However, there was not the expected change to more sophisticated strategies. Children stayed with *Counting* and, where they could, *Basic fact* strategies, and there was some evidence of movement to strategies based on the written algorithms. There was growth in the use of the *Wholistic* strategies where it was appropriate, but not to the extent that might be predicted from the deliberate favouring of these strategies in the choice of numbers in the tasks. There was little use of strategies based on non-standard algorithmic procedures, which was different from addition and subtraction mental computation (Cooper et al., 1996)

In the world of computers and calculators, estimation appears to be a more useful human ability that correct written calculation. Estimation seems better served by trial and error strategies (one of the *Wholistic* strategies), particularly when it is used mentally (as it so often has to be in real world situations). This study shows that many children, by the end of Year 6, were able to use quite advanced *Wholistic* strategies for larger number combination multiplication and division. However, another (although less efficient) strategy for these larger number combinations was *Counting*. Considering the numbers involved, *Counting* was reasonably efficient, certainly more efficient for 168÷21, than *LR separation*.

There appears to be a need, in multiplication and division mental computation as well as estimation, for assistance to be given to children to use strategies different from those associated with traditional computation (e.g., trial and error and *Wholistic*, and, maybe, some forms of non-standard *separation*). This would seem to imply a reduction of emphasis on written algorithms for multiplication and division (even their removal from the syllabus), a growth in instruction time spent on arithmetical properties and alternative computational strategies, and a change to more child-centred and flexible approaches to teaching operations.

A GOOD PUPIL'S BELIEFS ABOUT MATHEMATICS LEARNING ASSESSED BY REPERTORY GRID METHODOLOGY

Kirsti Hoskonen
University of Joensuu, Finland
Kirsti.Hoskonen@Helsinki.fi

Abstract: *What kind of beliefs pupils have on being good or poor at mathematics? What kind of characteristics does a good mathematics pupil have? How does the pupil act? What are the most important things in mathematics learning? Teachers are interested in responses to this kind of questions. In this case study, the ideas of one pupil about what makes a good mathematics pupil are assessed. One girl at the end of the lower secondary school was the informant. Her responses were used as elements in the repertory grid interview. Constructs were then elicited. She developed her own model how to act in studying mathematics. She thought that the most important things in learning mathematics were her own attitude towards studying and independent work she was ready to do.*

This research is concerned with a pupil's beliefs about what is needed to be a good mathematics pupil. Pupils have their own ways of coping with mathematics, and their own ideas about how to succeed in learning mathematics. The objective of this research is to assess one pupil's beliefs about her own mathematics learning. The emphasis if the study is to find out a student's beliefs based on his own ideas and expressed with her own words. The methodology is based on personal construct theory and utilised the repertory grid method (Kelly 1955).

Theoretical background

The methodology used to assess a pupil's ideas about mathematics learning is based on Kelly's personal construct theory. In his theory, a person is like a scientist who observes the world through transparent patterns built by himself. He makes assumptions, tests them and creates his own theory of the world around. With these patterns he wants to make sense of the word around. Kelly defines the central concept *construct* of his theory, as follows:

> "*Let us give the name constructs to these patterns that are tentatively tried on for size. They are ways of construing the world. They are what enables man, and lower animals too, to chart a course of behaviour, explicitly formulated or implicitly acted out, verbally expressed or utterly inarticulate, consistent with*

other courses of behaviour or inconsistent with them, intellectually reasoned or vegetatively sensed." (Kelly 1955, p. 9)

An other concept in Kelly's theory is an *element* which is defined in the following way: "*The things or events which abstracted by a construct are called elements*" (ibid, p. 137). When a person is asked to categorise elements he is thought to organise patterns. The categories are then called constructs. The constructs are bipolar so that every construct has its opposite, e.g. honest vs dishonest. Persons make sense out of their world by simultaneously noting similarities and differences. In addition to the theory, Kelly developed a method for assessing an individual's personal constructs. Elements and constructs which are core concepts in Kelly's theory are also important in the method, the repertory grid technique.

Kelly's constructs can be understood as beliefs (e.g. Jones 1980, Williams & al. 1977). Schoenfeld (1992, p. 358) describes belief as "an individual's understanding and feelings that shape the ways that the individual conceptualises and engages in mathematical behavior". One of the main components of beliefs is 'beliefs about mathematics learning'. It consists of 'beliefs about the nature of learning mathematics', 'beliefs about how learning should be organised', 'beliefs about what the role of the learner is', 'beliefs about what the degree of autonomy expected from pupils is', and 'beliefs about who sets the criteria for correctness' (e.g. Pehkonen 1995, p. 20). E.g. Martha Frank has interviewed four pupils of the seventh and eight grade. She reports as one of pupils' beliefs "the role of the mathematics pupil is to receive mathematical knowledge and to demonstrate that it has been received" (Frank 1988, p. 33), i.e. a pupil should sit and listen to his teacher's talk, and do his routine homework. Garofalo (1989, p. 503) describes three common beliefs in lower secondary schools. One of them is "only the mathematics to be tested is important and worth knowing". Another widely held belief is "doing mathematics is simply a matter of memorising and reproducing the fact, rule, procedures, and formulas" (Mtetwa & Garofalo 1989, p. 611). These both deal with the nature of learning mathematics. Understanding mathematics seems not to be important.

The repertory grid technique

The repertory grid technique is originally used in psychology. The informant is asked to produce a list of persons, who are important to him (e.g. mother, father, sister, etc.). The persons are then the elements in the method. After that he is given a triad of persons and asked to think in what way two of them were similar to each other and also different from the third. All the persons are included in one or more triads. The categories obtained from this task are the constructs. According to Kelly's theory the constructs are bipolar. A person makes sense of the world through categorising elements. Nowadays the method is used in many different domains. and the elements are objects or aspects of that domain.

The elements in columns and the constructs in rows form a matrix, a grid, which is important in analysing a person's ideas. In the method the person is asked to judge the matrix. Fransella & Bannister (1977) have described this process of judgement, as follows: "Behind each single act of judgement that person makes (consciously or unconsciously) lies his implicit theory about the realm of events within which he is making judgements. Repertory grid technique is, in its multitude of forms, a way of exploring the structure and content of such implicit theories." Kelly (1955) used factor analysis to analyse the grid.

The repertory grid methodology is a tool which has been used in mathematics education to assess teachers' beliefs about mathematics (Jones 1990, Lehrer & Franke 1992, Middleton 1995, Williams, Pack & Khisty 1997). With this methodology, however, there are some research about pupils' beliefs on mathematics (Chapman 1974, Thomas & Harri-Augstein 1985), but there seems to be none about pupils' beliefs on mathematics learning. Thomas & Harri-Augstein (1985) investigated college pupils' responses to certain 'command' words, as prove, define, etc., used in mathematics. Pupils responses were emotionally loaded constructs: engaging vs disinterest, reassuring vs despair, etc. In an other research (Chapman 1974) collage pupils of mathematics were asked to write down the one word which best typified their reaction to mathematics. About one hundred first year college pupils used constructs of which 70% were totally emotional. These pupils construe their mathematics by emotional constructs.

Data collection process

This is a part of a pilot study the aim of which was to clarify a pupil's beliefs on mathematics and its studying and learning. In this paper the focus will be a pupil's beliefs on mathematics learning. The informant in the study is Brita, a talented ninth-grader, who has done well in school and especially in mathematics. The author as her teacher considered her as suitable research object, since she seemed to have a clear and well-structured view of learned mathematics. Additionally, she was willing to co-operate and share her beliefs. In mathematics Brita was interested in open-ended problems, in problems which require a lot of thinking, and in project work. Right from the beginning she did her homework, nevertheless how demanding they were. She asked for help, if something was unclear for her, and in lessons she was ready to present her solution process and describe it to the whole class.

The method used for data collection was the repertory grid method. Its purpose was to find out Brita's beliefs based on her own ideas and expressed with her own words. The data collection began with an interview, where Brita was first asked to think about a pupil who is good at mathematics. Then the following questions were put forward: What do you think that it means to be good at mathematics? What is a good pupil like? How can you describe such a pupil? Her answers formed a list of a good pupil's characteristics, and these were called elements. She was also asked to

describe a pupil who was poor at mathematics. Such characteristics were elements, too. The elements were written on cards. When Brita had the cards on the table in front of her she was asked to check that they were the same ones she described. She was asked to chose the cards she thought could suit herself. She selected all the cards that she had told to be a good pupil's cards except one, 'active'. These elements were the attributes with which she seemed to make sense of the world around. The 20 elicited elements for a good mathematics pupil are given Table 1 (in certain groups described below).

The first interview continued and Brita was asked to sort the cards in any way which made sense for her. After she had finished the grouping, she had piles in front of her and she was asked to describe the similarities of the elements in each pile. To sort the cards was not an easy task for her: She began with 9 piles, but changed her mind in the case of some cards, and resulted with 7 piles. In Table 1 you can see Brita's 7 categories of similar elements. The names of the categories originated from Brita. Table 1 can be considered as Brita's first mental model for her thinking on studying mathematics.

Pupil's own attitude towards maths: enterprising, does eager the homework, is not afraid of the word maths, appreciates maths as a school subject, does not lose her enthusiasm to maths studies if she fails in tests, understands what maths is, finds that maths is interesting and challenging
Goal is to keep maths with in the future: receives a new matter easily, is interested in learning new things, intends to continue and deepen her maths studies after the comprehensive school
Studying in a group: studying in a group, is able to work in a group together with others, considers all pupils equal
Maths belongs to the leisure-time: is ready to think about maths in her leisure-time, tries to solve everyday problems by means of maths
Repetition and strengthening the former studied things: brush up old things; if she hasn't learnt a new item during the lesson, she takes care of learning it at home; asks the teacher for help if she has problems with learning new things
Adaptation to maths studies: is ready to learn maths in many different ways not only in the old customary way
Appreciation the studying: is not only "hunting" good marks, but studying maths is the most important thing

Table 1. Brita's first mental model consists of seven categories.

Further in the interview, Brita was asked to describe differences between the piles comparing them two by two. The similarities and differences were both called constructs. Since in the repertory grid technique constructs are considered bipolar, Brita was asked to determine the opposite of each construct. At the same time, she

should explain which of them, construct or its opposite, suited better for her and give reasons for her choice. In the case of all constructs, she was not able to give its opposite.

The construct / opposite pairs with Brita's words were:

- *"a pupil's own attitude towards maths / indifferent, maths hasn't much to do with oneself*
- *the goal is to keep maths with in the future / tries to get out of maths*
- *studying in a group*
- *maths belongs to the leisure-time / only at school*
- *repetition and strengthening the former studied things / without repetition go straight to a new thing*
- *adaptation to the maths studies / no adaptation to the studies*
- *appreciation the studying*
- *a pupil's qualities which influence the studying / one does not pay attention to a pupil's qualities*
- *discussion and debate at school /pondering at home or elsewhere*
- *tutored studying at school / independent studying*
- *studying on one's own initiative / strictly guided studies*
- *clearing up things to oneself / doesn't clear up things*
- *studying for future / only for present time*
- *different ways to learn / only one certain way to study*
- *behaving in a classroom*
- *relations between pupils*
- *an important part in studying maths*
- *how a pupil treats mathematical knowledge*
- *studying in the leisure time / studying only at school*
- *making things clear together in a group /making things clear independently"*

The elements and the constructs are set into a grid where elements are in rows and constructs are in columns. For data analysis, a form with the grid was given to Brita, and she was asked to rate the grid on the scale 1 - 2 - 3 - 4 - 5 (1 = the construct was not important to the element, 5 = the construct was very important to the element). Thus, all the elements are rated on all the constructs.

The main result

Since there was a big variety of information, the 20 x 20 matrix with loading from 1 to 5, factor analysis was selected to condense it. The completed grid was analysed factorially to determine relationships among constructs and to condense the information in a pupil's pattern. This is in coherence with the leading principle of factor analysis, as one can read e.g. in Cohen & Manion (1994, p. 330): "Factor analysis is a way of determining the nature of underlying patterns among a large number of variables". In realising the factor analysis, two constructs 'Studying for future' and 'Important part in studying maths' were not allowed to be with in the analysis, since all their ratings were the same (5). Because of no variance, they should be deleted in the factor analysis. When using the criteria "roots greater than one", the factor analysis resulted five factors

Since aims of the study was to find out a student's beliefs from her point of view, Brita was asked to check the validity of the results. In the second interview, she was inquired, whether the five-factor solution was meaningful for her. The task was a difficult one for her, since it did not make any sense to her. Therefore she tried to improve the solution by making a regrouping, and resulted four categories of the constructs. Brita was asked to name the four categories. Furthermore, the ranking list of the categories was expected from her.

Attitude towards studying (1)
Pupil's own attitude towards maths, Appreciation the studying, Goal is to keep maths with in the future, Adaptation to the maths studies, Pupil's qualities which influence the studying
Independent studying (2)
Studying on one's own initiative, Clearing up things to oneself, Repetition and strengthening the former studied things, Different ways to learn
Skill to handle mathematical knowledge (3)
How a pupil treats mathematical knowledge, Studying in the leisure time, Maths belongs to the leisure-time
Studying with support (4)
Studying in a group, Making things clear together in a group, Relations between pupils, Discussion and debate at school, Tutored studying at school, Behaving in a classroom
Studying for future, Important part in studying maths

Table 2. Brita's second mental model for mathematics learning.

The author realised the factor analysis with four factor, and the solution was shown to Brita. Again, she was not satisfied, and wanted to make some changes. At the end

she named the categories and arranged them in the order of their importance. The results of Brita's evaluation of the four-factor solution is given in Table 2. This may be considered as a mental model for Brita's beliefs on mathematics.

Conclusions

In the repertory grid interviews, Brita has told something of her ideas how to learn mathematics, her beliefs about learning. She had to make her unconscious ideas conscious. Through these ideas she told her main goal: "to keep maths with in the future". To reach this goal she had to set some other goals and she told about the ways how to cope with mathematics e.g. that she was interested in learning new things. She thought that her own attitude towards the mathematics studying and her relation to mathematics were the most important constructs. She told "my own relation to mathematics is good". She appreciated the studying of mathematics and did eager the homework. Brita was not like the pupils in the study of Frank (1985). Independent studying was very important to her. She used to clear up the topics to herself, to brush up and strengthen the former studied topics. "I definitely stand for clearing up the things to myself. At the same time I repeat and learn the difficult things. If I don't clear the things up to myself I might later tumble over them". It was not enough for him only to sit, listen and do her homework. She wanted to understand what she was doing. She was eager to do mathematics in a different way as usual. "I am absolutely of the opinion that the teachers have to change their methods. Then studying is more meaningful."

Mathematics was not just computation for Brita. "The use of mathematical knowledge could be its application. If you have learned the thing, it is worth using and revising now and then." Mathematics was everywhere in her world. "You should take interest in maths in your leisure time, too. Mathematical applications could be good in every day problems." She wrote: "I like learning in the leisure time. Then a pupil has her own peace and a lot of time to study. The repetition for the test and doing the homework belong to one's studying in her leisure time. Studying in one's leisure time is an important part of all learning."

Studying in a group gave support to the members of the group. They could clear up the topics together, discuss and debate in their group. "I like to study both independently and in a group. You must get used to both of these. Different situations need different ways to study." The group of students discussed problems in order to understand them. "I stand for clearing up the things together. An independent work is more responsible and then you need to work more, since there is none who could give you advice." She thought that group work was good in a certain kind of a group. "They greatly influence on the learning if the pupils are 'on the same wave length' and have the same attitude to the studying. Therefore a good team spirit is also important."

LINKING INFORMAL ARGUMENTATION WITH FORMAL PROOF THROUGH COMPUTER-INTEGRATED TEACHING EXPERIMENTS

Celia Hoyles and Lulu Healy[1]
Institute of Education, University of London, UK

Abstract: *In this paper, we present the results of two computer-integrated teaching experiments (one in algebra, one geometry) designed to help students connect formal proof with informal argumentation. The results are interpreted from the basis of findings from a large-scale survey of students' proof conceptions.*

Background: Research in mathematics education has consistently highlighted students' difficulties in engaging with formally-presented, analytical arguments and understanding how these differ from empirical evidence (Balacheff, 1988, Bell, 1976, Chazan, 1993 and more recently papers to PME 22, e.g., Arzarello et al, 1998, Furinghetti & Paola, 1998). The current National Curriculum for mathematics in England and Wales prescribes an approach to proving, partly as a response to these student difficulties, in which the introduction of formal proof is delayed until after students have progressed through stages of reasoning empirically and explaining their conjectures largely in the context of data-driven investigations (see Hoyles, 1997). This approach to introducing proof to school students has been the subject of considerable criticism. To provide systematic evidence in this debate, we started a research project in 1996 to describe how high-attaining students who have followed this curriculum conceptualise proving and proof in mathematics and to explore ways to address any difficulties through new teaching approaches.

The research comprised two phases: a paper and pencil survey of the conceptions of proving and proof held by 2,459 students aged 14/15 years at a high level of mathematics attainment, (about the top 20%), followed by two computer-integrated teaching experiments in geometry and in algebra. This paper is concerned with phase 2 and aims to present the principles underlying the design of the teaching experiments and the major findings from their evaluation. It will incorporate findings from phase 1 (see Healy & Hoyles, 1998) only in so far as they informed the design and analysis of the teaching experiments.

Methods: Our phase 1 analysis showed that students, even in this high attainment band, had a limited view of proof and this had a significant and negative influence on their competence in proving. Yet the majority of students recognised that a valid proof should be general and valued arguments they felt convinced and explained. Most students felt that formally-expressed arguments would receive the best marks, but few used deductive reasoning, with formal arguments occurring very rarely.

Our teaching experiments in algebra and geometry aimed to build on the evident strengths of our students in narrative explanations and help them develop a multi-faceted view of proof, which included verification, systematisation and deduction (see de Villiers, 1990), along with more formal presentation. Given that to construct on a computer[2] requires explicit attention to the processes used, we hypothesised that students would be better able to formalise explanations derived from computer-based activities.

1 Research funded by ESRC, Project Number R000236178

2 In algebra, we built a microworld in Microworlds Logo; in geometry a dynamic geometry system, Cabri.

Teaching experiments were piloted with 6 students in three schools (one mixed, one boys, one girls) and modifications made on the basis of feedback from students and teachers. These included more precise procedures for the collection of systematic written data from the students and the imposition of a common structure on both experiments; i.e. students were to construct mathematical objects on the computer, identify and describe the properties and relations that underpinned their constructions, use the computer resources to generate and test conjectures about further properties, and make informal explanations as to why they must hold. This was to be followed by a teacher-led introduction to writing formal proofs using paper and pencil examples, where students would be helped to organise the arguments generated during the computer activity into logical deductive chains in the appropriate formal language. Finally, the students were given a challenging computer construction to be explained and proved, followed by an opportunity to use the properties proved to explain why a subsequent construction was impossible (named here for reference the possible/impossible construction).

Each teaching experiment comprised 3 lessons and 3 homeworks and was conducted by the two authors. A total of 15 students, 5 from each school, undertook both experiments within a 5-month period[3]. The students were chosen by their teachers according to our criterion of high-attainment, but also so that the group experience would be beneficial both individually and collectively. All students completed the phase 1 survey before the teaching experiments and were interviewed immediately after them, when they were given the opportunity to review some of their survey responses as well as to reflect on the teaching experiments.

The mathematics teachers of the student group in each school completed the school survey[4] as well as the multiple-choice proof survey questions. They were also interviewed to provide further contextualising data on the school, class and mathematics curriculum followed, and the individual students involved in the experiments.

Data analysis: To cope with the complexity of all the data collected (i.e. students' and teachers' survey responses, worksheets completed by students during class and homework sessions, students' computer work, two sets of observation notes, transcripts of final interviews, school questionnaires and transcripts of teacher interviews), we adopted a cyclical and iterative process of analysis, during which we constructed student case histories, first by considering student and school variables, and then weaving in consideration of group, task and software. We also documented how students responded to the computer and how they viewed it as a tool to learn mathematics. Finally, we sought to take account in assessing progress of how the students interacted and worked together during the teaching sessions.

Results: Each individual student case history provides a rich research study in itself, but here we focus on general trends and school differences rather than individual responses and progress.

3 We planned to have 3 pairs of students per school, but in each case one student did not attend every session.

4 The school survey was used to find out about a school, its curriculum and the mathematics teacher of the class selected to complete the proof survey

Deductions from properties: As described earlier, in both geometry and algebra, the students were asked to undertake a possible/impossible construction, as summarised in Table 1 below.

Construction	Necessary Property (explained & proved)	New Construction
Geometry: Construct with Cabri a quadrilateral in which the angle bisectors of two adjacent angles cross at right angles. Write down its properties and prove them.	One pair of opposite sides *must be* parallel (i.e. trapezium).	Predict if you can construct a triangle in which two adjacent angle bisectors cross at right angles. Predict yes or no, try to do it, and then explain why your prediction was right or wrong.
Algebra: Construct 4 consecutive numbers in Expressor, write down any properties of their sum and prove them.	Sum of 4 consecutive numbers is even but *not divisible by 4*	Predict whether you can find 4 consecutive numbers that add up to 44. If yes, write them down, if no, explain why it cannot be done.

Table 1: Using properties to make predictions: possible/impossible constructions

All the students managed to complete successfully the first construction — albeit after time and help. In geometry, 11 students predicted they could construct the triangle. After trying to do this, all realised it was impossible and 13 could explain why, using the parallel property identified in the quadrilateral construction. In algebra, 6 students predicted it was possible to find 4 consecutive numbers adding up to 44. After trying to find these numbers, all then realised it was impossible, but only 6 referred to the necessary property they had proved about non-divisibility by 4, and 4 of these still did not regard this as adequate refutation and went through a calculation process, i.e. showed 4n + 6 was not divisible by 4.

Overall, we found the students' responses to be surprisingly consistent, i.e. despite being utterly convinced of the necessity of the property in the initial construction, few students used it to deduce the impossibility of the new construction. Having noted this in respect to this particular task, we searched our observation data and found numerous instances of similar problems in making inferences from deduced properties, which will be shown in the presentation. Overall we conclude that the students were poor at making deductions from properties they had discovered, explained, and even proved.

Evaluation of visual arguments: In phase 1, we had analysed whether students assessed a visual argument in algebra and in geometry to be general or specific and found rather more thought them specific than general: 50%, 31% compared to 21%, 18%[5]. In analysing the responses of our 15 case study students, we found similar proportions. Clearly many students were unfamiliar with the power of visual representations and their potential to serve as generic examples, a conclusion supported by our process data: for example, the presence of a picture in a request for a geometry proof confused some students about whether it was general or not. Visual arguments were also frequently attributed lower status than other forms, and described as 'simple' or 'daft', even by those who acknowledged their explanatory power.

5 First percentage is algebra, second geometry.

Summarising the case studies: Apart from the general trends above, we found differences in progress across the schools, so report other findings categorised by school. First we present the school profiles, brief characterisations of each school, mathematics department, and teacher.

School A: School A was mixed-sex and comprehensive with mixed-ability teaching practised in the mathematics department. Students in Year 10 studied 3 hours of mathematics/week, and specialist interest in mathematics was encouraged by additional after-school activities, in extra sessions, and visits to outside school mathematics lectures. Proof was not taught as a topic until Year 11. The computer was rarely used in mathematics lessons. The teacher clearly valued different expressions of proofs, recognised students could construct good 'intuitive proofs' but had difficulties with formalising them. It was also apparent that the students were encouraged to take risks and challenge themselves mathematically.

School B: School B was a girls-only comprehensive where again mixed-ability teaching was practised in the mathematics department from entry, but there were few 'extra' mathematics sessions. Students in Year 10 were taught 2.75 hours of mathematics/week with proof addressed through investigations and coursework. The computer was not used regularly in mathematics lessons, although there were two machines in each classroom. The teacher thought of herself as an educator "not a mathematician" and fostered a collaborative and nurturing approach where students would not be faced with unnecessary challenge.

School C: School C was boys-only, with the boys set by attainment in mathematics from Year 8. 95% of the top set sat the higher GCSE paper. The students studied 3 hours of mathematics/week and proof was taught through investigations. The computer was not used in mathematics lessons, although there were well-resourced laboratories in the school. The teacher was a highly-qualified mathematician with no formal teaching qualifications, who described himself as computer-illiterate. He fostered a strong emphasis on exams in his department, and discouraged coursework as he felt the higher achievers spent too much time on this.

We then summarise the background, process and outcome profiles of the 15 students grouped by school. For the background profile (Table 2) we used five dimensions to capture the most salient aspects: KS3 test score[6]; views of proof and constructed proof score as assessed in the proof survey; and prior knowledge of algebra and geometry as assessed in the survey and from teacher interviews and classwork.

Though the process profile (Table 3) was harder to draw up, careful analysis of the case histories led us to draw out 3 dimensions, which though overlapping, could usefully be distinguished: reaction to the computer work as evidenced in observations and student interviews; nature of interactions with the computer and with peers; and modes of expression used in explanations and in proof (i.e. narrative, symbolic, visual).

[6] Level 8 is highest grade attainable in Key Stage 3 (KS3) tests (about the top 1/2%). These tests are administered nationally at the end of Year 9 (ie age 13/14 year old students).

	School	Summary Description
KS3 Test	A	4 level 8; 1 level 7
	B	5 level 7
	C	3 level 8; 2 level 7
Views of proof	A	Only referred to proof in algebra
	B	Only described proof as verification
	C	Unclear about proof and what it was for
Constructed proof scores (range 0-3)	A	6 0's; 2 1's; 5 2's; 6 3's. Highest score for a formal proof 3
	B	11 0's; 6 1's; 1 2; 2 3's. Highest score for a formal proof 0
	C	3 0's; 9 1's; 2 2's; 6 3's. Highest score for a formal proof 1
Algebra	A	Mainly for expressing generality, and finding specific unknowns
	B	Very little algebra
	C	Some experience with algebra manipulation and finding specific unknowns, very little in expressing generality
Geometry	A	Very little geometry
	B	Very little geometry
	C	Knew a few geometry facts

Table 2 : Background profiles of school groups

	School	Summary Description
Reaction to computer work	A	Enjoyed the challenge of building and investigating computer constructions
	B	Found computer constructions difficult and took a long time to build them
	C	Focused on procedures "how to get it constructed" rather than structure of the constructions
Nature of interactions	A	Experimental and collaborative
	B	Insecure when unsure, helped each other
	C	Not very experimental, highly competitive
Modes of expression	A	Used many modes of expression flexibly
	B	Slow to adapt to new ways of working, dependent on others and teachers to validate methods and outcomes; used variety of forms of expression but made only fragile connections between them
	C	Liked to finish quickly using only one mode of expression; generally prioritised formal and rejected visual

Table 3: Process profiles of school groups

Finally, for the outcome profiles (Table 4), we distinguished five dimensions: competence in proof in algebra and geometry as evidenced in homeworks and final interviews, and reactions to the role of the computer and the teaching experiments as evidenced in students' written evaluations following each teaching session.

BEST COPY AVAILABLE

	School	Summary Description
Proof	A	Ended with multi-faceted views of proof, geometry as well as algebra
	B	Extended their views of proof to include explanation as well as verification
	C	Limited "internal" sense of proof; "external conviction" view still predominated
Algebra	A	Split between those who learnt algebra routines and those who connected algebraic to other forms of explanation
	B	Began to express algebraic relationships in context of microworld
	C	Learnt algorithmic approaches to constructing algebra expressions
Geometry	A	Learnt geometry facts, could separate explicitly givens from properties to be deduced, still some difficulties in constructing complete chains of argument
	B	Learnt geometry facts, began to distinguish givens from properties to be deduced, still experienced problems with local deductions
	C	Still found it difficult to organise geometry facts into logical steps within a formal proof
Evaluation of role of computer	A	Algebra: saw connection between programming and proof Geometry: helped to identify and see properties but not prove them
	B	Reaction same in algebra and geometry: i.e. helped to be accurate and locate properties; few links between constructing and proving
	C	Strong emotional reactions — hated or loved software; allowed work to be done more quickly and made it easy to construct things; few links between constructing and proving
Evaluation of teaching experiments	A	Writing formal proofs described as hard with specific problems identified — but enjoyable
	B	Writing formal proofs described as generally hard with no specific details
	C	Learning to use computer described as hard and proof mentioned infrequently

Table 4: Outcome profiles of school groups

School differences: The summary data shows that the teaching experiments were most successful in school A, had some success in school B and were least successful in school C. In school A, students made progress in algebra, geometry and most crucially developed a multi-faceted and connected sense of proof. This is illustrated in the case-history of one student,Tim from school A:

Tim enjoyed the computer work because 'it was different'. In his evaluations, he described the most enjoyable parts in algebra as 'programming', 'watching the programs work' and 'proving'. When asked he clearly saw a strong connection between proving and the computer work on algebra.

T I liked the programming stuff - that helped [to write proofs] because it sort of showed how it was constructed so... It helped prove because it showed you how they were made....how that construction was made step by step.

In geometry, this link between informal and formal proof was more tenuous. The computer work helped Tim 'see' relationships, but not to prove them formally, although it may have performed an important role in satisfying his need to be convinced.

T Well you could actually see if they were congruent - you could take however much you were allowed to take and actually make a triangle. If it was congruent then you could tell it was.

C Tell it how?
T Just by seeing....
C And did that help you write your formal proofs?
T Not really - not the formal stuff. ....Well it made it more enjoyable.

We conjecture that factors in the overall success in school A were that students were used to the experimental approach required by our activities, they had an adequate knowledge base to engage with the activities, and they were willing to share knowledge and help each other. In school B, the students started from a weaker knowledge base than anticipated in the activities, and although they were beginning to appropriate a broader conception for proof, they needed more time to consolidate this and gain confidence in experimenting with the software to learn algebra and geometry. This group of girls was much less secure — they were willing to share but lacked the competence and confidence to do so. Finally, in school C, the students viewed the activities more as learning to use the computer software than to explore the mathematics. They seemed more used to learning procedures and techniques than striving for conceptual understanding. As a 'typical' group of high-achieving boys, they were competitive and preferred to work on their own.

Individual variation: Clearly, individuals within a school group varied on all the dimensions of the three profiles, but in each school there was at least one individual (and rather more in School A) who adopted a flexible approach to proving which interweaved verification with seeking understanding and explanation. From our case histories, it was clear that interaction with the computer helped students to make and maintain these connections — they were able to reflect on the steps they had made in constructing their explanations and re-use these steps in deductive arguments. In these cases, internal conviction was achieved using a combination of empirical and anaytical methods, logical arguments were constructed and expressed in a variety of ways (including formal expression) while keeping narrative explanations in mind. We also found that in each group there was at least one student (and rather more in School C) who ended with a view of proof that prioritised 'external' over 'internal' conviction. These students moved quickly from informal argumentation to the production of a formal proof and in the process lost touch with the sense of the problem to be proved. We also found (particularly amongst students who had planned to drop mathematics after it was no longer compulsory), a tendency to be satisfied with their narrative arguments and remain unconvinced of the need for any formal proof. In both cases, we interpreted the responses to be a consequence of the mismatch between our goals, teaching style and experimental activities and the students' views of mathematics and of proof.

Our data also suggest that in part these individual variations can be accounted for by reference to: the adequacy of an individual's knowledge base as evidenced in the background profile — particularly crucial in a group where sharing/helping was not prevalent; a readiness to explore different ways of presenting mathematical ideas, an attitude to learning mathematics which included problem-solving and experimentation as appropriate learning strategies; and an approach to technology that did not preclude seeing computer interactions as relevant to appropriating mathematical ideas. Of course, fulfilling these conditions cannot guarantee success — the composition and dynamics of the group, and the nature of its interactions also serve as intervening influences — but not fulfilling them is likely to inhibit progress.

Conclusions: Our results show that the computer-integrated teaching experiments were largely successful in helping students widen their view of proof and in particular link informal argumentation to formal proof — a transition known to be problematic. Not all students however made the anticipated progress, pointing to the well-known complexity of the cognitive and metacognitive processes that need to be appropriated in learning to prove.

Our research also highlighted rather particular problems our students had with respect to local deductions and visual reasoning. Since these problems emerged in all 3 schools and in both algebra and geometry, we are led to conclude that these two processes are given rather little emphasis in the current curriculum for younger students — a conclusion supported by an analysis of the National Curriculum and by data from our teacher interviews. Our students are simply unused to making deductions and predictions — an unfamiliarity which our research shows inhibits their capacity to engage with the demanding complexities of proof at higher levels.

Finally our study identified considerable variability in responses between students and between students grouped by school — despite identical activities and teaching. We interpret this differential progress at the school level to be related to the match or mismatch between our expectations of the students' prior knowledge and their actual knowledge, and our goals and constructivist orientation and those of the mathematics department as mediated through the student group. There were also other variables that influenced success, such as attitude to computers and their role in learning mathematics among students and staff, and the gender mix and internal dynamics of the student group. Taken alongside evidence from previous research that more 'traditional' methods of teaching proof have variable success, our findings suggest that teaching can make a difference to students' competence in proving *but* the same activities and the same teaching approaches *inevitably* will not be equally effective in all schools or with all students.

Alternative Assessment for Student Teachers in a Geometry and Teaching of Geometry Course

Bat-Sheva Ilany and Nurit Shmueli,
Beit Berl Teacher Training College, Israel

This work presents one of the assessment tools that we employed in the Geometry and Teaching of Geometry course, named "Three-Stage". This tool is composed of a group test, classroom discussion and individual test. With the help of the assessment tool we sought to achieve the following aims: examine the ability of the students to present and argue their solutions, and their ability to form links between various areas within the mathematical framework. The findings show that in general the tool reflects the students' knowledge. The tool examined understanding of mathematical concepts, methodological knowledge (such as ability to prepare activities for students), while expressing the students' skills and diversity and the processes of coping with working in groups.

With the appearance of the document Curriculum and Evaluation Standards for School Mathematics (NTCM, 1989, 1991), an effort was made to transform mathematical education and prepare it for the 21st century. This document proposed a new approach to the teaching of mathematics, ascribing special importance to independent and critical thinking, and recognizing that assessment and curricula standards could not be fully implemented without changing the manner in which mathematics is taught.

The document stressed development of ways of thinking and problem solving strategies, stressing the solution process (and not only the assessment of the finished product). These trends affected the nature of the contents in teaching mathematics. The changes in content and style of teaching mathematics necessitated corresponding changes in the assessment process as well (MSEB, 1993). As a result, a variety of methods and tools have been recently proposed for assessment of students in addition to, or instead of, the customary assessment by testing (Stenmark, 1991).

Clarke and Sullivan (Clarke, Sullivan, 1992) believe that performance tasks are the appropriate tool for guiding and assessing students in the area of unconventional problem solving. In performance tasks, each student is able to choose the strategy appropriate for the level at which he finds himself.

Since performance tasks make it possible to achieve different and original ways of solution, they make it possible to examine the student's mathematical ability, stressing the solution process rather than focusing on the final result. In the assessing the student's mathematical ability great importance is ascribed to **monitoring the solution process** and the thinking processes guiding the student. Tasks of this type are suitable to be used as an assessment tool in accordance with the new trends in mathematics instruction. Since we are striving to base teaching and learning in the classroom on the inquiry and discovery processes that take place in the course of solving problems, student assessment should also be based on tasks of this type.

The tool presented here was constructed for the purpose of assessing the "Geometry and the Teaching of Geometry" course. The course focused on acquaintance with geometric shapes, the relationship between them, their characteristics, as well as general didactic aspects. The course was given as part of a workshop while employing demonstration means relevant to the subjects being taught. Moreover, the

course incorporated various teaching means and didactic methods, and presented various studies and theories, such as the theory of Van Hiele. Teaching methods included work with heterogeneous groups emphasizing performance tasks requiring inquiry and discovery, mathematical discourse, both within the group and in the plenum.

We sought to adjust the assessment methods in the course to our teaching methods. The object was to examine the students' mathematical and methodological knowledge of geometry, to express the inquiry processes in the group and the individual knowledge and diversity among the students.

Methodology

The population and the framework: Thirty-five student teachers and elementary school and junior high school teachers attended the course. The course participants were a very heterogeneous group, composed of students who specialized in mathematics, those who did not specialize in mathematics, as well as teachers (both Arab and Jewish) who attended the course to complete degree requirements or as part of in-service teacher training.

Assessment tools: We employed for assessment the "Three-Stage" tool, developed by a Weizmann Institute team.

The tool is composed of three activity stages:

Stage 1 – The Group Test. Students worked on an activity in groups and write a joint report on the work performed by the group. Each group writes a single report and submits it to the teacher, without any intervention on the part of the teacher. The group report reflects the process that the group went through, including erroneous assumptions that were made. The students become accustomed to being aware of the process they are going through, to express themselves within the group, to explain to others and to conduct a mathematical discourse. Moreover, the group report can serve as a protective grade for weaker students.

Stage 2 – Classroom discussion, whose function is to summarize and consolidate the work of the various groups. The discussion is based on mathematical principles related to an activity prepared in advance by the teacher, as well as on the teacher's impression of the group activity and difficulties that arise in the course of the work of the various groups. The teacher's role in the discussion is to arrive together with the students at a generalization, a global outlook and greater depth of understanding.

Stage 3 – Individual test, the stage at which the students complete individual questionnaires and submit an individual report. The questionnaire contains questions related to the joint work carried out by the group at Stage 1. Each student is examined at this stage as to the extent to which he is capable of answering questions based on the group work. The personal report has two central aims:

1. To examine the students' personal knowledge of the subject matter worked on in the group, but without help from the group. Information is thus obtained on what the students learned in the group work and in the subsequent discussion conducted by the teacher. Students who can achieve deeper and broader understanding by themselves, can express such ability in their individual work.
2. Creating motivation for self-involvement of each group member in the group work, with each student knowing that he will be personally questioned on the work.

It is important to complete Stages 1 and 2 during the same lesson or in consecutive lessons. Stage 3 is to be carried out in another lesson, after the teacher has had the opportunity to study the reports of Stage 1.

For assessment of the course, we constructed a Three-Stage tool appropriate for the subject covered in the course. Chosen for inclusion in the Three-Stage tool were didactic and mathematical tasks in the subject matter dealt with in the course. In the group test we included questions that examined mastery of mathematical concepts, awareness of typical errors, familiarity with various demonstration means and their integration in teaching. At the second stage, a discussion was conducted which was primarily a summary of the mathematical and didactic principles related to the group task, where we have chosen to focus on the advantages and disadvantages of each model and to discuss additional demonstration means which could be used (some already encountered during the course). At the third stage, the individual test, we gave questions based on the group test and the class discussion. The remaining questions were based on the group test tasks.

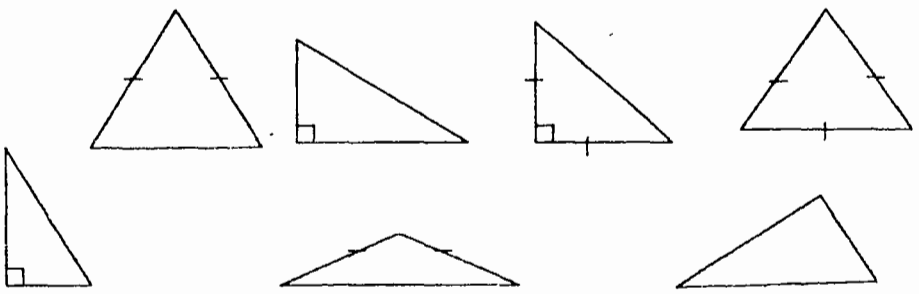
For examining the individual and the group tests we constructed specific criteria typical of each question, where each criterion is assigned a value, with each of the criteria detailed and explained in Tables 1 and 2. We defined various performance levels in performing the task, and each of the reports was given a "genergrade" (100 maximum) according to the performance level. The assessment of each student was based on a combination of his work in the group part (50%) and his individual work (50%). The course grade was based on the performance of several tasks, one of which was this assessment task.

Presented below are representative questions from the assessment tool (a variety of demonstration tools means was available to the students):

Group Test

Question 1

Two teachers meet in the teachers' room. One holds straws and pipe cleaners, the other a worksheet.



Teacher A: I understand that both of us are dealing with triangles.

Teacher B: Right, here is a worksheet suitable for this subject.

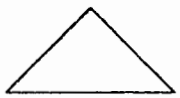
Teacher A: I prefer to use straws and pipe cleaners.

1. Propose an activity suitable for the "triangles" subject by using straws and pipe cleaners (list each of the activity stages, aim of activity, what it examines, etc.)
2. Study Teacher B's worksheet. Add your comments, propose activities and discuss both proposals: straws and worksheet. What are the advantages and disadvantages of each method. Explain.

Student worksheet:

Question 2

1. Record typical pupil errors regarding the concept of the diagonal.
2. Compose test questions whose aim is to examine the pupils' knowledge in respect of each typical error.



Note alongside each question which typical error it examines, and why.

Class Discussion (following the group test): A discussion was conducted on the advantages and disadvantages of using the worksheet and the straws. This point was chosen for the class discussion as representing a central issue dealt with by the students in the group report.

Individual Test:

Question 1

1. Propose an activity suitable for the "triangles" subject not using either straws, pipe cleaners or a worksheet, but rather another aid. Specify for each stage the purpose of the activity, what it examines, etc.
2. Assign two names to the following triangle (the students had various accessories on the table before them, which they could use to examine the characteristics of the given triangle):

3. Which of the two names was given by the majority of the class, and why?

Question 2

Construct a page of examples and non-examples of diagonals. Bring at least 5 examples and 5 non-examples, argue and explain.

Findings

To assess the work, we constructed criteria for checking the individual and the group tests. The following tables list the criteria and the overall score. Scores are also listed for two group tests (good and weak test scores), and two individual tests (good and weak test scores).

An example of criteria constructed for Question 2 in the group test (the criteria for Question 1 in this test are similar to the criteria for Question 1 in the individual test):

Criterion 1: List of Errors

Level	Details	Total Score	Good Score	Weak Score
1	No list of errors or incorrect list	0		
2	Partial list (less than five errors)	3	3	3
3	Complete list (at least five errors)	5		

Criterion 2: Understanding Concept of Diagonal

Level	Details	Total Score	Good Score	Weak Score
1	No understanding	0		
2	"Partial" understanding	3		3
3	Full understanding	5	5	

Criterion 3: Sample Questions

Level	Details	Total Score	Good Score	Weak Score
1	Samples unsatisfactory	0		
2	Samples satisfactory – no explanations	2		2
3	Samples satisfactory – partial explanations	3		
4	Samples satisfactory with explanations	5	5	

Criterion 4: State the error examined by each example

Level	Details	Total Score	Good Score	Weak Score
1	No	0		0
2	Yes	5	5	

Analysis of the entire "good test score" shows that the students made correct use of the various demonstration models and used them in the proper place and manner. They were able to construct different and varied activities for the pupil, activities that link inquiry and discovery and require using the demonstration means. They were aware of the difficulties encountered by pupils in the subject being studied, aware of the typical errors made by pupils in this subject, were familiar with their origin and knew how to deal with them. They had mastery of the subject being studied (mathematical as well as didactic), possessed good communication ability and used mathematical language while reasoning and explaining.

From the analysis of the entire "weak test score", we found that students did not use the demonstration models correctly. They failed to construct different and varied activities for pupils and did not relate to the aims of the activity. Their communication ability is faulty and they do not sufficiently reason and explain. Their understanding of concepts is unsatisfactory and they are insufficiently familiar with the difficulties encountered by students in the subjects being studied.

Example of criteria constructed for Question 1 of the individual test (Section 1)

Criterion 1: Understanding Concepts: Using mathematical concepts relevant to the activity, namely the student mentions a concept and shows that he understands it.

Level	Details	Total Score	Good Score	Weak Score
1	No use of mathematical concepts and/or incorrect use of concepts	0		0
2	Partial use of concepts	3		
3	Correct and full use of concepts	4	4	

Criterion 2: Manner of Using Model (demonstration means)

Level	Details	Total Score	Good Score	Weak Score
1	No use of model	0		
2	Attempt made to use model	1		1
3	Correct use of model	3		
4	Correct full and sophisticated use of model	4	4	

Criterion 3: Communication

Level	Details	Total Score	Good Score	Weak Score
1	Constructed unsuitable activity	1		
2	Activity not detailed	2		2
3	Activity detailed but not fully	3		
4	Activity fully detailed	4	4	

Criterion 4: Manner of Presenting Task

Level	Details	Total Score	Good Score	Weak Score
1	Unclear presentation of task	0		
2	Certain parts of presentation are clear	2		2
3	Presentation clear but details lacking	3		
4	Presentation clear, detailed and prepared in an organized manner	4	4	

Criterion 5: Relating to Activity Aims

Level	Details	Total Score	Good Score	Weak Score
1	Aims of activity were not detailed or no relating to aims	0		0
2	Activity partly relates to aims	3		
3	Activity fully relates to aims	4	4	

Criterion 6: Originality
Original work was awarded 2 points.

Analysis of the entire "good test score" (grade 100) showed that the student:
Is familiar with various demonstration models, knows how to use these in the right place and manner and is capable of constructing different and varied activities for the pupils, which link inquiry and discovery and require using different demonstration means. The student is aware of the difficulties encountered by the pupils in the subjects being learned, the typical errors made by pupils in this subject, the source of these errors and how to deal with them. The student has mastered the subjects being learned (from the mathematical and didactic aspects), possesses good communication skills and uses mathematical language with reasoning and explanations. To summarize, it is evident that this student has deepened and expanded her knowledge, while extracting the most from her ability in the individual test, beyond the group test (in which she received a grade of 89).
From the analysis of the entire "weak test score" (grade 55), we found that the student is insufficiently aware of the pupils' typical errors in the subject of "diagonals in polygons". Her work lacks reasoning and explanations, even though she was asked to provide these. Moreover, she is unfamiliar with the different triangle types.

Analysis

At the first stage (the group test), the students worked diligently, in cooperation, and conducted mathematical discourse. They enjoyed this very much and one of the students said: "It was really fun, even though I'm certain I didn't get 100, but I don't care, because I learned a great deal and enjoyed myself very much." The students noted that they prefer working in groups rather than individually "because it is much more interesting and productive."

Analyzing the results, we found that the score obtained by 14 students in the group test was higher than their score in the individual repor(by more than two points). The score of 10 students in the group test was lower (by more than two points) than the score in the individual test, while 9 students had a similar score in both.

In the group test, students at different levels worked together, mutually supporting and enriching each other, and it appears that therefore weaker students scored higher in the group test and lower in the individual test. The group score constituted a protective grade for the weaker students. Examination of additional work submitted in the course and the impressions gained in the classroom of this group of students whose group score was higher than their individual test, indicated that it is the lower grade in the individual test that reflects their knowledge.

As to the students whose individual scores were higher than their scores in the group test, it can be assumed that they learned from the group test and the class discussion.

We found special cases such as: a student who attained 90 in the group test and 52 in the individual test. Acquaintance with this student in the classroom and with her other work showed that she has not mastered the material sufficiently. However, in the group test she was together with students who have mastered the material well, and it can be assumed that they dominated the group test, thus the gap between the grades. On the other hand, another student received 65 on the group test and 98 on the individual test. Upon examining the composition of her group, it turned out that it included two students who have not mastered the course material. From an interview with the student, it turned out that she is lacking confidence regarding her knowledge and was thus unable to dominate the group.

Summary and Discussion of Results

It should be noted that the use of the Three-Stage tool achieved several objectives:

By examining the test results we learned about the central points in our work in the course, such as:

Importance of the mathematical discourse. Importance of working in groups, which develops skills of cooperation as well as supporting and helping others (beyond the mathematical discourse). Importance of employing the various demonstrations means. The various mathematical and didactic aspects.

The need to change the assessment methods in accordance with the teaching methods.

This method of assessment provided the students with an example of how to adapt the assessment method to the teaching method: Throughout the course, the students raised the question of how they would be assessed in light of the new trends. The question that was asked repeatedly was: "Since we are working in groups, will the test be a group test?"

Reflecting the students' knowledge: We can see from the results that the tool generally reflects the students' knowledge. The tool examined the understanding of mathematical concepts, methodological knowledge (such as the ability to prepare activities for pupils), understanding the task, originality and creativity, organizing the work and communication. The students fully cooperated in the group work, held discussions, made assumptions, and learning took place with mutual support. The tool expressed the skills and the diversity among the students and the processes of coping and working in groups.

Additional advantages in the group segment: Reduced test anxiety, support for the weaker students and creating motivation toward cooperation.

The individual test reflected and balanced the results of the group test and related differentially to each student in the group. Namely, information was provided on the knowledge of the various students by their level, by what they learned working in the group, and following the discussion conducted by the teacher. It was furthermore possible to see that some students deepened and broadened their knowledge of this subject by themselves, fully utilizing their ability in the individual work.

The individual test pointed out the knowledge gaps between the student teachers and the teachers. For example, it was possible to detect among the student teachers typical errors that occurred among pupils, such as in Question 1 of the individual report, in which only the student teachers assigned the incorrect name to the triangle, "acute angle triangle" or "equilateral triangle". In the question where they were asked to point out typical pupil errors regarding the concept of the diagonal, only teachers were able to link their answer to the thinking levels of Van Hiele.

To summarize, the "Three-Stage" is the appropriate tool for the new assessment and teaching approaches. It reflects the students' knowledge and expresses the skills and diversity among students, the processes of coping with working in groups, to originality, creativity and mathematical communication.

CHARACTERIZING UNDERGRADUATE MATHEMATICS TEACHING

BARBARA JAWORSKI, UNIVERSITY OF OXFORD
ELENA NARDI, UNIVERSITY OF EAST ANGLIA
STEPHEN HEGEDUS, UNIVERSITY OF OXFORD

The Undergraduate Mathematics Teaching Project[1] *(UMTP) is a one-year study aiming to characterize, and identify issues related to, mathematics teaching in undergraduate tutorials. It builds on earlier research into mathematics learning in undergraduate tutorials and involves a research collaboration between mathematics educators and mathematicians. From participant observation, semi-structured interviewing, and group discussion, it develops a set of qualitative data which is analyzed through repeated critical scrutiny to distil characteristics and issues of the teaching experienced which might be seen as germane to a wider variety of settings. Research is ongoing, but issues and indications from analysis of pilot-study data are included.*

Rationale

The broad aim of the Undergraduate Mathematics Teaching Project (UMTP) is to explore, in a collaboration between mathematics educators and university mathematics teachers, current thinking and practices in mathematics teaching at first year undergraduate level. It seeks to elicit relationships between the enacted teaching, the mathematics being taught, the aims and objectives for students' learning, and the perceptions of those teaching (the tutors) and those observing (the researchers). In doing so it will begin to provide a knowledge base on which to make decisions affecting practice in university mathematics teaching and illuminate an under-explored area of influence on mathematics teaching more widely. The objectives of the study are:

1. To identify practices and processes in the teaching of mathematics at first year undergraduate level, and the thinking and beliefs which underpin them.
2. To examine such practices and processes in a collaboration with university mathematics tutors and develop a pedagogical discourse based on collaborative reflection by both researchers and practitioners.
3. To inform university tutors about the nature and implications of existing practices and processes, and the potential of alternatives. The research will explore the impact of these implications on current thinking and beliefs.

The research develops from two previous studies. The first explored undergraduates' mathematical learning difficulties in first year tutorials (Nardi, 1996) – in particular students' appreciation of abstraction and formalism. The

[1] This project is funded by the Economic and Social Research Council (ESRC) Award Number R000222688.

BEST COPY AVAILABLE

second study followed from the first: data, in the form of transcripts of tutor-student dialogues, and analyses were presented to the tutors (whose tutorials were observed in the first study) to explore their related thinking and reactions (Nardi, 1998). The first study provided a rich account of students' difficulties with mathematical abstraction in a range of topics. The second provided insights into tutors' thinking about their students' learning, and, although very small scale, was encouraging as an indication of the value of further exploration into the teaching of mathematics at this level. Both studies provided strong evidence of the potential of tutorials as a source of rich data, allowing insights into learning and teaching processes and practices.

Background and theoretical perspectives

The UMTP study should be seen in relation to key issues in mathematics education currently in the UK. The number of students opting for mathematically-oriented studies at university is decreasing and recruitment of good mathematics graduates to mathematics teaching at school levels is at an all-time low. Profound changes in secondary education, pedagogy and curriculum have contributed to an increased gap between secondary and tertiary mathematics teaching approaches and to a debate as to the preparedness of undergraduates for university study in mathematics. One response to these changes has been to modify university mathematics curricula to adjust to current needs of students. However, universities are now being required to be accountable for the quality of their teaching and there is an emerging realization that reform should be focusing on teaching. The above imply that there is a need for a revision of the underlying principles as well as the practices in the teaching of mathematics at university level. The UMTP study aims to explore critically the nature of undergraduate teaching and its potential for the future of mathematical learning at a variety of levels.

The research is embedded in a growing theoretical area which focuses on the development of knowledge in advanced mathematics, and the difficulties students face in dealing with mathematical abstraction. The work in the area of Advanced Mathematical Thinking (e.g. Tall, (1991) and Sierpinska, (1994)) is highly relevant and the work of Nardi, quoted above, fits into this tradition. The current study seeks to relate these theoretical perspectives to issues in teaching.

There is an extensive, curriculum-based, literature in this area, mainly in North America, which seeks to relate undergraduate learning to methods of teaching. For example, alternative approaches to calculus (e.g. Ferrini-Mundy & Graham (1991) and Selden & Selden (1993)) and linear algebra (e.g. Leron & Dubinsky 1995) reflect, in part, attempts to make these subjects more engaging and meaningful for the majority of students. However a general perception remains that the teaching of mathematics at the undergraduate level

has not to date made sufficient effort to deal with the backgrounds and needs of present day students. The research described here aims to go beyond particular practices, to seek more general awarenesses and understandings of the relationships between teaching and learning at undergraduate level. It draws also on research at other levels of mathematics teaching, seeking commonalities and differences. For example, it explores the use of the Teaching Triad, a construct used to characterize and analyze mathematics teaching at secondary level (Jaworski, 1994).

Project Initiation and Methodology

The UMPT is a one-year study (from October 1998) of a small sample – largely purposive and opportunistic – of first year undergraduate tutorials. It aims to study in depth the teaching of 5 university mathematics tutors from a list of volunteers willing to collaborate in the project. Over a period of one university term (the second of the year, January to March) data will be gathered by observing one or two consecutive one-hour tutorials per week for each tutor, and interviewing each tutor soon after each observation. Periodic meetings of researchers and tutors will be held to establish a community of practice within the project, to encourage open sharing and debate of practices and issues, and as an alternative source of data for validation purposes.

The UMTP methodology might be described as critically qualitative with a strong emphasis on participation, drawing on experience from previous research by Jaworski (1994, 1998). *Qualitative* data is sought to allow access to the complexities of tutors' epistemology and its relation to pedagogy. The *critical* nature of the research is in its questioning of processes and practices at all levels. Questions from researchers to tutors seek access to tutors' thinking underpinning observed actions. The earlier research suggested that such questions will lead to questioning by the tutors themselves of their own practices and associated theories and beliefs. Meetings between all the research participants are designed to encourage an airing of tensions and issues. As part of the analysis, feeding back into data collection, researchers will reflect critically on questions asked, to examine and expose their relation to underlying theoretical perspectives, and influences on tutors' responses.

The *participative* nature of the research is designed to develop a community of practice within which such questioning can take place. It is necessary to recognize overtly the differing perspectives and objectives of tutors and researchers (as identified in the aims of the project above), while fostering trust and mutual respect. The relationship is designed to be one of "clinical partnership" in Wagner's (1997) terms:

> The researcher is clearly the agent of enquiry, and practitioners are the people whose work is the focus of analysis and reform. But practitioners can also engage in the enquiry, at least by assisting their researcher colleagues, and

attention is given by both to the process of researcher-practitioner consultation itself. (p. 15)

Analysis *during* data-collection involves scrutiny and annotation of observation notes to produce observation-protocols and suggest questions for interviews. Analysis after data-collection involves scrutiny of recorded interviews and production of interview-protocols for use in extracting characteristics and issues. Protocols act as second-order data to inform subsequent analysis which involves a critical scrutiny of observations interviews and discussions to elicit relationships. Discussions in research group meetings are recorded and support the analysis of the interviews. Characterization involves seeking processes, practices and issues which might be seen to be germane to a larger number and wider variety of settings. Rigour is to be ensured through triangulation between alternative data sources, and a transparency of contextualization and critique (Delamont and Hamilton, 1984; Ball, 1990).

Indications and issues arising from pilot-study analysis

The pilot study focused on 7 tutors, which would reduce to 5 for the main study, once timetables in the second term were known. The purpose of the pilot was to try out observational and interview approaches, data gathering techniques and analytical procedures; to induct tutors into research practices; and to enable the researchers to adjust, critically, the mutuality of their perceptions of the research methodology. We shall offer some insights into the data emerging from one tutor and our preliminary analysis of it. In addition we shall identify, tentatively, an emerging issue, that of the nature and importance of interaction between tutor and students in the tutorial, with reference to data from a number of tutors.

Tutor-1: Data and Preliminary Analysis

Tutor 1 talked about his teaching strategies. For example, he used a (white)board to facilitate communication between tutor and students. He valued "teaching by example", offering reasons for providing his own examples. He emphasized the importance of "explanation skills". Developing students' confidence was one of his main aims.

In parts he was critical of his own teaching: for example, suggesting that he was "going too fast when student K was struggling", that he needed to be sure of basic understanding, that he had produced a "poor" diagram – it represented three vectors in the plane, but might have been seen as a set of three orthogonal axes in R^3. He said, "I should have been more careful ...".

He recognized his emphasis on the importance of "the formalizing process", or "proof", saying "I'm the only source of rigour they have". He indicated a tension between "getting ideas right" and "giving them a feel for rigour".

Analysis involves critical scrutiny of the data, seeking links to other data items, and recognizing patterns which might be judged characteristic. In the pilot study, only two tutorials were observed from each tutor. Thus, pattern seeking is at a very early and elementary stage. Nevertheless there are analytical remarks to make about the above data. We provide, as exemplars here, three points which may be indicative of forthcoming characterization.

1. *Teaching strategies*: It is interesting that the tutor refers to various strategies he uses in his teaching. With regard to use of examples he says

> I like teaching by example, especially when you've got something abstract to say and certainly I think ... I consider it quite important. The reason I like to give my own examples sometimes is you quite often get the student who's done the ones on the sheets[2] and a student who hasn't done the ones on the sheet, so you don't want particularly to set the examples on the sheet[3].

'Use of strategies' might become a *characteristic*. It will be important in other data to look out for tutors' references to strategies they use. In this case, one example of a strategy is the tutor's use of 'his own examples' to provide alternative experience from that offered by the lecturer, and for discussion purposes in the tutorial. With this tutor it will be important to explore further his construction and use of such examples.

2. *Developing students' confidence*: The tutor's words were:

> I think the biggest thing to developing confidence is to make them not feel at all uneasy about being wrong. I mean ...you don't have to have a wonderful rapport but just enough of a ...never be patronizing and you know, just, er, OK, OK, tell them the question's hard, whether it is or not because that's sticking with them, tell them it's hard and [as] such it's, it's just a matter of er, getting your, your confidence to, to, to be wrong, you know is is a very good thing.

Some of the hesitation is left in here to indicate the tutor's struggle to articulate his perception of dealing with students' confidence. This statement points towards a 'sensitivity to students' on the part of the tutor – a teaching concern directed at the students' needs, in this case in the *affective* domain. It suggests that doing what he can to encourage confidence is going to help the student to tackle concepts more effectively. His criticism of his misleading diagram might be seen as sensitivity which is more *cognitively* focused: he suggested the diagram might have been construed by students in an alternative way to that intended, potentially leading to misunderstanding by the student.

---

[2] He refers to the lectures which are open to all students, and the problem sheets, set by the lecturers, for students to tackle questions related to the lecture material.

[3] Quotations are edited slightly to take out hesitations and repetitions, unless these seem crucial to the sense with respect to the analytical point being made. Analysis, however, looks carefully at the whole data and considers the relevance and import of pausing, hesitation etc.

Sensitivity to Students (SS) is one of the elements of the Teaching Triad (Jaworski, 1994, Jaworski & Potari, 1998), the others being Management of Learning (ML) and Mathematical Challenge (MC). The teaching triad research suggests that SS is closely allied to MC which characterizes a teachers' interaction with the student in the domain of mathematics, attempting to encourage the student's cognitive development. The tutor's use of the diagram could be seen as a means of challenging students, which was unsuccessful because of the inadequacy of the diagram. Thus there are indications in this very early data of the inter-relationship of SS and MC leading to issues about teaching for students conceptual development.

3. *Ensuring Rigour*: A longer extract seems worth inclusion to indicate the potential of this data in early analysis:

> T1 Yes. Well, I mean (pause). My role is to have them... I mean my role is an important one is that the, er, I am their only source of rigour that they have in the, really in the, in the, the first year. They'll, it, it's me explaining things and introducing style and er proof. But at the same time ideas I'd like to get er, it's it's a balance between getting ideas right, er, and giving them some feel for them but then also being able, being somehow being able to (pause) convince them that they feel they have to do er... concept is the same as the rigorous definition that might be on the board.
>
> Ten lines omitted. Then:
>
> I think, I think the important role of the tutor is to make sure the, try and give them handle on both things but that's often difficult. I mean one way is usally geometric and one way is analytic and a lot of people only think one way and not the other but er, at the same time I usually tell them as long as they can do it one way it's a good thing but it's always nice to have two ways of thinking about it. ...

Scrutiny of the transcript shows that this statement is one of Tutor 1's longest statements in the interview. Although very hesitant, perhaps unused to articulating his personal principles or theories, Tutor 1 presents a clear rationale for his emphasis on, and approaches to, rigour. This length and clarity are interpreted as indicating issues of significance to the tutor – in particular, perhaps, the issue of "getting ideas *right*" versus "giving [students] some *feel* for them" (our emphasis). In this case, the mathematics in question is linear algebra. It will be important to follow up further references to 'teaching for rigour' in subsequent data, and to question their relationship to particular topics, or their cross-topical generality. (c.f. Nardi, 1996).

An emerging issue, *the nature and importance of interaction*

Interaction in tutorials, unsurprisingly, is perceived and enacted in different ways by different tutors. Many students are typically silent unless asked to

speak, and so their uttering a word indicates interaction. In some cases the interaction is little more than a question from a student, followed by a monologue by the tutor. In others it involves a student in presenting ideas to the tutorial group, with comments and questions from other student(s) and tutor. Some tutors seem to see interaction as little more than an unfortunate necessity for discovering what is problematic, especially with weaker students. Others see it as a tool for empowering students' mathematical communication.

From the current data, we have identified elements of tutor 'inciting' interaction and 'empowering' interaction. In the first case, it is necessary to recognize a *need* for interaction. In the following quotation, a tutor recognizes that inappropriate imagery is a barrier to understanding, so that exposing this imagery – "you need to listen" – is essential for the tutor in judging appropriate support.

> I think they have just utterly different pictures in their heads sometimes. They have, they have completely the wrong picture in their head and you, you need to listen to what that is to push them in the right direction. So if there's the wrong picture in their head and you start talking about something based on the picture you have in your head or that you think they have in their head you, you just confuse them more. (Tutor 2)

The following quotation emphasizes the belief that interaction is a necessity for helping weaker students – "I very often ask them to explain it to me" – but unnecessary for "rather better" students where a monologue suffices.

> Um, I think it's actually more to do with the students ... because they are very weak. In trying to find out whether they understand something I very often ask them to explain it to me or say something about it. Because, er if I just say OK this is a Cauchy sequence and they nod I don't actually know whether they're just nodding to just to be polite ... Er, my Monday afternoon students are, are rather better and tutorials tend to be much more of a monologue. Um, I don't, I don't need to ask them what a Cauchy sequence is because they've demonstrated in their work that they know. (Tutor 3)

Using tutorials to *empower* students has emerged from some of the current data. For example, Tutor 1, above, spoke of the importance of building students' confidence, for example, of acknowledging that certain concepts are "hard", and of seeing "being wrong" in positive terms. Although these ideas were not expressed explicitly in terms of interaction, it might be believed that this tutor would engage his students in dialogue to expose "wrong" perceptions, to cut through hard mathematical concepts.

Another tutor (Tutor 4) talks explicitly of using dialogue for empowerment in students' learning "how to do mathematics" – "I want them to actually be doing it rather than me telling them how to do it".

I think I view it that the point of a tutorial is for them to learn how to do mathematics so I want them to actually be doing it rather than me telling them how to do it because I think they learn less by me telling them the answer to a dozen questions instead of, OK, how do I think of these solutions, how do you think of these solutions? How do you think of these solutions now and when you're back in your room without me prompting you how to do it?

In Conclusion

It is important to emphasize that we have as yet only a small set of data to analyze, so that the issues indicated above only just start to suggest characteristics which might be seen as more widely germane. However, the pilot has fulfilled its purpose in clarifying methodology and establishing initial relationships, quite apart from its promise regarding issues and characteristics. We look forward to presenting results from our main study at the conference.

CAS, CALCULUS AND CLASSROOMS

Margaret Kendal and Kaye Stacey
Department of Science and Mathematics Education
The University of Melbourne

Abstract

Three teachers helped design and then taught an experimental program of introductory calculus in which students had full access to calculators with a computer algebra system (CAS) in the classroom, at home and during tests. Each class obtained similar mean scores on the test. However they made very different use of the CAS and performed very differently on items. One class frequently used the CAS. The second preferred by-hand algebraic techniques. The third group of students, with weaker algebraic skills, used CAS more selectively and demonstrated good understanding built from illustrating algebraic ideas graphically. The study demonstrates how teachers "privileging" impacted on student learning.

Introduction and Background

Computer algebra systems (CAS), incorporating graphical, numerical and symbolic algebra capabilities, have much to offer in the teaching of calculus. By reducing the obstacle of manipulative algebraic skills, they can release time in calculus courses to spend on concept development, problem solving and investigations (Hillel, 1993). In addition, the capacity to provide multiple representations and the ability to move freely between them makes CAS a teaching tool to enhance conceptual development. Several experimental studies now support these expectations. For example, Heid (1988), O'Callaghan (1998) and Repo (1994) have claimed that students using a CAS developed better conceptual understanding although they differ about whether this is accompanied by a loss of computational skills. There is also some research evidence to support the belief that students become better problem solvers while using a CAS (Heid, 1997). The availability of symbolic algebra on calculators, rather than on standard computers only, and the attendant reduction in unit price has stimulated even more interest in teaching calculus with CAS. Cappuccio (1996), for example, describes specific ways to teach calculus using the TI-92, a Texas Instrument calculator which incorporates a CAS similar to the desktop DERIVE.

The study reported in this paper is part of a larger study conducted with colleagues Barry McCrae and Gary Asp which explored the implications for state-wide assessment of teaching and learning calculus with CAS. In this paper we describe how three different classes of students used CAS in different ways while learning introductory calculus using the same teaching program. As such it is a study of the

type recommended by Penglase and Arnold (1996, p.79) "which directly attempt[s] to address the issues of graphics calculator use within particular learning environments."

The data reported here show how the outcomes for students in the three classes were quite different and we attempt to link these to the personal style and philosophy of each teacher. A wide variety of factors may affect the impact of an innovation such as new technology in the classroom. Amongst these are teacher-related socio-cultural factors such as attitude towards technology, prior experience teaching with technology and personal beliefs about the ways students should be taught (Thomas, Tyrrell, & Bullock, 1996). Of particular interest in this paper is Wertsch's concept of "privileging" which Berger (1998) describes as "the social setting and values which may elevate one form of mental functioning over another and in this way privilege a particular form of mental operation such as algebraic or graphical reasoning (p.19)."

The teaching trial, research methods and data collection

Early in 1998 a team including McCrae, Asp, the first author and three volunteer teachers designed a twenty-lesson introductory calculus program that aimed to use CAS to enhance conceptual understanding, connections between representations and appropriate use of the technology. Subsequently the teachers each taught the program to one class. In total there were 59 students in three Year 11 classes (students aged approximately 17 years) from two schools. The three classes had similar distributions of mathematical ability, but Class C had the weakest algebraic skills. All the students were familiar with the TI-83 graphical calculator. For this study, they were given a TI-92 graphics calculator for use during lessons, at home and for most testing. The three teachers were experienced in teaching mathematics with the TI-83 graphical calculator but inexperienced with the TI-92.

Students regularly completed questionnaires, challenging questions and log sheets to describe their feelings and progress with the calculus and technology. All students completed a written test (sample items below) and for each item they indicated whether they had used the calculator. Seventeen students were given a task-based interview by the first author, who also observed approximately half of the lessons and maintained a journal. The teachers wrote a brief reflective evaluation after each lesson and completed questionnaires and Likert items before and after the program.

Results

Table 1 shows the mean scores for each class on the written test (maximum possible score was 70). Although the absolute scores seem low, the results were very pleasing because of the difficulty of the items for Year 11 students. One third of the written test items were taken from state examination papers for Year 12 students and the study classes performed well in comparison to Year 12 classes.

Table 1 shows that the three classes performed similarly overall. However, the item-by-item analysis in Tables 2 and 3 shows differences. Table 2 indicates the relative amount of calculator use. For each class, it shows the number of items where that

class made the greatest or least percentage use of the calculator. For example, on 25 items, use was made of the calculator by a greater percentage of students in Class A than in Class B or C. Clearly Class A students used the calculator to a much greater extent than Classes B and C. Class B students used it least.

Table 1. Mean scores and standard deviation for total test by class.

	Class A (N=15*)	Class B (N=18*)	Class C (N=13*)
Mean	24.1	26.7	27.9
Standard Deviation	9.4	12.0	10.3

* *Not all students participated in all tests, so the numbers in the Tables vary.*

Table 2. Number of items where each class made greatest and least use of the calculator.

	Class A (N=15)	Class B (N=19)	Class C (N=16)
Greatest % calc use	25	3	5
Least % calc use	5	17	11

Table 3. Number of attempted items correct and incorrect by calculator use and by class.

	Class A (N=15)		Class B (N=19)		Class C (N=16)	
	calc	no calc	calc	no calc	calc	no calc
Correct	152	61	156	124	147	101
Incorrect	111	86	78	129	47	92
Total	263	147	234	253	194	193

Table 3 shows the total number of items attempted by students in each class broken down by calculator use or non-use and by success. This item-by-item analysis confirms the results in Table 2 that Class A students chose to use the CAS most frequently (64% of items attempted) and Class B least (48%), slightly less than Class C (50%). The Table 3 analysis shows more difference in overall success than does Table 1, with Class A correct on 52% of items attempted, Class B 57% correct and Class C 64% correct. This shows that there is no simplistic conclusion that greater use of CAS leads to better results. Class C achieved a higher success rate on items attempted both with and without the calculator. The percentages of items correct where students had used the calculator were 58% (Class A), 67% (Class B) and 75% (Class C) and without the calculator 41% (Class A), 49% (Class B) and 52% (Class C). This indicates that Class C made best strategic use of the CAS calculator, as will be explored in the next sections.

Conceptual and procedural errors

Despite the program's emphasis on conceptual development using technology, many students had difficulty with fundamental concepts, particularly rates of change and distinguishing between the gradients of secants and tangents. Test responses were analysed and errors were classified as conceptual and procedural. We classified as conceptual errors those which occurred when understanding was not demonstrated or the process to use was not correctly formulated. This is similar to Orton's (1983) definition of structural errors which "arose from some failure to appreciate the relationships involved in the problem or to grasp some principle essential to solution" from Donaldson in 1963. Procedural errors were algebraic, graphical, and numerical in origin or related to incorrect use of the calculator. Conceptual errors cannot be eliminated with CAS use; procedural errors may be avoided with CAS use. On a group of items attempted by all but a few students, the conceptual error rate per student was 7.3 for Class A, 5.7 for Class B and 4.9 for Class C. However, the procedural error rate was similar for all classes despite varying CAS use: 2.3 per student for Class A, 2.4 for Class B and 2.8 for Class C. In the CAS environment, procedural errors were less frequent than conceptual errors.

Success on specific item types

Many of the test items were grouped for analysis into "*core*", "*symbolic*" or "*options*" groups. There were approximately 5 items of each type. *Core* items were characterised by high conceptual and low procedural demands. In these items, using CAS is no advantage. One example is an item that gave the graph of a function and asked the student to select the graph of the derivative from five possible graphs. CAS would not be useful as no symbolic representation of the function was given.

Symbolic items have high demands on algebraic procedures and low conceptual demands. In these items, the symbolic manipulation capability of the calculators could be useful. One example on the written test was "Find dy/dx for $y = x^3(2x+1)^2$ giving your answer in factorised form". With CAS, an item like this is nearly trivial, but without it, remembering the differentiation rules and the algebraic manipulation can be difficult.

The *options* items are those that present the student with a choice between graphical and algebraic approaches. Using CAS may be advantageous. The following example item was accompanied by a diagram which gave a graph of the equation over a relevant domain:

> Given that a rider on the track of a super roller coaster follows the curve with equation $y = 1/720(x^3 + 20x^2 - 1200x)$, find the maximum height above the ground reached by the roller coaster.

This problem is an *options* item because it can be solved algebraically or graphically. The graphical route is conceptually easier than the algebraic pathway, which requires several conceptual formulation steps. With CAS the algebraic and graphing procedures are easy but not without it.

Taking the results for *core* items as indicating conceptual understanding shows that Class C students demonstrated the highest level of understanding (53.9% of approximately 80 attempts were successful) and Class A the least (40.0% of attempts were successful). We believe that the high score on these *core* items in Class C was due to the way the teacher demonstrated concepts in both graphical and algebraic terms. In total there were only 13 attempts to use the calculator (inappropriately) on these items, mostly from Classes A and C and they were mainly unsuccessful, as would be expected.

In contrast, on the *symbolic* items many students sensibly chose to use CAS. Class A had the highest CAS use and was most successful. Classes B and C both under-utilised CAS, making unnecessary mistakes in algebraic manipulation. In the interviews, students from Class A and B showed greater proficiency than students from Class C in using the algebraic facility on the calculator. For example, to find a gradient at a point, over half of the students interviewed from Classes A and B used a one-line instruction to differentiate the function and substitute the value. In contrast, nearly half of students from Class C attempted a graphical approach.

The *options* items could be solved algebraically or graphically. More Class B and C students used the calculators here than for the *symbolic* items. However, Class C students more often used the graphical facility in contrast to the algebraic route favoured by Class B students. This observation is supported by the student interviews. For example, on an *options* item used in the interviews, a graphical approach was selected by one out of five Class A students interviewed and by one out four Class B students but by 3 out of 5 Class C students. Confirming the previous result about choice of CAS, all 5 Class A students used the calculator, whereas half of the 4 Class B students worked by hand.

The differences between the behaviours of the classes that have been derived from the analysis above are summarised in Table 4. The terms used in the table express relative achievement only. For example, "higher" is relative to the other classes and is not an absolute judgement.

Table 4. Summary of the behaviours of the three classes in the study.

Behaviour	Class A	Class B	Class C
Use of calculator	most frequent	least frequent	frequent
Decision to use calculator	too frequent	discriminating	discriminating
Preferred approach	algebra by calculator	algebra by hand	graphical
Algebraic proficiency	moderate by hand	higher by hand	lower by hand
Graphical skills	lower	moderate	higher
Procedural competence	good	good	good
Conceptual understanding	lower	moderate	higher

Classroom influences

Teacher predictions

Prior to the teaching trial the teachers used a Likert scale to describe their own students' competence and probable reaction to using the new calculators. Table 5 shows their ratings. Again, the table entries express relative positions rather than absolute judgements. The table is highly consistent with the profile of each class that emerged by analysing the test results above. In particular, Class C has an orientation to graphical approaches and Class B to algebraic approaches.

Table 5. Teachers' predictions about class abilities and reactions.

Class characteristic	Class A	Class B	Class C
Algebraic competence	moderate	higher	moderate
Graphical competence	moderate	moderate	higher
Reaction to new technology	likely to succeed	will probably succeed	very likely to succeed

Teaching styles

During the teaching of the CAS program, about half of the lessons were observed by the first author and these observations lead to the descriptions summarised in the first half of Table 6. Table 6 also reports responses to three key indicators from a set of Likert-type items completed by the teachers (with additional written comments) at the end of the program. We summarise these observations as follows. Teacher A had a very positive attitude to technology, encouraged his students to use it as often as possible and gave priority to algebraic strategies. Students were taught efficient calculator procedures for standard tasks. Teacher B preferred the traditional algebraic approach using graphs when essential. He emphasised by-hand algebra, being wary that students might not otherwise develop adequate skills. Teacher C encouraged his students to use both algebraic and graphical methods and to explore connections between them. His explanations used the links between representations.

Discussion

The mean scores for each class on the written test were very similar and a casual observer would assume that learning outcomes for all students were similar. In fact this is not the case. During the teaching trial, the students in each class had very different cognitive experiences evidenced by the different ways the calculator was used. Each class acquired different conceptual understandings, a different set of competencies and different abilities to discern whether or not it would advantageous to use the various features of the calculator. These differences can be linked to the different teaching styles, personal philosophies and cognitive preferences of the teachers, even though they all helped plan the program and were thoroughly aware of

Table 6. Comparison of teacher characteristics

Characteristics	Teacher A	Teacher B	Teacher C
Classroom observations			
Teaching style	Direct instruction	Guided discovery	Guided discovery
Direction of lesson	Followed lesson plan	Controlled exploration	Open exploration
Attitude to using CAS	Enthusiastic	Reserved	Enthusiastic
Structured lesson around use of calculator	Mostly	Sometimes	Mostly
Used algebraic explanations	Very often	Very often	Often
Used graphical explanations	Sometimes	Sometimes	Often
Used both algebraic and graphical	Rarely	Rarely	Often
Teachers' own perceptions			
My usual teaching style suited the CAS Calculus project	Agree Θ	Disagree #	Agree *
There was little formal emphasis on by-hand skills and using pen and paper techniques	Agree	Disagree	Less emphasis, not little
Students enjoyed learning calculus while using CAS	Most yes, some enthusiastic	Some yes, some no	Most yes, a few no

Θ"I did not find it difficult to incorporate the changes" #"I found it difficult to monitor student work"
*"I have already used graphic calculator technology (especially with the view screen) for demonstration in classes."

the aims of the project and taught with the same guidelines. Teacher A privileged technological and algebraic approaches. Teacher B privileged conceptual understanding and by-hand algebraic approaches and Teacher C privileged graphical approaches and conceptual understanding built from illustrating algebraic ideas graphically. As a consequence, Class C's conceptual error rate was lowest. These students understood what to do in algebraic contexts so they could compensate for poor algebraic skills by appropriate use of the calculator and by substituting algebraic with graphical procedures whenever possible.

As we noted in the introduction, many authors have drawn attention to the great potential of CAS in providing multiple representations of mathematical concepts and objects. Multiple representations provide opportunities for students to employ different methods of problem solving and support students finding individual ways of understanding. However, the capacity to provide multiple representations will also lead to greater diversity of teaching methods. The three teachers in our study intended to teach the same material in the same way, according to the lesson guidelines that the whole team prepared. Yet the implementations of the lesson

guidelines varied significantly and the differences translated into substantial differences in how their students solved problems and what they understood.

This research raises two questions for our future research. Firstly, the teachers judged their students' abilities and attitudes to technology quite accurately. Did they adapt their teaching practices to take into account the abilities of their students or did they project their own mathematical preferences onto the students and teach in accordance with these? Secondly, the mean scores on the test were very similar, so is there a privileging or teaching style that should be recommended to teachers? Perhaps each particular privileging enhances development in certain directions and constrains it in others. What privileging (if any) constitutes the most advantageous learning environment for students?

"Calculus in context": A study of undergraduate chemistry students' perceptions of integration

Phillip Kent and Ian Stevenson,
University of London, U. K.

ABSTRACT. We have carried out a formative evaluation study of a computer-based "mathematics laboratory" programme for chemistry undergraduates, where the intention is that students will develop their mathematical understanding as a natural part of doing chemistry. We report in this paper on one particular episode from the laboratory, when the students had to calculate the total energy of a chemical system by mobilising and interconnecting their knowledge of mathematics (integral calculus) and science (ideas of work and potential energy). By means of observations and interviews, we have analysed the "breakdowns" in the students' problem solving activity, and we discuss what this analysis reveals about the students perceptions of integration in context.

Introduction

The mathematical training of scientists and engineers has come under increasing scrutiny in the last decade. Whilst computer technology is allowing working scientists and engineers to make use of more and more sophisticated mathematical techniques (normally hidden away beneath convenient interfaces), there is growing evidence (in the UK and elsewhere) of a general decline in the mathematical preparedness of science and engineering undergraduates. Responses to the resulting pressure on the mathematical content of science and engineering degrees have taken several forms: one has been to simply reduce the mathematical content, and to rely on computer-based tools to do much of the mathematical computation involved in scientific work. However, there is a growing recognition that this approach is unsatisfactory for both mathematicians and engineers since it misses the notion of mathematics as "a precise analytic tool" (LMS 1995, p. 7). An alternative is to increase the mathematical content, but challenge the students to develop their understanding in the context of their subject specialism. However, a set of difficult questions emerge at the intersection of cognitive and epistemological domains: to what extent must the structure of mathematics be understood in order for it to be used effectively as a tool? Can mathematical procedures be learned effectively without appreciation of their place in the structure of mathematics? What is the impact of new mathematical technologies when they are used to highlight mathematics in the context of a science specialism rather than hide it?

In this paper we want to probe the connections between mathematics and science in the context of a computer-based "mathematics laboratory" programme for first year undergraduate chemistry students, which one of us (P.K.) has been involved in

developing at Imperial College (University of London) since 1994. (For a general history of this work, see Templer et al. 1998.) The laboratory makes use of a particularly powerful piece of mathematical software, *Mathematica* (Wolfram 1996), and in so doing plays down the teaching of the large body of mathematical methods which comprise the traditional mathematical training of a science or engineering student. The thinking behind the "maths lab" programme has been described by our colleagues as follows:

> We are trying to introduce mathematics as a natural, integral part of chemistry; *Mathematica*'s power gives the students the opportunity to do this in an authentic, uncontrived way, with something of the flavour of real research. ...
>
> As one might expect, students experience a mixture of emotions when presented with this sort of challenge. One of these is certainly shock. We have deliberately set out to stretch students, but not in a way that they would expect. Their anticipation is that they will learn the techniques and tricks which most perceive as being the proper realm of mathematical experience. Instead we present them with the sort of chemical problems found in research, and with the help of a powerful mathematical toolbox, ask them to investigate the chemistry using those tools. That is not to say that they are not learning any mathematics, far from it. The problems are designed in such a way that they have to understand the mathematical processes that are being performed and the limitations that these may impart on their results.
>
> (Ramsden & Templer 1998)

We report here on a formative evaluation of the "maths lab", focussing on one of the "chemical-mathematical" coursework assignments that required students to think explicitly about how mathematics is used in chemistry to *model* chemical processes.

A student assignment: Modelling the dynamics of ion collisions

In this assignment, the students study the different possible interactions between three ions (two chloride, Cl^-, and one sodium, Na^+), in a Newtonian model, where the ions are treated as charged point particles, and the equations of motion are solved numerically. Although this problem is somewhat simplified from a "real" research problem—it is restricted to one dimension, so the particles are moving on a straight line—the students are explicitly working with a sixth-order, nonlinear differential equation system. The solution of the equations is treated a "black box" operation by *Mathematica* (it would be very difficult to do otherwise, and fortunately it turned out that *Mathematica*'s code is highly reliable). However, the students are asked to check on the reliability of the numerical solutions (and hence, in part, the validity of the Newtonian model) by showing that the total energy of the ion system is (or is not) conserved. Calculating the energy required the students to

integrate force equations to find potential energies, and in the process they needed to mobilise and interconnect mathematical knowledge (integral calculus), physics knowledge (work and energy) and chemistry knowledge (ionic interactions). We wanted to analyse this process, as an entry point to a more extensive study of the cognitive and epistemological aspects of the "maths lab" approach.

Our study data consisted of (*i*) observations of six volunteer students in the second term of their first year as they carried out the ions activity, and (*ii*) follow-up interviews which examined the students' experiences of doing the activity. The observation data suggested that focussing on the students' understanding of integration in the context of energy conservation might be particularly rewarding. Integral calculus is an interesting example of an important mathematical idea that has both a complex structure and multiple uses. Our aim in analysing both data sets was to map out how integration was understood in this chemical context, and how that understanding might be related to integration as an "object of mathematical study".

Following Noss et al. (1998), we looked for (and in the interviews tried to provoke) "breakdowns" in the students' activities, in an attempt to reveal the potentially hidden connections between mathematics and the context. Breakdowns represent "the interrupted moment[s] of our habitual, standard, comfortable 'being-in-the-world'; breakdowns serve an extremely important cognitive function, revealing to us the nature of our practices and equipment, making them 'present-at-hand' to us, perhaps for the first time" (Winograd & Flores 1986, pp. 77-78). From this point of view, the present study represents the beginnings of work in an "academic" setting that is comparable with recent work on mathematics in "vocational" situations, such as banking and nursing (Noss et al. 1998, Pozzi et al. 1998).

Observations: Working with *Mathematica*

We observed three pairs of students altogether, usually for one two-hour session each week, over a period of three weeks. Our data collection consisted of video and/or audio recordings, computer "dribble files" (an automatic record of the students' inputs to *Mathematica*, from which we could later reconstruct both inputs and outputs) and the students' *Mathematica* working documents from each session.

The energy conservation task caused the major breakdowns in the students' understandings of what they were doing. It was intended as a 10 or 20 minute task, 30 at the most; the students had been given all the necessary ideas in a lecture course several months earlier, in addition to encountering the principles of force and potential energy in school physics and chemistry. But as it turned out, *all* the students that we observed, with mathematical backgrounds ranging from basic matriculation to pre-university specialists, spent around 2 hours on it. Whilst the kinetic energies were calculated in a couple of minutes, calculating the potential

energies generated significant confusions that took much effort for the students to resolve.

The task involved using the positions and velocities of the three particles as functions of time, as output by the numerical equation solver, to construct a function for the total energy as a function of time. The students also knew the expressions for the force between like-charged or oppositely-charged ions (i.e. Cl^- or Na^+), separated by a distance r:

$$F_{like} = -\frac{e^2}{4\pi\varepsilon_0 r^2}, \quad F_{opp} = \frac{e^2}{4\pi\varepsilon_0}\left(\frac{1}{r^2} - \frac{(r_0)^8}{r^{10}}\right),$$

where r_0 is a constant.

In activity, the students are focussed on solving the given problems, and not, necessarily, on clarifying the definitions and relationships of the concepts that they are making use of. Thus, they are not necessarily thinking about mathematics, physics or chemistry with any clear separation. This explains, for example, why a student, highly qualified in mathematics, when faced with the need to write down an expression for potential energy, initially proposed, and then immediately rejected, the statement that the integral with respect to r of $\frac{1}{r^2} - \frac{(r_0)^8}{r^{10}}$ is $-\frac{1}{r} + \frac{(r_0)^8}{r^5}$, because "half of 10 is 5". Whereas this kind of breakdown is most likely a temporary mistaking of an integration "fact", other kinds of breakdowns may be far more subtle in nature.

For example, it is true that the total force on an ion is the sum of all the individual forces, each of which arises from pair-wise interaction with another ion; it is also true that "energy is the integral of force"; but it is not true, as several students tried to assert, that a "total potential" can be assigned to each ion. Such thinking leads to the construction of a total potential energy expression that contains only equal and opposite terms which sum, at all times, to zero. A characteristic of this kind of breakdown is the *lack of detail* in the knowledge that the students fall back on as they attempt to correct an error or find a solution. But the breakdown can also be a means to develop a correct understanding, and, for two of our student pairs, this zero result provided the stimulus to make the final, correct construction of the energy expressions.

Another reason for factual breakdowns in algebraic calculation may be that the task largely requires working in a graphical mode, where graphs tell a story about ion interactions. For example, Figure 1 shows the total kinetic energy of the 3-ion system against time for an interaction in which, at time zero, a single (Cl^-) ion is fired at a pair of ions that are bound into a molecule (NaCl); there is a collision during which there are large variations in energy, and then a molecular bond is re-established with a free ion travelling off to large distances (hence the repeating

pattern of energy variations as the molecule vibrates). A fact which all of our students missed, but which would have helped them considerably, is that if total energy is conserved then the total P.E. as a function of time must be the reflection of this K.E. graph in the straight line which represents the total energy. Instead of this, the students were faced with having to produce an elusive P.E. graph whose shape they had little idea about.

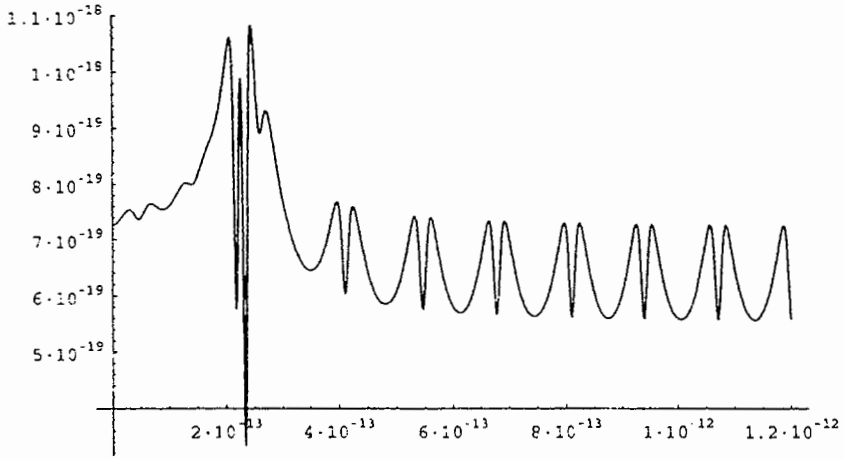

Figure 1: Student graph for the total kinetic energy of the system (in Joules), as a function of time (in seconds).

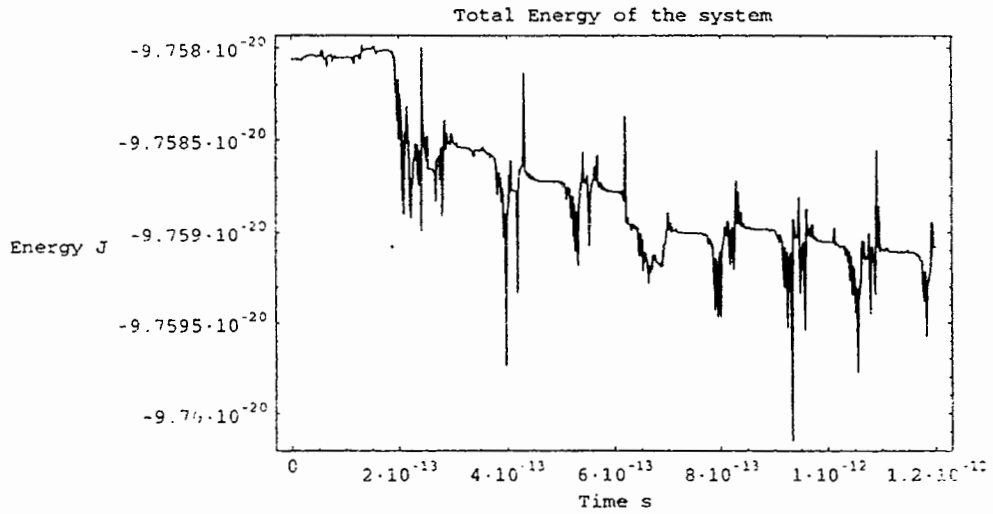

Figure 2: Student graph for the total energy of the system.

In fact the total energy graph is not quite a "straight line" after all—see Figure 2. The limitations of the numerical calculation, as well as the choices made by the graphing algorithm of the software, lead to a graph whose appearance is counter-

BEST COPY AVAILABLE

intuitive. It requires a critical reading with attention to scales and numerical magnitudes: the variations, apparently huge, are just ±0.01%!

Interviews

Some weeks after completing the ion collision assignment, each of the six students were interviewed for about one hour, and the interviews were audio taped and transcribed. The students were asked about their perceptions of the ion activity, its purpose, and what they felt they had gained from the experience in terms of their chemical or mathematical knowledge. The students were then asked to explain the ion activity to the interviewer (I.S., a non-chemist). Our interest was in how they viewed the "intersection" between mathematics and chemistry, which we hoped to trace out by probing their ideas about how energy and integration are connected.

All the students, as they talked about the energy conservation aspect of the activity, described the potential energy as the integral of force with respect to distance. In a sense, one might be surprised if they had not expressed this connection, since it represents a principle that forms part of the general background of "physical" discourse. The interesting question is what the students meant by this description, and how it related to the chemistry context. In the following interview extract, *A* (a male student with a strong mathematical background) articulates his understanding of the connection. Although the extract is continuous, it has been broken down into three parts to aid analysis.

In response to the question of why integration gives energy, *A* begins by connecting the ion interactions to energy:

Interviewer: Why integrate to give you the energy?

A: erm.... to change potential you're having to do work. If you have two ions that are bonded, simply because they have ... out of the nature of their charges, if you remove one you are doing work on it, and, hence you get the, um, energy.

Next, he connects energy with the area of a graph:

A: You have a force-distance graph, you're then, um, have the work done is the force times the distance... It's the area under that graph will be the, err, work done and hence the change of potential [energy].

Finally, when A is pressed, he connects area and integration:

I: So why is it the area?

A: Why the area? It's because you are multiplying the two axes together.

I: How then does that connect with integration?

A: Integration is a method of determining that area under a curve.

So what has *A* connected? In this sequence he articulates clearly an identification between energy and its representation as the area of a graph. First, *A* relates the

abstract concept of energy with work and its visual representation on a graph. Next he takes a feature of the graph—its area—to express the connection between force and distance, finally introducing integration as a mathematical(?) "method" for calculating the area.

When pressed, the other interviewees also made the connection between energy and the area of a graph, but varied in the degree of coherence and detail of their explanations about their notion of integration. One student tried to describe the process of approximating the area under a graph by the "trapezium rule where you just take loads of rectangles and stuff... eventually until you get to infinity, where you have an exact approximation, rather than an approximation, you get an exact answer". Another student—who had just been trying to revise the mathematics—spoke about limits as "the sort-of value that you are allowing the size of your delta's [displacements] to be". However, neither of these students could explain why the limiting process actually gave the exact value for the area in *every* case or why this might be an important question, from a mathematician's point of view.

Discussion

Most of the students seemed to have developed a working principle from their previous experience that "integrating the force gives the potential energy". This encapsulates a combination of scientific and mathematical knowledge: the change in potential energy is equal to the work done by a particle against a force, and the work done is the integral of the force with respect to distance. The principle "anchors" —to borrow Noss et al's (1998) term—the students, both in the sense of providing them with a secure approach to problems, and in fixing their knowledge in specific chemical contexts.

What can be said about this working principle at the intersection of mathematical and chemical knowledge? The process of trying to break down students' understandings revealed a connection that they made between energy and "area under a graph". It displays an understanding tied to visual images and qualitative arguments, but with varying degrees of analytic content, recalled mostly from somewhat distant school experience. The central role that energy plays in making the connections between chemical and mathematical knowledge suggests that integration-- where it is seen as relevant—is understood in a purely functional, tool-like manner. One of the defining characteristics of tool-like behaviour is the transparency of the tool to the user—its "ready-to-handness"—with a consequence that tools become apparent as entities to the user *only* when they fail to be tools (Heidegger 1962, p. 98). The evidence from the observation and interviews suggest that, unless one provokes some kind of breakdown in the functionality of integration, the students will not focus their attention on integration as a concept. This is particularly significant if one is considering how mathematical ideas might be developed in the context of a scientific specialism.

As many others have noted previously (e.g. Harel & Papert 1991, Noss & Hoyles 1996), the demands for formal precision which a programming environment places on its user serve both to expose any fragility in understanding, and to support the building and conjecturing activities required for the (re)construction of concepts by learners. An important difference for our relatively sophisticated undergraduate students, compared with the younger students that have mostly been studied in the literature, may be that the learning experience seems to be largely one of anti-climax, a rather gruelling reorganisation of previous knowledge. We asked the students on several occasions what they felt that they had learned, and the typical response was that they didn't feel that they'd learnt any mathematics or chemistry except "in this particular area". We think that their perception is rather accurate, and that understanding the relationships between knowledge domains is precisely about establishing connections in a sequence of "particular areas".

CHANGE PROCESSES IN ADULT PROPORTIONAL REASONING : STUDENT TEACHERS AND PRIMARY MATHEMATICS TEACHERS, AFTER EXPOSURE TO *RATIO AND PROPORTION* STUDY UNIT

Yaffa Keret

Levinsky College of Education

Abstract

The reported study examined change processes in knowledge and proportional reasoning among 87 student teachers and 20 teachers. A study unit on "ratio and proportion" was designed for this purpose, following a gradual developmental approach to the proportional scheme, based on the work of Fischbein (1975), Noelting (1980) and others. This approach, as opposed to Piaget and Inhelder's (1958), assumes that the proportional scheme does not mature of its own accord during adolescence. To elicit the maturation of the potential proportional scheme, a process of training is required. The present findings were obtained by means of individual tests, interviews and observations, and they led to the conclusion that since most learners had mastered the concept subsequent to studying the unit they could be considered "proportional reasoners".*

Introduction

Proportional reasoning is a person's ability to effectively use the proportional scheme. This ability plays a central role in the development of mathematical thinking while also being of practical importance in so far as it functions as an action plan that supports problem solving in a variety of fields, eg, mathematics, the sciences, and economics.

Much like any other type of mathematical activity, solving proportional problems requires three main knowledge components: intuitive, formal, and algorithmic knowledge (Fischbein, 1993). Acquisition of these components, and the ability to combine them, equips a student with the concept of proportion by means of which she or he will probably correctly solve ratio and proportion problems (Harel & Confrey, 1994; Thompson & Thompson, 1994).

Let us define a "proportional reasoner" as a person who makes intelligent use of the proportional scheme when solving ratio and proportion problems. This requires a three-step action program: (a) identification of the direct or the inverse proportional relation between the relevant factors - intuitive aspect ; (b) presenting the relation in the form of a mathematical model – formal aspect, and (c) use of this model in finding a quantitative solution to the problem - algorithmic aspect combined with the intuitive and formal aspects.

Piaget and Inhelder (1958) were the first to find that the proportional scheme develops in three stages. They also claimed that, like any other operational scheme, it suddenly develops during adolescence. This may lead to the conclusion that adults are

---

* This study is part of a doctoral dissertation, written under the supervision of the late Prof. E. Fischbein at the School of Education, Tel Aviv University, Israel

universally in the possession of the proportional scheme, which they spontaneously and intelligently use as an action plan for the solution of ratio and proportion problems. Numerous studies, however, have revealed that reality looks different: adults, at different levels of education, encounter difficulties when solving this type of problem (Fisher, 1988 ; Keret, 1994 ; Tourniaire & Pulos, 1985).

Studies on the development process of the proportional scheme subsequent to the work of Piaget and Inhelder have upheld the existence of the three stages, but contested these authors' developmental approach. Most of the criticism is directed to the types of tasks chosen, and their dependence on physical knowledge. Moreover, it has been argued that Piaget and Inhelder's relative lack of attention to judgement strategy and explanation led them to draw over-generalized conclusions, thereby leaving the developmental process insufficiently elucidated. .

Already in the seventies, Fischbein, Manzat, and Barbat (1975) delineated a gradual-continuous developmental process which depended on learning of the proportional scheme, mainly among children in the concrete stage. These findings were then confirmed by Noelting (1980a,b) and others, who gave children tasks that did not require physical knowledge (Tourniaire & Pulos, 1985). In the nineties, researchers set out to study young children's thinking to reveal patterns that develop prior to the acquisition of formal strategies and the proportion formula. Findings suggest that the strategy quality develops from additive thinking through qualitative to quantitative proportional reasoning. And that the same learning process that makes the development of these patterns possible, also assists in the development of proportional reasoning (Harel & Confrey, 1994; Lamon, 1993; Thompson & Thompson, 1994).

The above studies all share a developmental approach which, in contrast to Piaget and Inhelder, assumes that proportional reasoning develops gradually rather than making its sudden appearance in adolescence. As the child grows older, she or he acquires new action plans on a higher level of difficulty. Learning requires appropriate training - thus the potential proportional scheme comes to mature.

In the present study, this approach was examined with reference to adult participants. For this purpose, a study unit on ratio and proportion was designed which encouraged the development of proportional reasoning. We examined the processes of change in the knowledge of learners of this unit; whether, and to what extent, the study unit improved participants' ability to make intelligent use of the proportional scheme. That is to say, our question was : Did learning transform a dormant proportional scheme into an actualized one?

Methodology

Subjects

The study included 107 participants, subdivided into two groups : (a) 87 student teachers and teachers who were enrolled in two educational colleges, training to be primary mathematics teachers; 55 of these participants studied the study unit and 32

served as controls; (b) 20 primary school math teachers who all studied the subject as part of their inservice studies.

Instrument

1. A diagnostic test on ratio and proportion.

The test was administered both prior and subsequent to exposure to the study unit and was divided into two parts : The first part included 27 ratio and proportion problems of three general types : 13 proportion problems involving direct ratio, 9 with inverse ratio, and 5 problems referring to other "ratio" problems. Respondents were asked to solve each problem by means of more than one solving strategy, and to write down every stage in the solving process. An unexplained quantitative response was considered incorrect.

Problems referred to a variety of knowledge areas, referring to both daily situations and to more particular phenomena like balance and scale. These problems were content analyzed to represent problems involving proportional relations that were either obvious, or suggested or concealed, as well as problems including different types of numbers, i.e. integers, rational numbers, and percentages.

The second part included 10 open questions that required respondents to define and explicate the following concepts : ratio, proportion, the relation between two parts of a whole (e.g. the relation between profit and investment or the number of boys and girls in class), balance, speed, the difference/similarity between ratio, percent and division.

2. Individual, 20-30 min. interviews: these were conducted following exposure to the study unit among a sample of learners: 15 student teachers and teachers from the colleges and five practicing teachers.

Interviewees were asked to give verbal explanations to how they had gone about solving the problems in the first part of the diagnostic test. This made it possible to determine whether, and to what extent, they had been using the proportional scheme, i.e., whether they had been consciously aware of a direct/indirect proportional relation, and whether they could intelligently explain their choice of a mathematical model and its working. The interviews also offered an opportunity to investigate the source of typical errors.

3. A specially designed study unit on ratio and proportion, requiring eight weekly hours of teaching-learning.

The study unit was constructed on the basis of two main principles : (a) mastery of the intuitive, the formal, and the algorithmic components of knowledge in this topic and the ability to combine them, may assist to develop proportional reasoning, and (b) the importance of inclusive, extensive presentation of the topic that refers to both its mathematical and psychological-didactic aspects (Even & Tirosh,1995).

Learners were exposed to problems relating to different knowledge areas and to various solving strategies (preferably more than one strategy per problem) using

proportional reasoning. Learners were introduced to published research concerning proportional reasoning proposing different teaching techniques for conceptualization of ratio as a part of the development of mathematical thinking.

Results

Two types of results were yielded: (a) solutions to problems and verbal written statements, generated both before and after learning, and (b) interviewees' verbal statements, post learning.

The statements were content analyzed and the solutions were examined with reference to four categories :

1. Correctness of solution

Results generally indicate substantial improvement in ability to solve ratio and proportion problems following use of the study unit, while controls showed no change. Post-study unit, 86% succeeded to produce correct solutions. This is true for a variety of problems, relating to both standard and non-standard contexts, and including both obvious, submerged and concealed proportional relations.

We shall present a sample of problems (Table 1), which were solved correctly by only a small proportion of participants before exposure (not exceeding 30%, and sometimes less than 20%), and which, subsequent to learning, were answered correctly by a much larger percentage of participants (an increase of 50% or more).

Table 1: Distribution (percents) of a sample of problems and correct answers (pre/post course)

No	Type	Problem content	Pre	Post
1	Direct ratio problems	For each 2 turns of the wheels of a bike, its pedals turn 5 times. What is the speed of the wheels, if we know that the pedals are turning at 60 times per minute?	27	79*
2		The shortest, air-distance between two villages is 40 km What would be the length of the straight line representing their distance on a map whose scale is 1: 200.000 ?	16	76*
3	Inverse ratio problems	If 6 workers can paint a hall in 7 hours, how long will the same hall take 4 workers? (All workers have the same output and they all work all of the time.)	30	92*
4		On an antique bike, the front wheel is large, with a circumference of 462 cm, while the smaller back wheel measures 132 cm. What distance has the bicycle covered if we know that the back wheel has made 30 turns less than the front wheel?	19	77*
5	Other "ratio" problems	The ratio between the areas of two circles is 1 : 9. What is the radius of the larger one, if we know that the smaller one is 5 cm ?	10	73*
6		We have a chart whose scale is 1:400 If you photocopy the chart and reduce it by two, what will be the scale of the resulting chart?	15	64*

*$p < .01$

2.Solving strategy

Both teachers and student teachers, pre- and post-exposure, select from the same wide variety of solving strategies. All chosen strategies share a multiplicative orientation, as suits proportion problems (Tournaire & Pulos, 1985). While the unit did not affect the variety of strategies in use, it did influence two other aspects:

(a) Post-learning, most participants succeeded to solve at least some of the problems by means of more than one strategy - 22% of the problems received more than one solution. This was especially pronounced for the direct ratio problems (41%). And (b) post-learning, the quality and correct usage of chosen strategy improved significantly (see Table 2). Even though 71% of the participants chose proportional strategies before the study unit, most of these were at the pre-formal stage (58%). Post-learning, 89% of correct answers used proportional strategies, with about half (43%) using proportion formula correctly.

Table 2: Distribution (percents) of correct use of strategies (pre/post course)

Chosen type of strategy in learners group			Pre course	Post course	Difference
Proportional Strategies	Pre-formal	Qualitative	40	31	- 9
		Quantitative	18	15	- 3
	Total of pre-formal strategies		58	46	- 12
	Formal	Proportion formula	13	43	+ 30
Sum total of proportional strategy choices			71	89	+ 18
Other strategies	Algebraic equations		12	6	- 6
	Other arithmetic operations		17	5	- 12
Sum total of other strategy choices			29	11	- 18

The change in the quality of strategies used (i.e., more correct applications of the proportion formula, especially as related to inverse ratio problems) suggested that this finding might serve as a useful indicator of proportional reasoning.

3. Extent of intelligent use of proportional scheme -proportional reasoning

Proportional reasoning is a mental process, which is put into operation when a person solves a proportional problem. We looked at our findings concerning solving strategies, correct solutions, and content analysis of written and spoken explanations to solutions to examine this process. All these data were needed because correct answers alone do not always provide unambiguous information about intelligent use of the proportional scheme. Correct technical use, for instance, of the formulas might lead to successful solution of direct ratio problems, despite the absence of proportional reasoning. The same cannot be said about inverse ratio and other types of ratio problems, where correct solutions are not so likely to ensue from technical ability alone.

To examine degree of proportional scheme use we examined the findings with reference to three measurable features that can be derived from our above definition of a 'proportional reasoner' : 1. ability to identify a proportional relation (intuitive and formal aspects interacting) - reflected in choice of solving strategy with a multiplicative rather than an additive orientation : 2. ability to differentiate between inverse and direct ratio (intuitive and formal aspects interacting) - reflected in application of solving procedure fitting each type of relation, and 3. ability to find a quantitative solution (algorithmic aspect) - reflected in the appropriate algorithmic activity for particular problem.

946

As regards (1), the findings that indicate the absence of any attempt to employ an additive strategy suggest that all participants, both pre- and post-training, are able to identify a multiplicative relation, whether consciously or unconsciously. In regard of feature (3), after exposure to the study unit, 86% of the participants, on average, correctly solved most of the problems. We may therefore conclude that they have good algorithmic ability, which helps them find a correct, quantitative solution to the problem.

In the case of (2) - ability to distinguish type of ratio - it was more difficult to draw conclusions. We combined three types of findings : 1. The finding that after training, in 63% of correctly solved inverse ratio problems the participants used the proportion formula allows us to conclude that these participants correctly distinguished between the two types of ratio. They must have consciously used this ability when they referred to the proportion formula, because without this ability they most likely would have failed. Their high rate of success can be taken to indicate high correct use of this ability. 2. We used content analyses of statements accompanying correct answers illustrate that participants are aware of the need to check the type of ratio prior solving problems. Classification was done by answering the question what happens to one element when the other one is de/increased. Once conclusions have been drawn, participants appear to be using the fixed ratio model for the direct ratio problems and the fixed multiplicative model for the inverse ratio problems. And finally, 3. We used content analyses of spoken statements deriving from the interviews indicate the same, as it is presented in Table 3.

Table 3 : Statements related to problems in Table 1, after learning

No	Type	Spoken statements in response to the question: Please explain your considerations as you were solving this problem.
1	Direct ratio problems	"If we teach the notion of speed as a description of movement, students will have no problem understanding that, here, the greater the number of turns, the faster the bike will go- and therefore what we have here is direct ratio."
2		"Scale is really nothing but the description of a direct ratio between the distance on the map and distance in reality -that's also how you should present it to students: reduction or enlargement of the real world according to a given ratio "
3	Inverse ratio problems	"The larger the number of workers, the less time it will take them to finish the job. That means an inverse relation between number of workers and days of work necessary to complete the job."
4		"Here the product between the circumference of the wheel and the number of turns it makes is fixed, and the larger the circumference of the wheel, the smaller the number of turns - inverse ratio."
5	Other "ratio" problems	"Unlike the direct ratio between the radius of a circle and its circumference, here we need to get the ratio between radius and area It looks like direct ratio (as the one increases, so does the other), but the factor changes, and therefore we must find a new proportion, which is $S_1 / S_2 = r_1^2 / r_2^2$ "
6		" The more we reduce the chart, the larger- by the same factor (2)- will its representation per centimeter on the map become. So the new scale will be 1:800 "

We can conclude that exposure to the unit made participants widely apply all three features of the ratio and proportion solving procedure. The findings suggest that most

BEST COPY AVAILABLE

participants had mastered the topic, and that they had combined intuitive, formal and algorithmic elements. Participants had acquired the concepts and were in command of proportional reasoning.

4. Analysis of typical errors

In 90% of the erroneous solutions obtained before exposure, the chosen strategy had been wrongly applied. This came about in three ways : (a) erroneous identification of type of ratio (45%) : applying procedures suitable for direct ratio problems to inverse or other types of ratio problems ; (b) language error (8%) : the fact that Hebrew writing moves from left to right may lead students to put the nominator in the place of the denominator; (c) wrong performance of procedure (37%) : wrongly isolating the unknown for solving the equation ; multiplication instead of division ; erroneous change of measures ; always dividing a larger number by a smaller one, etc. (This type of mistakes is typical especially for direct ratio problems.)

It should be noted that after training, very few errors were made (7.5% of all responses were wrong, and 7.5% of the participants did not respond at all).

Discussion and Conclusions

Even though the development of proportional reasoning is an issue of major importance, the topic of ratio and proportion receives scant attention in the colleges in Israel that prepare math teachers. The present findings suggest that inclusion of a study unit on the topic in teachers' training will go some way toward developing teachers who can use proportional reasoning.

This study unit should present the relevant concepts through a wide scope, and allow teachers to practice action strategies that involve intelligent use of the proportional scheme. Moreover, teachers should be exposed to problems referring to various, standard and non-standard, knowledge areas, and formulations should be of both the obvious, indirect and concealed types.

The present findings show that exposure to a study unit that was constructed on these principles caused most participants to acquire the three knowledge components and the ability to use them in combination. This in turn led to ratio and proportion conceptualization and to the maturation of the dormant, potential proportional scheme. This could be seen from the fact that most participants, after learning, made intelligent use of the proportional scheme as an efficient mental tool for the solving of proportion problems relating to various knowledge areas. They successfully identified direct or inverse ratio, expressed these by means of mathematical models, and made intelligent use of such models in problem solving. This is tantamount to concluding that they had become 'proportional reasoners'.

This conclusion has some significant educational implications : First, we can say that with the right type of learning, adult students' concepts of ratio and proportion and their ability to use the proportional scheme can be significantly extended. In this respect our results confirm the findings of Fischbein and others concerning children.

Second, it is important to include the topic of ratio and proportion - taught with reference to both mathematical as well as psychological-didactic aspects - in mathematics teacher training and inservice training. This is likely to raise participants' awareness of the importance of mathematical conceptualization of the topic, and of the development of proportional reasoning as part of the development of mathematical thinking.

THE INTRICATE BALANCE BETWEEN ABSTRACT AND CONCRETE IN LINEAR ALGEBRA

Alkistis Klapsinou & Eddie Gray

Mathematics Education Research Centre
University of Warwick
Coventry CV4 7AL

Abstract

This paper focuses upon the strengths and weaknesses of disparate approaches to Linear Algebra. By identifying the theoretical distinctions between the abstraction-to-computation approach and the computation-to-abstraction approach, it presents examples of how one lecturer, recognising the cognitive obstacles associated with the nature of Linear Algebra, used the latter in the development of a first-year University course. Student reaction suggests that this laudable effort may be addressing procedural difficulties, but compounding conceptual ones, since the delivery of advanced mathematics material in a 'concrete' manner, can militate against the use of concept definitions and this may have broader implications for further mathematical development.

Introduction

Linear Algebra is one of the first courses of advanced mathematics at University level. Along with Analysis, it is intended to shift the students' way of thinking from school mathematics towards advanced mathematical thinking. It is probably the first 'real' mathematics course that students have to encounter, since it requires limited mathematical prerequisites, yet its theory is systematically built from the ground up (Tucker, 1993; Hillel & Sierpinska, 1994). In addition, Linear Algebra brings together methods and insights of geometry and algebra, and its wide range of applications in modern mathematics make it an essential component of all scientific courses (Tucker, 1993). Most importantly though, students have to become familiar with its main themes, such as vector spaces and linear maps, since they are central in the further development of pure mathematical theory (Tucker, 1993).

This paper intends to summarise the existing literature concerning the cognitive obstacles within Linear Algebra and some of the teaching methods employed to overcome these difficulties. Also, it considers how a particular Linear Algebra course was delivered, having those difficulties in mind, and what the impact was on a small group of high achieving students. It concludes by suggesting that there should be a balance between concrete and abstract approaches in Linear Algebra, however difficult to achieve, since, in some instances, in our effort to solve a problem we may create a new one.

Difficulties within Linear Algebra

During their pre-university courses, mathematics students will have met some components of the course, such as matrix arithmetic and solution of simultaneous linear equations (AEB GCE Syllabuses, 1999; NEAB GCE A/AS Syllabuses for 1998) . This, unfortunately, does not guarantee a smooth transition to the stark (?) Linear Algebra. On the contrary, as Hillel and Sierpinska (1994) argue, "both the teaching and learning of linear algebra at the university level is almost universally regarded as a frustrating experience" (p. 65).

Some of the reasons for the difficulties faced by the students are not confined to the content of Linear Algebra, but are a result of the transition from elementary to advanced mathematics.

> The move from elementary to advanced mathematical thinking involves a significant transition: that from *describing* to *defining*, from *convincing* to *proving* in a logical manner based on those definitions. This transition requires a cognitive reconstruction which is seen during the university students; initial struggle with formal abstractions as they tackle the first year of university. It is the transition from the *coherence* of elementary mathematics to the *consequence* of advanced mathematics, based on abstract entities which the individual must construct through deductions from formal definitions. (Tall, 1991, p. 20)

Linear Algebra, though, has certain particularities which can also impede students' learning and understanding. The heart of these is that Linear Algebra was developed to unify, simplify and model already existing problem solutions, rather than to solve new problems (Harel &Trgalová, 1996). Students can solve many problems within a linear algebra course without using the relevant theory but by mere implication of direct manipulation techniques (Hillel, & Sierpinska, 1994).

Harel & Tall (1991) distinguish between three types of generalisations within advanced mathematics; *expansive, reconstructive* and *disjunctive generalisation*, and argue that the successive generalisations of vector sum and scalar multiples from $\mathbf{R}^2$ to $\mathbf{R}^3$ to $\mathbf{R}^n$ are an expansive generalisation for the students, since it involves "applying the same techniques to each coordinate in successively broader systems" (p. 39). The passage from $\mathbf{R}^n$ to the abstract concept of a vector space, on the other hand, requires a re-constructive generalisation.

> The learner is presented with a name for the concept ("the vector space V") and some of its properties (the axioms) and –usually guided by an expert–must follow a subtle and difficult process of construction and meaning of V and its properties by deduction from the axioms. This is further complicated in the learner's mind by the fact that the properties *to be deduced in V are known* to hold $\mathbf{R}^n$, causing the problem for the student that, although these properties are "obvious" in the (only) examples (s)he understands, judgement must be suspended on their truth in V until they are shown to follow by deduction from the axioms. (Harel & Tall, 1991, p. 39)

Even though the theory of Linear Algebra is universally applicable, when it comes to solving problems, there is a wide variety of algorithms for any certain task, with the restriction that different algorithms work in different settings. Thus, students are faced with the further difficulty of having to decide which is the most appropriate algorithm to tackle their problem. Carlson (1993), for example, notes that the procedure needed to find a basis for a vector space of row vectors is different than that to find a basis for a vector space of functions.

An additional disadvantage of the unifying character of Linear Algebra is the variety of representations that students have to get accustomed to. The word 'vector', for example, firstly introduced in the context of concrete $\mathbf{R}^n$ subspaces, can mean different things depending on the corresponding vector space. Hillel & Sierpinska (1994), argue that the initial representation of a vector as a string of numbers, becomes shaken when students realise that the representation of a vector depends on the choice of basis.

As linear algebra is one of the first undergraduate mathematical courses, students are required –probably for the first time– to deal with abstract concepts instead of numeric manipulations (Carlson, 1993). They have to start "thinking about the objects and operations of algebra not in terms of relations between particular matrices, vectors and operators but in terms of whole structures of such things: vector spaces over fields, algebra's, classes of linear operators, which can be transformed, represented in different ways, considered as isomorphic or not, etc." (p. 65).

This particular difficulty is not restricted to the context of Linear Algebra, but is common in almost all areas of mathematics. To understand a new notion in elementary mathematics students have to undergo a cognitive shift incorporating lengthy procedures in mathematical concepts. This conversion of actions or operations into what Piaget (1945) described as "thematised objects of thought or assimilation" (p. 49) was described by the term *encapsulation* (Dubinsky, 1991).

Cottrill, Dubinsky, Nicholls, Schwingendorf, Thomas & Vidakovic (1996) formulated the APOS theory, from the acronym of the words action, process, object and schema. *Actions* are physical or mental transformations of objects to obtain other objects. When these actions become intentional they are characterised as *processes* which may be encapsulated to form a new *object*. A coherent collection of these actions, processes and objects, linked in some way, is identified as a *schema*. A schema can be reflected upon and transformed and thus result in the formation of a new object.

The disadvantage of such an approach in Advanced Mathematics is that the students who are taught in this manner are not given a formal definition of the new object until the end –if then– of this whole learning process. Vinner (1991) argues that "it is hard to train a cognitive system to act against its nature and to force it to consult definitions either when forming a concept image or when working on a cognitive task" (p. 72). This situation can only get worse if the students' concept image has been built through actions and processes, without considering the concept definition.

The course

The Linear Algebra course under consideration took place in the Mathematics Department of a very demanding British University. The duration of the course was 30 hours, split into hourly sessions three times a week, for ten weeks in the second term. The lecturer provided the students with complete and explicit notes, so that they could concentrate on understanding the material, instead of keeping their own notes. There was also a recommended textbook, which was Anton's (1994) *Elementary Linear Algebra*. We should also note that the course was designed not only for Pure Mathematics students but also for students following combined degrees (Mathematics & Physics, Mathematics & Statistics, Mathematics, Operational Research, Statistics & Economics (MORSE)), a fact which explains the process-oriented nature of the course.

There seem to be two ways of sequencing the contents of Linear Algebra; the computation-to-abstraction approach and the abstraction-to-computation approach (Harel, 1987). The first approach suggests that matrix arithmetic and linear systems should precede vector spaces and linear transformations, in order to enable the students to develop the language and reasoning needed for understanding the more abstract material. The second approach starts with vector spaces and linear maps and then matrices and simultaneous linear equations are treated as applications of the former.

In this particular Linear Algebra course the approach chosen was the computation-to-abstraction one, because the lecturer felt it would be more beneficial to start with already familiar concepts and use them as building blocks for the development of the more abstract notions of vector spaces and linear transformations. Various introductory strategies were used in order to present the new material, such as 'abstraction' –introducing abstract ideas by initially illustrating them by specific examples (Harel, 1987)– and 'embodiment' (Dienes, 1960) –translating definitions and theorems in terms of given situations. The difference between these two processes lies in the timing of the presentation of the particular situation; in abstraction it comes before the concept is defined, whereas in embodiment, it follows the formal definition.

In order to demonstrate how these teaching techniques were employed, we have two extracts from the lecture notes; the first extract is a case of abstraction and the second of embodiment. These examples were chosen so as to reflect the nature of the delivery of the whole course.

Abstraction

Preparing for Eigenvalues and Eigenvectors

1. Draw a set of axes on a piece of paper.
2. Choose a vector from $\mathbf{R}^2$ and draw it on the axes.
3. Now multiply it be the matrix $A = \begin{bmatrix} 2 & 2 \\ 3 & 1 \end{bmatrix}$ to get a new vector. Draw the new vector you get.
4. Repeat these three steps 3 or 4 times, choosing a new vector each time. Notice that A sends

vectors all over the place.

5. Now draw a new set of axes and plot the vectors $\begin{bmatrix}1\\1\end{bmatrix}$ and $\begin{bmatrix}2\\-3\end{bmatrix}$.
6. Multiply each of these vectors by A and draw the result. Notice that these vectors stay on the line they started on. They have just been "stretched" in a positive or negative sense.
7. In these two cases,
   $\begin{bmatrix}2&2\\3&1\end{bmatrix}\begin{bmatrix}1\\1\end{bmatrix}=\begin{bmatrix}4\\4\end{bmatrix}=4\begin{bmatrix}1\\1\end{bmatrix}$ and $\begin{bmatrix}2&2\\3&1\end{bmatrix}\begin{bmatrix}2\\-3\end{bmatrix}=\begin{bmatrix}-2\\3\end{bmatrix}=-1\begin{bmatrix}2\\-3\end{bmatrix}$
8. So, for certain vectors, multiplication be A just results in a "stretching" (which can include a change of direction) of the vector; in other words a scalar multiplication of the vector. Such a vector is called an **eigenvector** of A. The "amount of stretch" undergone by such a vector is called an **eigenvalue** of A.
9. So $\begin{bmatrix}1\\1\end{bmatrix}$ and $\begin{bmatrix}2\\-3\end{bmatrix}$ are eigenvectors of A, and 4 and -1 are corresponding eigenvalues of A.
10. In general, an eigenvector of A and its corresponding eigenvalue are related by the matrix equation

$$A\mathbf{x}=\lambda\mathbf{x}$$

where $\mathbf{x}$ is the eigenvector and λ is the eigenvalue.

Embodiment

Definition We define the **adjoint matrix** of A, denoted adj A, to be the *transpose* of the cofactor matrix

Example $A=\begin{bmatrix}2&3&1\\4&1&2\\5&3&4\end{bmatrix}$

We replace each element of the matrix with its cofactor, to get the *cofactor* matrix, C.

$$C=\begin{bmatrix}\begin{vmatrix}1&2\\3&4\end{vmatrix} & -\begin{vmatrix}4&2\\5&4\end{vmatrix} & \begin{vmatrix}4&1\\5&3\end{vmatrix}\\ -\begin{vmatrix}3&1\\3&4\end{vmatrix} & \begin{vmatrix}2&1\\5&4\end{vmatrix} & -\begin{vmatrix}2&3\\5&3\end{vmatrix}\\ \begin{vmatrix}3&1\\1&2\end{vmatrix} & -\begin{vmatrix}2&1\\4&2\end{vmatrix} & \begin{vmatrix}2&3\\4&1\end{vmatrix}\end{bmatrix}=\begin{bmatrix}-2&-6&7\\-9&3&9\\5&0&-10\end{bmatrix}$$

We transpose the cofactor matrix to get the *adjoint* matrix, adj A.

$$\text{adj A} = C^T=\begin{bmatrix}-2&-9&5\\-6&3&0\\7&9&-10\end{bmatrix}$$

Another strategy used for the introduction of vector spaces, in particular, was consistent with the APOS theory (Cotrill *et al.*, 1996). Starting with vectors in $\mathbf{R}^n$, objects already familiar to the students, addition and scalar multiplication were defined, initially as actions on these vectors. When these actions were interiorised, along with their properties (the 10 vector space axioms), they became processes, which then were used to form the new object 'vector space'. These notions were later

extended to include vector spaces other than $\mathbf{R}^n$, resulting in the schema of a general vector space.

The students

The fact that this research is taking place in a highly regarded British Universities, as we noted earlier, means that the students who take part have a solid mathematical background, as indicated by the results in their A-level exams (University entrance requirements in Mathematics is 3 A's) and their initial 'mathematics techniques diagnostics test'. Our sample consisted of 8 high achieving Pure Mathematics students, seven of whom achieved first class grades in the course assessment (90% written examination, 10% awarded through weekly coursework).

The research was carried out by fortnightly videotaped group discussions (with two interviewers taking part), where the issues brought forward were associated both with the delivery of the course and the students' understanding of the new notions. Some issues were brought up by the students themselves, initiated by certain difficulties they faced when doing their coursework.

In the following extracts from the transcripts of the discussions, the talk revolves around the notions of vector space, linear dependence and independence, bases and spanning sets. Having under consideration that the definition of vector space was introduced in the APOS pattern (as described above), we can clearly see that the students' concept image of a vector space remains restricted to $\mathbf{R}^n$ spaces.

Int: Why are you always using the examples of $\mathbf{R}^2$, $\mathbf{R}^3$, .., $\mathbf{R}^n$?

J: Because these are the easiest examples of vector spaces.

Int: But why are you associating the word 'vector' with vectors in space? We defined vector space as a set that satisfies those 10 axioms and any element of this vector space is a vector. So it does not have to be a vector in $\mathbf{R}^n$.

L: Because when we were first taught about vectors they were vectors in $\mathbf{R}^2$ and $\mathbf{R}^3$. And that's what is still in my mind about what a vector is. I mean we have managed to extend it to $\mathbf{R}^n$ but not to other sets.

Int2: Does the previous image of vectors, the 2 or 3-dimensional image actually get in the way?

A: Yeah, actually it does.

When asked what the basis of a vector space is, no student gives the formal definition but they instead give an answer that applies only in a very specific context, in the same way that Carlson (1993) reports that "basis of a vector space" is for some students "the result of one specific algorithm applied in one specific context" (p. 29).

Int: What is the basis of a vector space?

J: Any two linear independent vectors.

Int: Can you have two linear independent vectors being a basis for $\mathbf{R}^3$?

J: Why not?

I: For a vector space of order n you need n linear independent vectors to span it

A: Should the elements of a basis be all linear independent?

J: Yeah.

On the issue of the course delivery, the students seemed to have divergent views. Some appreciated the clarity and completeness of the setting out of the material, as well as the provision of algorithms for carrying out tasks, but for others the essence of mathematics lies in the challenge of having to struggle with theorems and proofs.

J: In specific cases there are tricks or rules you can use and it makes things easier than if you take the general approach to it. You have the general rule to cover yourself if you have any doubts.

Int: But why do you prefer to use these tricks?

J: Because it makes life easier. Would you use the definition of derivative in order to find the derivative every time?

Int: But is it not essential to know how you came up to this derivative, to know how to prove it?

I: It's not that essential to always carry in your head how to prove it, but to know where the results comes from and how it was derived. I think you'd be better off with knowing why it's true; that's what matters to me. If you just want to know the results you might as well study Physics!

L: Yeah, in applied maths we just had to use the tools, we didn't have to prove them.

Int: Do you think that the shift from school to University would be made easier if they gradually tried to change your way of thinking from the A-level to the more abstract?

J: There's something to be said about the 'shock treatment'. I think the sooner you get into the new way of thinking the better.

A: I think I'm learning the Analysis better because the lecturer threw us more or less straight in the deep end at the beginning of the course and we had to cope with it.

J: If you do the gradual thing then you might get the wrong impression. A year or something in the course you might realise "this isn't really for me". It's more honest to have the 'shock treatment'; this is what it's really like.

Conclusion

The position of Linear Algebra, as an initial course of advanced mathematics, implies that a bias towards either concrete or abstract approaches may cause difficulties. In this context, developing a Linear Algebra course based on the computation-to-abstraction approach does not imply that the students will not be introduced to both the concrete and the abstract aspects of the course. However, putting the emphasis on the 'concrete', may sway the students towards overlooking the 'abstract'. As a result, their concept images becomes enriched in processes but not in objects.

It is widely accepted that undergraduate students have to make a huge cognitive shift from school mathematics to advanced mathematical thinking. To this end, it is imperative that the balance between concrete and abstract is not only maintained but safeguarded in every possible manner.

TEACHING MATHEMATICS USING EVERYDAY CONTEXTS: WHAT IF ACADEMIC MATHEMATICS IS LOST?

Hari Prasad Koirala
Eastern Connecticut State University

Mathematics education researchers argue that mathematics should be taught using everyday contexts so that the learning of mathematics can be meaningful to students. Although the learning of mathematics through everyday contexts is interesting for most students, many of them cannot make a leap from these contexts to academic mathematics. Because of this difficulty, teachers need to make a deliberate attempt to help students connect everyday and academic mathematics.

Introduction

During the past two decades, mathematics education researchers, who are especially interested in ethnomathematics, have explored the relationship between mathematics in and out of school (D'Ambrosio, 1985; Gerdes, 1996; Nunes, 1992). Out of school mathematics is usually carried out in everyday setting, which is very different from an academic setting of schools (Carraher, Carraher, & Schliemann, 1985; Saxe, 1991). While academic mathematics is still viewed as a culture and context free discipline, mathematics in everyday settings is determined by socio-cultural backgrounds of students. Ethnomathematicians, however, believe that mathematics both in and out of school must be based on socio-cultural practices of students. According to Gerdes, ethnomathematics researchers "emphasize and analyze the influences of socio-cultural factors on the teaching, learning and development of mathematics." (p. 917).

The psychology of mathematics education has been deeply influenced by the findings of the research carried out from a socio-cultural perspective. In the 1998 annual meeting of the International Group for the Psychology of Mathematics Education, one major theme of research was focused on mathematics in and out of school. The researchers in the meeting argued that the learning of mathematics becomes meaningful to students if their own cultural contexts are used in mathematics classrooms (Civil, 1998; Presmeg, 1998). If mathematical concepts, ideas, and skills are developed through students' everyday contexts, they may be more motivated to learn and develop a better understanding of mathematics.

The task of connecting students' everyday contexts to academic mathematics is not easy (Lave, 1988; Saxe, 1991; Walkerdine, 1990). These educators argue that students construct their everyday experiences in contexts different from the school context, and transferring ideas from one context to another is hard because the emergent goals are different. This may explain the discrepancy between school and

out-of-school mathematics experiences reported by numerous educators (Carraher, Carraher, & Schliemann, 1985; D'Ambrosio, 1985; Nunes, 1992; Saxe, 1991).

Although the above researchers have shown a discrepancy between school and out-of-school mathematics, their main focus was not to see whether students' mathematical abilities could be enhanced when taught using their own everyday contexts. Nor was their focus to investigate students' feelings and interests about mathematics when taught through such contexts. Instead, these researchers focused on how students' understanding of mathematics is embedded in their culture and personal experiences. More research is needed to demonstrate how students can be helped to learn academic mathematics using students' socio-cultural contexts. In this paper, I examine the influence of everyday social contexts in the teaching of mathematics to future elementary school teachers.

Methodology of the study

The data for this study were collected from a group of preservice teachers enrolled in a course entitled "Number Systems" taught by this investigator at Eastern Connecticut State University. The majority of the preservice teachers in this group did not have a sound mathematical background. Only about 10% the preservice teachers had taken some advanced mathematics courses such as calculus. For the majority of the preservice teachers this was their first college mathematics course. These preservice teachers did not have a good experience of learning mathematics in schools. They feared and even hated mathematics.

The purpose of the course was to teach academic mathematics using students' everyday contexts as far as possible. All students were required to keep journals throughout these courses describing their mathematical understandings and feelings. Students were evaluated based on various quizzes, class presentations, journals, midterm and final examinations. In all these evaluations, they were required to demonstrate their understanding of academic mathematics. Although various types of problems were asked to the preservice teachers the following problem called a "shopping problem" was used to evaluate preservice teachers' ability to understand academic mathematics using their everyday cultural contexts. The problem was modified from one of the textbooks usually used in the "Number Systems" course and represents the types of everyday socio-cultural contexts used in the class.

> Two friends are shopping together when they encounter a special "3 for 2" shoe sale. If they purchase two pairs of shoes at the regular price, a third pair (of lower or equal value) will be free. Neither friend wants three pairs of shoes, but Pat would like to buy a $56 and a $39 pair while Chris is interested in a $45 pair. If they buy the shoes together to take advantage of the sale, what is the fairest share for each to pay? (Adapted from Musser & Burger, 1997, p. 15)

The above problem was asked as a pilot problem to a group of preservice teachers in the previous year. The majority of the preservice teachers in that year did not provide a mathematical response to this problem. Their responses varied from "since Pat and Chris are friends they could divide the saving in any way they wanted," "I would not worry about the split but treat ourselves with a good lunch," to "just split the savings of $39 evenly". Because of these general responses obtained from preservice teachers in the first year, preservice teachers in the succeeding year were specificaliy asked to provide their *mathematical reasoning* to the problem. All 32 preservice teachers in the class wrote their responses in the blank sheet of paper provided by the investigator.

After the analysis of the written responses, a total of six preservice teachers were interviewed to explore more about their solutions. The selection of preservice teachers was purposive in order to include preservice teachers of various ability levels. Since the interviews were conducted after the completion of the course, final grades of the students were used to determine their ability levels. One preservice teacher was a high achiever who obtained *A* in the course. Four were middle achievers, who got *B*'s in the course. One was a low achiever, with a *C*. Each interview lasted approximately 20-30 minutes. During the interviews, the preservice teachers were shown their written work and asked why they chose their responses. They were told that they could change their responses if they wanted.

Data Analysis Procedures

Preservice teachers' written responses to the problem were categorized, coded, and tabulated to determine their frequencies. Each interview tape was first audiotaped and then transcribed. Preservice teachers' strategies of solving the problem were determined by analyzing their written responses. The responses to the interview were used to determine the reasons why preservice teachers chose their solutions in the written task. Interview transcripts were also used to determine whether or not preservice teachers were consistent in their thinking.

Results and Discussion

All 32 preservice teachers in the class agreed that they commonly encounter these kinds of sales in their everyday life in the United States. However, the majority of them did not provide an appropriate academic solution to the problem. Since they had studied ratio, proportion, and percent in the class, an appropriate mathematical solution to this problem would have been to use a method to determine the amount of savings to Pat and Chris on a proportional basis. The following two solutions are considered appropriate based on the teaching in the classroom:

(i) The total cost of three pairs of shoes is $56+$45+$39=$140. The cost for Pat is $56+$39=$95 and the cost for Chris is $45. Since there is a saving

(ii) of \$39 out of \$140, Pat should save $39 \times \frac{95}{140} = \$26.46$ and Chris should save $39 \times \frac{45}{140} = \$12.54$. So Pat should pay \$95-\$26.46=\$68.54 and Chris should pay \$45-\$12.54=\$32.46.

(iii) Pat and Chris save a total of \$39 out of \$140. So their percent saving is $\frac{39}{140} \times 100 = 27.85\%$. Hence, Pat should save 27.85% of \$95, which is \$26.46 and Chris should save 27.85% of \$45, which is \$12.54. So Pat should pay \$95-\$26.46=\$68.54 and Chris should pay \$45-\$12.54=\$32.46.

Not a single preservice teacher in the class gave one of the above two responses. Their solutions widely varied. Out of 32 respondents, eight said that "Pat should pay 2/3 of the price and Chris should pay 1/3. The total cost of the three pairs after the saving is \$56+\$45=\$101. Two thirds of \$101 is \$67 (rounded to the nearest dollar) and one third is \$34 (rounded to the nearest dollar). Hence Pat should pay \$67 and Chris should pay \$34." Here is a representative response from a preservice teacher:

> Chris and Pat would need to add up the cost of the two pairs of shoes that cost the most money because in a "3 for 2 sale" you pay the price of the two most expensive ones. The total of the two most expensive shoes would be \$56+\$45=\$101. Pat wants two pairs of shoes and Chris is only getting one pair, they need to divide \$101 by 3. The result when divided by 3 is \$33.66. Chris who is getting only one pair of shoes would pay 1/3 of the cost as \$33.66. Pat who is getting 2 pairs should pay 2/3 of the cost, which would be \$67.32. And everyone is happy. Chris saved \$11.34 off of the original \$45 and Pat saved \$27.68 off of the two pairs of shoes.

The above solution is clearly communicated. However, the shares are not distributed proportionally based on the cost of shoes.

Approximately the same proportion of the preservice teachers (seven out of 32) thought that both Pat and Chris should divide the savings of \$39 evenly. They said if there was no sale Pat would have paid \$56+\$39=\$95 and Chris would have paid \$45. Hence "Pat should pay \$95-\$19.50=\$75.50 and Chris should pay \$45-\$19.50=\$25.50." For example,

> The fairest thing would be to split the savings on the free pair in halves (\$39/2=\$19.50) and use the \$19.50 to subtract from the total price of the shoes they want. So the amount for Pat to pay is (\$56+\$39)-\$19.50=\$75.50 and for Chris to pay is \$45-\$19.50=\$25.50.

Nobody was worried that the sharing using the above method was unfavorable to Pat. He was saving only 20.5% of his original price of \$95 whereas

Chris was saving 43.3% of his price of $45. When this was brought to their attention in the interviews, they argued that the sharing was still fair because both of them were willing to spend their original cost if there was no sale. Moreover according to these respondents they should not be arguing about how to split this money because both of them are friends.

Five preservice teachers decided to split the saving of $39 into three parts and provide $26 to Pat and $13 to Chris. Hence for them the fairest shares would be that Pat pays $69 and Chris pays $32. Here is one response that exemplifies this method:

> Pat gets 2 pairs or 2/3 of the total shoes and Chris gets 1 pair or 1/3. Since the third (free) pair, which costs $39, is free they should divide it by 3 and get $13 per 1/3 of savings. Chris bought one pair so he should pay $45-$13=$32. Since Pat has two pairs of shoes, he should pay $95-$26=$69. Although Chris did not get a free pair he did save quite a bit of money.

The preservice teachers who split $39 in three equal parts were mathematically fair than preservice teachers who simply split the money evenly. According to this new method Pat was saving 27.4% of the original price and Chris was saving 28.9% of the original $45. The percentage was quite close because $95 is only little bit more than the double of $45. However if the difference between the cost of two pairs $56 and $45 was too high the percent savings would have been substantially different. This kind of complex proportional thinking was not demonstrated in any of the methods provided by the preservice teachers.

There were other preservice teachers who did not demonstrate any mathematical understandings. Three preservice teachers said that since both Pat and Chris were friends they could simply divide the total of $101 evenly and each pay $50.50. When asked why Chris should pay $50.50 when the original price of the shoes he wanted to buy was only $45, they could not give any mathematical reasoning and simply stated that if Chris is a really good friend then he should not mind paying extra $5.50 for Pat especially because of a good bargaining opportunity. One of these preservice teachers said, "since Chris does not want three pairs of shoes she should be willing to pay the extra $5.50 because of the bargain." Three other preservice teachers said that since Pat spent more money than Chris Pat should get the $39 pair free. These preservice teachers were clearly not thinking mathematically. They were using friendship as a reason. It appeared that some of the preservice teachers, who had a weak mathematical background, simply wanted to avoid high level thinking required to solve this problem.

It is interesting to note that some preservice teachers who had a good mathematical understanding of the problem thought that dividing the saving evenly is fair. Ayaz was the most capable mathematics student in the class. He was the only student who got a perfect *A* in the class. He reasoned that the money should be

split evenly between Pat and Chris. I provided a counter argument saying that the sharing between Pat and Chris can be considered mathematically fair only if their savings are proportional to their original costs. The participants in the study accepted my argument as an alternative to their solutions. However many of them were not willing to change their thinking. In the final interview Ayaz said that they can split the saving of $39 evenly. So Pat would pay $95-$19.50=$75.50 and Chris would pay $45-$19.50=$25.50. He stated that they can also split money proportionally such as $39 \times \frac{95}{140} = \$26.50$ for Pat and $39 \times \frac{45}{140} = \$12.50$ for Chris. Nevertheless, he insisted that splitting saving evenly was still fair. The following transcript between the researcher (Resh) and a preservice teacher (Ayaz) illustrates this issue:

Resh: Is splitting evenly a mathematical response or an everyday common sense kind of response?

Ayaz: I think it's a mathematical response. The common sense response would be spending more so that I should get a larger discount.

Resh: I was thinking that common sense response would be "Let's make it half-half." Why bother?

Ayaz: I can see that. It's an easier way to do. Nevertheless, Pat would be happy as long as she spends less than $95. I would not even bother to split the money. I would rather go out and treat ourselves with lunch. I think it's a philosophical and political question.

The above transcript indicates that Ayaz was comfortable with his earlier solution even though he understood how to split money proportionally. Other preservice teachers had a similar kind of argument: Debi, for example, determinined that Pat should pay $67.33 and Chris should pay $33.67. When asked if her method was fair, she argued that the method was fair from a real life perspective. Below is the excerpt from the interview with her:

Resh: Is that fair?

Debi: Pat is getting two pair of shoes and Chris is getting one pair of shoes. It should not matter. It is a split of free money. Doesn't matter how much money they are spending.

Resh: Don't you think their savings should be proportional to the amount of money they are spending?

Debi: May be from a mathematical perspective; but not from a shopping perspective, because they each have a choice of how much they want to spend. She happens to like $56 and $39 pair shoes. Well then that's what she should be willing to pay. If they were buying exactly the same pair of shoes, the splitting of money [on a proportional basis]

should have been considered. Since they have a choice they don't need to consider the split [proportionally].

Other preservice teachers such as Mona, Riva, Andy, and Hana were all satisfied with their way of solving this problem, which was not based on proportion of their cost prices. While preservice teachers' responses to the shopping problem were mostly based on the context of friendship, their subject matter knowledge of mathematics was not always academically strong. Many preservice teachers solved the shopping problem using a simplistic mathematical procedure even when the problem required a complex thinking. Their solutions did not involve complex mathematical thinking such as splitting the saving on a proportional basis. The majority of the students simply decided to split the saving based on the number of shoes purchased without considering their cost prices. No one in the class split the saving based on how much Pat and Chris would have spent if there were no sale. A few students did not demonstrate any mathematical understandings at all.

Conclusions

The results of this study indicate that the teaching of mathematics using students' everyday contexts does not necessarily enhance their understanding of academic mathematics. Instead of using academic mathematical concepts such as ratio, proportion, and percent, many preservice teachers solved the shopping problem based on a concept of simple division. When asked why they did not use a proportional reasoning the preservice teachers argued that they would not really set up a complex proportional procedure if they had to split the saving in a real life situation. They argued that since the problem appeared real they used a simple division, which many of them would actually use in their real lives.

The preservice teachers did have difficulty in using a proportional reasoning in this problem. Does it mean that we should avoid these kinds of problems in mathematics classrooms? If we do not use real life contexts like this, preservice teachers will see mathematics as a collection of isolated facts and skills to be memorized. It is therefore important to use these kinds of problems. Actually we need to use more of these problems and emphasize the fact that students are required to provide appropriate mathematical response to the problem based on what is taught in the class. In the shopping problem, for example, the use of simple division would have been fine if the responses were from elementary school students. However the responses to the problem from preservice teachers should include higher level mathematics of ratio, proportion, and percent. It appears that we must make our expectations clear to students and emphasize the fact that the purpose of using real life context in a mathematics class is to learn as much academic mathematics as possible. If this emphasis is not made students will simply bog down in contexts and not learn mathematics. Also, as Walkerdine (1990) argues, teachers should be aware that everyday practice of mathematics is discursively different from school practice and so the relation between everyday and school

practices "is far more complex than is suggested by the notion of doing mathematical examples in familiar contexts" (p. 54).

Learning mathematics in heterogeneous as opposed to homogeneous classes: Attitudes of students of high, intermediate and low mathematical competence.

Bilha Kutscher The David Yellin Teachers College, Israel

Abstract

Seventh- and eighth-grade students, who studied mathematics in heterogeneous settings organized for small group work according to a 'cooperative seating plan', were examined as to their attitudes to studying mathematics in heterogeneous classes as opposed to homogeneous classes. The eighth graders concurrently studied part of their mathematics curriculum in homogeneous classes. All students believed that studying in these groups facilitated their learning. Most students favored learning in heterogeneous classes. However, the eighth-grade, low achievers were ambivalent: they favored heterogeneous classes provided their assessment grades were higher. In response, an evaluation model is proposed to answer both the learning and psychological needs of students of diverse abilities studying in heterogeneous classes.

Research has cast doubt whether tracking is the correct way of dealing with diversity in abilities in the classroom. Not only has research shown that learning in low tracks significantly reduces achievement (e.g. Gamoran & Mare, 1989) but it has also been shown that 'top track' mathematics students can achieve as well in heterogeneous classes as in the tracked classes (e.g. Linchevski & Kutscher, 1998). Theorists claim that tracking is a central source of social inequity (e.g. Braddock, 1990). All this suggests that, whenever possible, mixed-ability classes should be the preferred learning setting in school. Many researchers argue for the value of cooperative learning in groups as a means of promoting attitude, motivation and achievement (e g. Slavin, 1996) and for cognitive growth (e.g Webb (1989)). On the other hand Cobb suggests that small-group interaction is more productive when the interactions are multivocal and when the conceptual possibilities between the participants are relatively small (Cobb, 1996). This implies homogeneous grouping that "clashes with a variety of other agendas... including issues of equity and diversity" (ibid p.125).

This paper offers a 'cooperative-learning seating plan' that may reconcile these two seemingly contradictory approaches: cooperative-learning in small heterogeneous settings among participants whose cognitive capabilities are similar. This study examined a) the attitude of students who concurrently studied part of their mathematics curriculum in heterogeneous classes, where this cooperative-learning seating plan was adopted, and part of their mathematics curriculum in homogeneous settings and b) the attitudes of students who studied mathematics only in heterogeneous settings with this cooperative-learning seating plan. The conjecture was that all levels of students would prefer learning in these heterogeneous classes to learning in their homogeneous ones. These outcomes were expected since the heterogeneous learning environment was designed using the theoretical considerations and previous research results reported above.

Study Design

The population for this case study was drawn from the eighth grade of a junior high school and from the seventh grade of a demographically similar junior high. The eighth grade in the first school is divided into heterogeneous 'homeroom' classes: The idea is that students should learn most of the school subjects - social studies, general science, language and the like – in their own familiar, heterogeneous-environment 'homeroom' classes. However, for mathematics three tracks are implemented - 'Low', 'Intermediate' and 'High' - so that each student learns mathematics in one of the tracks. This junior high school agreed to participate in an experiment: Part of the eighth-grade mathematics program, that was originally to have been taught only in the tracked classes, would now be taught in heterogeneous classes. Both the tracked mathematics classes and the heterogeneous mathematics classes would address topics that were part of the traditional syllabus. Each student would thus be assigned two separate mathematics environments: the tracked class and the heterogeneous class. All students studied mathematics both in their own tracked mathematics class, where they studied mathematics for four hours weekly throughout the year, as well in their heterogeneous, homeroom classes for two hours weekly, for the duration of one semester. The heterogeneous mathematics class studied according to the principles of TAP (Linchevski & Kutscher, 1998), a learning model developed for learning mathematics effectively in a heterogeneous setting. This model calls for alternating between heterogeneous and homogeneous settings so that each student in TAP is concurrently a member of two groups, a heterogeneous group and a homogeneous one. In this experiment the way to materialize this alternation was through the 'cooperative-learning seating plan', that was designed to promote productive interactions in accordance with theoretical considerations reported above.

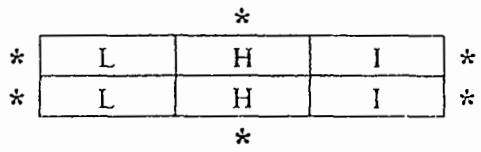
Seating arrangement of groups in a more diverse heterogeneous class



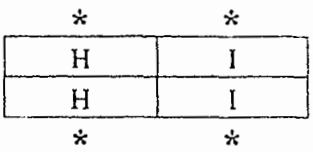


Figure 1b

Seating arrangement of groups in a less diverse heterogeneous class

L: Low-track students desk

H High-track students

I Intermediate-track students desk

* Students seated relative to their desk

The cooperative-learning seating plan of the heterogeneous groups was configured both to encourage interaction in dyads between students with relatively similar cognitive capabilities (homogeneous settings) and at the same time to allow interactions, such as asking for help and getting explanations for solving tasks between students with more diverse conceptual possibilities (heterogeneous settings). Figure 1 illustrates two typical seating plans. Figure 1a depicts a seating arrangement that accommodates the needs of a more diverse heterogeneous class where the distribution of low, intermediate and high achievers might be similar. Students of relatively similar cognitive capabilities are seated in close proximity to allow productive, multivocal interaction (Cobb, 1996). Nevertheless, concurrently these seating arrangements allow less competent mathematical students to be

supported, when necessary, by more mathematically competent neighboring students. In this manner the heterogeneity of the groups is upheld while providing sufficient "homogeneity" for multivocal interactions. Figure 1b offers an example of a similar configuration for a less heterogeneous class where there might be few weak students and where the intermediate-track and high-track students are evenly distributed. All the 'experimental' mathematics teachers constructed the groups for their class according to the principles of the cooperative-learning seating-plan.

Students' attitudes and perceptions about studying in heterogeneous mathematics classes might be affected by their learning concurrently in a tracked mathematics class; thus a complementary study was designed. A demographically similar school agreed that one of its seventh-grade heterogeneous classes have its mathematics lessons conducted in the same experimental format as the aforementioned school: The students would learn according to the principles of TAP in their homeroom classes with the specially designed cooperative-learning groups.

The data collected in this study were observations collected by the researcher in the experimental classes and transcripts of semi-structured interviews carried out with students toward the end of the school year. These interviews were conducted with approximately half the students who studied in the experimental classes. The students were chosen to represent high, intermediate and low achievers of each of the high-, intermediate- and low-tracks from the experimental eighth-grade classes. These students were observed during classes and interviewed toward the end of their semestrial mathematics course described above. Concurrently a similar population of students from the experimental seventh grade, described by their mathematics teacher as being low-, intermediate- and high-achievers (henceforth, in both the seventh and eighth grade, called 'Lows', 'Intermediates' and 'Highs') were also observed and interviewed. This report concentrated on two factors that might contribute to a students' attitudes to learning in heterogeneous settings as opposed to homogeneous settings: a) Their views, beliefs and feelings about learning in the cooperative-learning heterogeneous groups and b) their beliefs about learning in a heterogeneous setting as opposed to in a homogeneous setting.

Results and Discussion - Students' attitudes to learning in heterogeneous settings as opposed to learning in homogeneous settings:

a) Results and Discussion - Learning in the cooperative-learning heterogeneous groups:

The immediate reaction of most of these students was that this group work facilitated their learning. For example:

(8: eighth grade; 7: seventh grade; H: Highs; I: Intermediate; L: Lows)

Moran (H, 8): There's cooperation (in the group), *one can ask friends in the group, we're helped by them, we do together*

Ma'ayan (I,,8): It helps me"

Yossi (I, 7): The fact that I sit (in the group) *then if I need help, then they help me, those who are sitting with me in the group.*

Dudu (L,8): When I ask (the teacher) *the teacher can't be only with me; there are also other children.* (Asking a fellow student is less embarrassing than) *showing that I don't*

understand the material.. because I ask him quietly, a' ne. But if I ask the teacher aloud then the whole class listens.

Ran (L, 7): (He likes to study in the group because) *Yossi helps me sometimes when I need him and Ayelet* (the teacher) *helps me and so I improve little by little.*

Ran, a Low, spoke about being helped by the same Yossi, an Intermediate, who himself reported as being helped by others. It seems that the seating configuration did allow and encourage mutual support. A typical lesson portrayed students sitting in their groups, interacting with the study material and each other. Students could be seen asking for, receiving and bestowing assistance. Students of all levels seem to have enjoyed and to have appreciated the potential of the heterogeneous cooperative-learning group as a source of resource and support. Many of the students used the term 'fun' to describe their feelings about the group. When asked what they meant by 'fun' they elaborated this as mutual help. For example:

Yifat (H, 7): It's fun to help! It doesn't mean that if I am strong I know everything. So sometimes they help me and I help them.

Apparently working in these groups evoked positive feelings. Further investigation disclosed that both affective and cognitive factors contributed to these feelings. All students had mentioned the mutual help in the groups. Following this the students were asked whether they felt they gained more when they helped others or when they, themselves, were assisted in their mathematics.

Nirit (H,8): I prefer helping because I think that the fact that I help someone else, in actual fact I am helping myself, this opens my eyes more and I see that maybe I also have to go over and do it some more. The fact that I help someone (means) *more practice for me.*

Uzi (H, 7): (He gains more) *When I explain, because that's how I learn. From their mistakes I learn.*

Kokhi (I,7): Truthfully, both. Because when they help me then I 'get' it and then I can help someone else, and when I already know it then I can help someone else and then I understand it better. The more you'll go over it, then you'll understand it better.

Ma'ayan (I,8): (He preferred) *Helping.. because it's nice, a good feeling*

Ran(L,7)(Prefers helping) *because I feel I know many things.*

Interestingly all preferred helping, even the least competent students who, it would be reasonable to assume, of necessity received more help than what they gave. There seems to be a continuum in the reasons for this preference for giving rather than receiving help. The more competent students felt that explaining promoted understanding, intuitively sensing that "giving high-level elaboration to other members of the group is positively related to achievement' (Webb, 1989). They also mentioned affective factors, such as "a good feeling of helping a classmate" but it seemed clear to them that their gain was cognitive. The less competent mathematics students related their preferences more to affective factors, such as improving their social standing, self-esteem, 'good feelings' and the like. Generally, the latter students reported that they were more on the receiving end of the assistance. Perhaps more opportunities of high-level elaboration would highlight the cognitive-gain aspect also for these students and concurrently lead them to improved achievements.

b) Results and Discussion: Learning in a heterogeneous setting as opposed to in a homogeneous setting:

Lower self-esteem has been associated with learning in lower-ability groupings (e.g. Abadzi, 1984). Thus it would seem plausible that lower-track students would prefer learning in heterogeneous mathematics classes to learning in the lower-ability groupings. This indeed seemed the case with the Intermediates, but in the case of the eighth-grade Lows there was a surprising result.

The Lows: The eighth-grade Lows were ambivalent about learning in heterogeneous settings. They wanted to learn with 'everyone', but they were unhappy seeing others achieving high grades while they, themselves, were barely achieving passing grades In the case of the students who were also learning mathematics in the tracked classes this feeling was probably exacerbated by the fact that they concurrently attained much higher grades in their homogeneous mathematics class. Yael's views disclosed ambivalence although she declared that she preferred tracking:

*Yael (L,8): Because everyone is on the same level. And there is no one who succeeds more than you .. But if I were in Rola's (*her mathematics teacher in the heterogeneous class) *group I will get 60 let's say, and maybe I made an effort, I would feel that I'm getting nothing out of it.* (The price she thought was worthwhile paying for learning in a heterogeneous setting was a grade) *No lower than 65, the main thing is I will not fail. The main thing is that it* (the grade) *won't be lower than 55* (the passing grade).

What Yael seems to be saying is that the minimum requital for a diligent student is a passing grade. Following this she would prefer and recommend studying in heterogeneous groups:

Yael: Because also the children will help each other... Children will understand the material better and will have easier tests and they won't feel that they are the lowest. Let's say if there'll be a heterogeneous class it's preferable to being in the third (their lowest) *track, to feel that* (in the heterogeneous class) *they're in the middle, with all the* (students in the) *first, second and third tracks It doesn't matter if someone is a little better, a little worse, the main thing is that they will help each other.*

The Highs: Here there was a surprising difference between Highs who learned only in the heterogeneous setting (seventh graders) and Highs who also learned in tracked mathematics classes (eighth graders). The latter students generally were happy to study in heterogeneous mathematics classes. Their reservation was that they sometimes found it tedious listening to repetitive explanations and that the pace was sometimes slow. But they even had reservations to this and put it in perspective. For example:

Rania (H,8): Sometimes they go too fast (in the high track) . *and then I don't understand.*

Itamar(H,8): There are topics (in the heterogeneous class) *that are also difficult for me and also I need another explanation, but some* (of the explanation) *is a bit boring* (But the delay is worthwhile) *because here* (the good of) *friends are more important than to cover another half a page of exercises. It* (the delay) *is more worthwhile.*

However most of the High seventh graders were unable to imagine any disadvantages in learning mathematics in the high tracks. Even though they did enjoy and saw the benefits of learning with students less competent than they, they thought that studying in homogeneous

mathematics classes would prove the better option. For example, Efrat was eagerly awaiting the following year's mathematically tracked class:

Efrat (H,7): The moment we'll be in the same track the children will be on the same level as me, then (as opposed to the heterogeneous class) *she* (the teacher) *will certainly give all the class the same exercises that are suitable* (to all)... *If we had tracks we would be able to progress much, much faster.*

The Intermediates: Not surprisingly, the Intermediates in both grades were very happy learning mathematics in heterogeneous classes. Avishai (I,8) loved learning in the heterogeneous class. He described the class and its advantages both from the cognitive and from the social perspectives:

Avishai (I,8): She (the teacher), *like, integrates. She makes two groups and integrates, strong with weak and then everyone helps the other.. and then you learn more. What is learning more - you understand the material better Like, let's say she* (a student) *lagged behind in the previous* (work) *sheet then I help her, and then I understood. And it could be also that I made a mistake* (in this particular worksheet) *and then I correct mistakes.* (He prefers learning) *In heterogeneous groups because tracking makes the students competitive. They say that those who are in the low* (track) *are stupid and they say all sorts of not nice things and this makes them competitive. They're always fighting about this.*

Table 1 summarizes the attitudes of the students to studying in heterogeneous classes as opposed to homogeneous ones.

Table 1 Distribution of students according to 'tracks' and attitudes to studying in heterogeneous classes as opposed to homogeneous classes

	H(8) (N=9)	I(8) (N=10)	L(8) (N=8)	H(7) (N=6)	I(7) (N=7)	L(7) (N=7)
For	8	10	0	2	7	7
Ambivalent	0	0	6	0	0	0
Against	1	0	2	4	0	0

In Table 1, it can be noted that out of 47 students, 34 (72%) favored learning in heterogeneous classes, 6 (13%) – only eighth-grade Lows – were ambivalent, and 7 (15%) were against learning in heterogeneous classes. These findings, together with the findings that students believed that the cooperative-learning groups facilitated their learning, indicate that most students felt that learning in heterogeneous classes could be beneficial to them. While there might be other variables that influenced these attitudes, an effort was made to control for them. For instance, the students interviewed were selected to represent as many groups and as many classes as possible to reduce any effect that was particular to the make-up of a particular group or of a particular teacher. As previously mentioned, the teachers constructed the groups not according to the students' social preferences but according to the principles of the cooperative-learning seating plan thus reducing the 'socializing' or 'best-friend' effect during the formation of the student's attitude. Also it was ascertained (via the mathematics coordinator) that the mathematics teachers who taught the eighth-grade tracked mathematics classes were all well-liked and well-respected mathematics teachers thus reducing the 'special teacher' effect. Thus, it may be said that the eighth-grade Highs, who had learned in homogeneous classes, had a more positive attitude toward learning in heterogeneous mathematics classes as opposed to learning in

homogeneous mathematics classes than the seventh-grade Highs who had studied only in heterogeneous settings. Both the seventh and eighth graders in the heterogeneous classes studied in a learning environment conducted along the same principles. It seems that having had the opportunity of concurrently studying mathematics both in the experimental heterogeneous class and in homogeneous tracked class, the eighth-grade Highs saw that tracking was not necessarily a better option. All Intermediates preferred the option of studying in heterogeneous settings. The eighth-grade Lows, however, were ambivalent: Apparently the anxiety of not achieving good grades seemed to put a damper on the Lows' attitude towards learning in heterogeneous classes.

Although it may be concluded that most students in the experimental classes favored heterogeneous classes, this study indicates certain soft points. In the case of the seventh-grade Highs, a follow-up study is planned to examine their attitudes to learning in a heterogeneous mathematics class when they learn in an eighth-grade homogeneous mathematics class. Only then may one deduce with more confidence whether their rosy evaluation of learning mathematics in homogeneous settings was well founded or wishful thinking. As for the ambivalent eighth-grade Lows, how can conditions be created for them to feel more comfortable learning in a heterogeneous mathematics class? One condition could be lowering frustration levels as a consequence of low achievements. Clearly, a necessary condition for students to be motivated to study mathematics is the formation of a positive correlation between their diligence when learning mathematics and their achievements in mathematics. Yael (L,8) wanted to study with "all" the children; however she did not want to be too low an achiever. Seemingly Yael had not been achieving very highly in the heterogeneous class. She obviously thought that the only way to gain better grades was through less challenging tests. However, an assessment with too little challenge would most likely be counterproductive to the Highs' feelings of satisfaction when learning in a heterogeneous class; to some extent assessment should reflect all levels of learning in the class. The question is how to reconcile these two ostensibly contradictory requirements: a test that will challenge the Highs and at the same time allow the Lows to achieve reasonable grades?

TAP assessments are constructed of two parts: a basic component (usually comprising about 70% of the test) that assesses the core material in the relevant topic, and a complementary component (completing the basic component to 100%) that assesses material connected to the topic but on a higher level than the basic component. Thus, although the assessment is composed of two parts, the student receives a cumulative grade out of 100. This assessment format offers all students the opportunity for success in the basic component, while usually the more accomplished mathematics students show competence in the complementary component. Research has indicated that Lows who study in TAP's classes gain higher achievements than Lows who study in the low tracks (Linchevski & Kutscher, 1998). Thus, achievement-wise it is clearly beneficial for the Lows to study in a heterogeneous class. However, for students, research results do not offer requital. Students do not compare themselves with theoretical instances such as, for example, learning with mathematics students in other classes who are or are not studying in heterogeneous or homogeneous groups. Comparing themselves to their classmates, it is

only natural for all students to hope for positive feedback in the form of commendable assessment grades in return for their diligence and effort in their mathematics class. An evaluation model should take these psychological factors into account and allow all students to keep their self-respect in the heterogeneous class vis-a-vis their achievements and their classmates.

Proposed Evaluation Model in Heterogeneous Classes

Assuming the TAP model of assessment, it is proposed that each component of the assessment be treated grade-wise as a separate unit, each unit receiving a maximum grade of 100%. Thus, students would receive back their test papers with two separate grades, each evaluated out of 100%, one for the basic component, the other for the advanced component. They would be informed that the basic component assesses the core material and as such forms the primary part of the assessment; thus reasonable competence in this component is required. Similarly, students would be informed that the second part of the assessment, although recorded by the teacher, evaluates more advanced material connected with this topic and thus no minimum grade is required on this component. This evaluation process might reduce the less-competent students' frustration. At the same time the more competent students could receive the acknowledgement they need. By emphasizing the importance of the 'basic' grade, all students – and notably the Lows – who have performed adequately on this component could feel that they had received due recognition for their efforts, thus avoiding frustration. By virtue of the presence of the 'advanced' grade on the evaluated test paper, the more competent students could feel both motivated to rise to the challenge of the advanced component in the assessment and also feel recognized for this effort. Conceivably, such an evaluation model could answer both the learning and psychological needs of the whole mathematical community learning in heterogeneous classes. Further research should be done to examine the effect of such an evaluation model on students' attitudes.

TWO TEACHERS' BELIEFS AND PRACTICES WITH COMPUTER BASED EXPLORATORY MATHEMATICS IN THE CLASSROOM.

Chronis Kynigos* and Michael Argyris**

University of Athens and Computer Technology Institute*
University of Athens**

Abstract: *This paper describes two elementary teachers' beliefs and practices constructed after eight years of innovative practice involving one-hour-per-week computer-based maths classroom activity with small cooperating group of pupils. Participants were observed for 5 teaching periods, verbatim transcriptions were made from video recordings and semi-structured interviews were taken. Combined qualitative and quantitative analysis indicates that the teachers' actions may be influenced by their belief systems -not necessarily by one- as well as by wider cultural perspectives.*

Theoretical framework

In our effort to study the interrelations between teachers' espoused beliefs and their practice (Ernest, 1989, Lerman, 1992) we adopt a theoretical orientation which is influenced by two important paradigm shifts in the teaching and learning of mathematics: the appreciation of the teaching process and the formative role of the classroom to teaching practice. Perceptions of the teacher as implementers of prescribed pedagogy and curriculum have given way to those of the teacher as reflexive practitioner who's teaching is shaped by espoused beliefs and by practice itself (Hoyles, 1992). With respect to implementing innovation (as is the case in the present study), the teacher forms a personal pedagogy in the process of making sense of his/her environment as he/she acts upon it and is influenced both by his/her beliefs on teaching mathematics, the teachers role and the nature of mathematics itself and by the classroom culture and the wider culture (Olson 1989, Moreira and Noss 1995, Thompson 1992). The complicated relationship between teachers' beliefs and practices h s captured the interest of many researchers revealing a disparity between espoused and enacted beliefs (Raymond 1997). To this end additional research is necessary to illuminate and map the nature of the relation between beliefs and beliefs-in-practice (Lerman 1992). A second paradigm shift has been from constructivist and interactionist towards socio-constructivist perceptions of learning mathematics. These have given new impetus to classroom research with particular emphasis on the interplay between mathematical learning and social interactions. The study of mathematical teaching and learning in classroom situations has been one of the important means to develop theoretical interpretations

of learning as a reorganization and construction of concepts in social settings (Cobb et al, 1996, Baruch and Swartz, 1997).

In our effort to further analyze elementary teachers' practices and beliefs about their role, mathematics, teaching of mathematics, we build upon previous research (Kynigos 1996) where teacher interventions were described by means of a) the aspect of the learning situation to which they referred to and b) the type of pupil activity they intended to encourage. Our approach has been to study the teaching process in the context of using exploratory software to mediate innovation, taking into account Hoyle's (1992) suggestion that computational environments inevitably perturb the dynamics of a classroom, make more apparent the mathematical beliefs and understandings of teachers and students providing a window, a magnifying glass even, on the interaction process.

This is a report on research into two teachers' practices and beliefs constructed after eight years of such innovative practice involving a one-hour-per-week computer -based mathematics classroom activity with small cooperating groups of pupils.

Research Setting

This study was part of the "YDEES"[1] project which involved ethnographic investigation in a variety of aspects of classroom practice in school based innovation programs involving the use of exploratory software for small group mathematical project work. The teachers in question were observed during a two month project, the object of which was for each group of pupils to find out quantitative geographical information on Europe and represent it in a series of bar charts. The mathematics on the teachers' agenda was not only representing data by means of a bar chart but also the process of constructing the different bars (rectangles) in a sequence and finding ways with which the process would not have to be repeated for each chart. They used a piece of software developed within the project called "Component Logo with a Variation tool" (Kynigos et al, 1997). The variation tool is in the form of a "slider" which allows the continuous change of the graphical representation of a figure created by means of a parametric procedure as the value of the variable changes. The teacher wanted the pupils to suggest that they construct a rectangle procedure with one variable for its "height" and then use the variation tool to create a "bar chart machine", i.e. a piece of software for creating bar charts.

Method

[1] The study was carried out in the framework of project YDEES, "Development of Popular Computational Tools for General Education: The Computer as Medium for Investigation, Expression and Communication for All in the School", General Secretariat for Research and Technology, #726, E.P.E.T. II, 1995-1998

We employed an ethnographic approach (Hammersley & Attkinson, 1995) in order to a) to understand the teachers' beliefs regarding mathematics, the teaching of mathematics and their pedagogical role and b) to investigate their practices. More specifically, we wanted to investigate i) the nature of the role undertaken by each of the two teachers ii) the nature of the teachers' intervention regarding the mode of communication and the kind of activity they intended to encourage. To this end we built upon the previous works of Hoyles and Sutherland (1989), Farrell (1996) and Kynigos (1996), constructing a modified instrument for recording classroom events. First we studied observational data with the intention to trace the variety of roles and activities undertaken by teachers and pupils. Types of roles and interventions were allowed to emerge based on the data, instead of using data to test pre-existing hypotheses. To get a feeling for the balance of teacher actions in time, we then separated every teaching period in one-minute time segments and we studied the appearance frequency of each type of role and activity. Finally, we came back to the original text using the quantitative picture supportively in order to describe the practices of the two teachers. Each teacher was observed and videotaped for five class periods respectively. A remote microphone enabled transcription of all their utterances capturing responses of the group of pupils in which they intervened. Semi - structured interviews were subsequently carried out regarding their views on mathematics, teaching of mathematics, their pedagogical role and the role of the computer. Background data was also collected (i.e. observation notes and students written presentations of their work). Verbatim transcriptions of all audiorecordings and interviews were made.

Results

Kate has 27 years of teaching experience and Martin 26 years. In the last 8 years both of them have been working for one hour per week with their pupils organized in small groups in computer based classroom activities named "investigations". We present the results in two sections, one focusing on their beliefs as manifested in the interviews and the other describing aspects of their practice, i.e. the type of communication, their role and their practice when addressing the class as a whole.

a. Espoused beliefs

Martin enjoys doing mathematics and feels quite comfortable with the subject. *"I do like mathematics. And I think that I communicate this enthusiasm to the students. Many times before we start the daily curriculum I ask them what subject they want us to do and they select mathematics"*. He regards his role as *"a facilitator who provides students the opportunities to construct knowledge for themselves"*. Such statement could be regarded as consistent with the Problem-Solving view in the Ernest (1989) taxonomy. However, in some cases he articulates

views in which we may trace an impact of a Platonist view of mathematics. "*What I am trying to do is not to give answers but to guide students through the right questions to find the solution. I feel that I am responsible to guide children to reach the right solution*".

Kate, on the other hand, feels anxiety towards mathematics, a feeling that it has its origins in her school life as a student "*I had very bad experiences from mathematics as a student and now as a teacher I am most interested in removing any anxiety from students when they face a problem*". She regards mathematics as: "*facts and procedures for computing numerical expressions to find answers, something that you need in your everyday life*". A view that is most consistent with the Instrumentalist view of mathematics. This view doesn't restrain her to consider her role more as a counselor and a fellow investigator stating that "*although I don't feel quite comfortable using computers I enjoy this hour [she means the weekly hour mentioned above] as it gives us the opportunity to be students again. You see, we, the veteran teachers, tend to intervene too much. Using computers gives you the opportunity to think things different. Children don't need you to tell them what to do all the time. You have to permit them some autonomy*".

b. Teachers' practices

In order to describe teachers' practices we studied their verbal and nonverbal communicative behavior in the classroom characterizing their interventions, the roles they constructed and the activities they encouraged. We take two similar episodes, in the sense that they were points in time when the two respective pupil groups had not constructed a procedure with variable for the rectangle bar and both teachers intervened with an agenda for them to change course. We use these episodes to highlight a sample of the types of teacher interventions and then use the quantitative picture to discuss the full set of types and the balance of interventions in time.

b1. Teachers' interventions

Kate : Have you done the population of Athens?(means the construction of the appropriately sized bar on the chart)
S : Yes.
Kate: Right, Well done. Now you have to do what? Oh, wait a minute. Would it be better if you put all these commands in a procedure?
S : But it works this way Mrs.
Kate : Yes, but if you put all these commands in a procedure then you can do this thing [means the rectangle] as many times as you wish. It's better this way.
S : How?
Kate : Oh come on, you know that - Get me a pencil [She goes on modeling the move of the turtle on a piece of paper explaining the steps that pupils should follow].

In this episode Kate intervenes through her own initiative with a specific agenda to direct the pupils to construct the rectangle bar in a different way i.e. procedure with a variable so that they could change its length. Her argument is both

BEST COPY AVAILABLE

pragmatic and mathematical. Her mode of communication is exposition - explanation of they way they should do it.

In an analogous situation Martin reacts quite differently.

Martin : I can see that you are working without using variables
S : Yes. Does it matter?
Martin : What matters is that you don't take advantage of the software.
S : Well that doesn't really matter. It's still working.
Martin : Is it so difficult to use variables? I will help you if you want to.

[At this point a pupil from another group attracts his attention temporarily. Martin returns later to this particular group and observes their work silently without making any further comment although pupils insist on working without using variables. In the last lesson when every group presented its work he triggered a long discussion about the use of variables and set as an example the groups that used variables in their project].

Martin's unrequested intervention was in the form of a dialogue with the pupils aiming to explain the merits of using a procedure with variable for the bar. He did not, however, invest much in discussion and articulation of arguments. His argument was authoritative rather than mathematical or pragmatic, i.e. variables and the variation tool should be used because they were available rather than because the pupils could do such and such if they used them. After the pupils' resistance by means of a pragmatic argument, he withdrew without further instructional comments with the apparent intention that they reflect and make their decision.

The types of the two teachers interventions emerging from the data in this way are given in table 1 below.

Table 1 Characterization of teachers' interventions

The Initiative	Martin	Kate	*The intention*	Martin	Kate
requested	46%	50%	nudge	29%	37%
unrequested	54%	50%	discipline	1%	9%
To whom			directive	23%	36%
to the whole class	11%	13%	reflective	38%	22%
to a group	89%	88%	group dynamics	8%	21%
The mode of communication			motives	9%	20%
Verbal			procedural	12%	13%
exposition/explanation	15%	42%	supervision	39%	48%
dialog	50%	48%			
resource	17%	22%			
Nonverbal					
silent observation	31%	12%			
demonstration	4%	25%			

As it is quite clear from the quantitative picture about half of the teachers interventions were of their own initiative and Kate tended to 'explain' and demonstrate things more than Martin who preferred in more cases to observe

silently. Martin's interventions are characterized by his apparent tendency to promote reflection. Instead of providing answers he prefers to return the question to the whole group giving them the responsibility to monitor their progress and make up their decisions. Kate seems to emphasize issues of communication and motivation within the group and tends to direct the pupils into clearly described actions.

In the interview, Martin seemed to have conflicting beliefs that a) reflection is at the heart of learning mathematics and b) that it is of primary importance that they solve the problem. The time-dependent quantitative analysis shows that while in the first hour 18% of his comments were directive and 45% intended pupil reflection (like, for instance, in the excerpt above), in the last hour the picture changed dramatically (34% and 35% respectfully).

This tendency is even more clear in the case of Kate. Starting with a high percentage (41%) of one-minute segments containing interventions for promoting reflection she concludes with a very low one (6%). In total her intervention is mostly characterized by her directive comments. In some cases she even takes control of the machine demonstrating what the pupils should do by doing it herself.

b2. Teachers' roles

A second interpretative perspective of the teachers comments is that of the social role (i.e. the norm or shared understanding about it) which they encouraged in their relations with their pupils. Looking again at the above episodes, Kate seems to have adopted an instructional role, since the taken-as-shared communication context was that she would describe, explain and demonstrate what she wanted the pupils to do. In this case we have a consistency between the nature of her intervention and the role she adopts. In the case of Martin things are different. In the episode, after observing what the pupils were doing, he intervenes with an intention for them to reflect on whether they should use variable or not and seems to accept their pragmatic argument. In this sense he adopts a managerial role but does not pursue discussion on the mathematics at hand, so he does not instruct or explain. He offers counseling but does not insist when the pupils show no eagerness.

Working in this way and studying the social interaction between teacher and students we came along the following table.

Table 2. Characterization of the teacher's role

	Martin	Kate		Martin	Kate
instructor	12%	43%	counselor	30%	40%
manager	40%	44%	resource	11%	12%
task setter	6%	4%	fellow investigator	6%	13%
explainer	9%	8%	silent observer	38%	10%

As a whole, during the five lessons under study, Martin seems to constrain his managerial role in benefit of the 'silent observer' one, allowing students to undertake an exploratory role. In line with his view about his role, it appears to be a conscious choice to give students opportunities to express their ideas, experiment with them, interpret the feedback they receive from the computer and finally construct their knowledge. Kate on the other hand, in contradiction with her statements, seems to construct a more directive role. She walks around the classroom, checking groups work and often suggests what they should do next.

b3. Classroom activities

So far we were focusing on the social interaction between the teacher and a group of students. A third perspective with which we analyzed the data was that of the social interaction between the teacher and the class as a whole. Looking back in the above mentioned episodes regarding the educational activities we have two dialogues between teacher and students while the rest of the pupils are allowed to talk to each other in their groups as they investigate the project at hand. Studying the educational activities which were trigged by the two teachers in the whole sequence of the five lessons we formulated the following table.

Table 3. Characterization of classroom activities

	Martin	Kate		Martin	Kate
exposition	7%	1%	discussion		
investigational work	84%	93%	student - student	87%	92%
			teacher - student	81%	94%

Both teachers seem to refrain themselves from frontal teaching and their discourse is not in antagonism with pupils' discourse as it is the case in frontal teaching. Both seem to encourage students to undertake an investigational role as this activity was the one most commonly presented in their classrooms. This is not surprising as, after eight years of practice in this particular school, it is embedded in its culture that during this weekly hour students should be allowed to work cooperatively in order to investigate a specific subject.

Conclusion

The results corroborate the view that espoused beliefs may be inconsistent with actions during classroom teaching practice. However, in both cases we find that more than one of what we may describe as a belief system (i.e. a coherent set of views on mathematics, teacher roles and mathematical learning) may coexist in teachers' descriptions. In one case, for instance, we had confidence with mathematics and appreciation of encouraging reflection in Martin who's

interventions were infrequent and often lacking in mathematical content. In the other, Kate expressed uneasiness with mathematics, but was rather directive and mathematically explicit in her interventions. Both teachers were influenced by timing, becoming more directive towards the end of the course. Studying teaching process in terms of communication mode, type of encouraged pupil activity, adopted roles and classroom activity was illuminative in the sense that it provided means to describe some of these inconsistencies. For instance, Martin may have had a coherent intent for pupil activity which he may simply have not related to his view about his role and to the way in which he communicated with the pupils. The relation between espoused and enacted beliefs is a complex one and is not necessarily consistent. Further research is needed to illuminate the nature of teaching practice in the process of developing focused theory on learning in classroom settings.

BASELINE ASSESSMENT AND SCHOOL IMPROVEMENT: RESEARCH ON ATTAINMENT AND PROGRESS IN MATHEMATICS

LEONIDAS KYRIAKIDES
INSTITUTE OF EDUCATION, UNIVERSITY OF WARWICK, UK

ABSTRACT

This paper presents findings from research exploring the use of baseline assessment at entry to primary school to measure pupils' progress in Mathematics. Pupils' attainment in Mathematics when they entered the primary school and when they were at the end of year 2 were measured through external and internal methods of assessment. The predictive validity of baseline assessment for pupils' attainment at the end of year 2 was satisfactory. Pupil background factors were significantly related to pupils' attainment on the baseline assessment and to their attainment at the end of year 2. However, the baseline score was the most important factor in relation to pupils' progress. Both pupils who did not have any background in Mathematics when they entered primary school and those with a very good background made less progress than those who were typical in their age. Differences between schools' final results were reduced substantially when account was taken of their pupil intakes, but significant differences between schools remained supporting the conclusion that some schools are more effective than others in facilitating pupils' progress in Mathematics. Implications for the development of curriculum policy in Mathematics and areas for further research are drawn.

I) INTRODUCTION

There are four reasons why all school systems must have a strategy for finding out about pupils on entry (Blatchford & Cline 1992). First, baseline assessment may produce information about what children know and what they do not know in order to help teachers decide how to identify and meet children's learning needs and how to use their teaching time and their resources. An important implication of the identification of learning needs is that decisions about the next learning steps follow from this. A teaching plan, which is organised in such a way, might help teachers to plan class and individual programmes of work according to the different performance levels of the pupils. On the other hand, information gathered from baseline assessment can be used for summative purposes. However, there is widespread doubt that the summative and formative purposes can be achieved in a single set of assessment arrangements. (Brown 1991). Another important purpose of baseline assessment has to do with the fact that teachers may identify pupils with learning difficulties (Lewis 1995). Finally, baseline assessment as its name implies, provides the base for which pupils' subsequent educational progress can be measured.

Measures of the educational progress made by pupils in a school, relative to that made by similar pupils in other schools, have come to be called "value added" assessment and such measures are used in research into the effective teaching of Mathematics (Brown at al 1997).

The main purpose of the research presented in this paper is to explore the use of baseline assessment in Mathematics to measure Cypriot pupils' progress in the early years of primary school. The review of the purposes of baseline assessment helps us to see that this study can be linked with the following three aspects of curriculum policy. First, in Cyprus there is no policy in evaluating school effectiveness. However, the fact that in the Third International Mathematics and Science Study (TIMSS) substantial variation in Mathematics achievement between year 3 and year 4 Cypriot pupils was found revealed the importance of developing a policy on evaluating school effectiveness in Mathematics. Data derived from measuring pupils' progress may be more valid in exploring the effectiveness of a school unit than using outcome data only since variations in final test results of schools reflect partly the educational attainment of pupils when they entered the school (Fitz-Gibbon 1995). Thus, this study may contribute to evaluate school units in teaching Mathematics by adopting the technique of value-added assessment. Second, the fact that significant differences among the skills and knowledge of Cypriot school entrants have been identified (Kyriakides 1997) reveals the need for measuring the progress of different ability groups of pupils in order to explore the extent to which teachers respond to the learning needs of each group. Thus, the data of this study may provide implications for the importance of the formative purpose of baseline assessment. Finally, the measurement of pupils' progress may also help us to examine the extent to which the baseline assessment could be used to identify pupils "at-risk" of later educational failure. Although during the early 1980s considerable research was undertaken in European countries on screening instruments designed to identify pupils 'at risk' of later educational failure (Wolfendale & Bryans 1979) and significant positive correlations between attainment at the start of the school and subsequent attainment were reported, the research reduced in prominence because of the difficulties inherent in making predictions for individual pupils (Potton 1983). However, the findings of studies exploring the school effect on pupils' progress may help us to renew the interest of using baseline assessment to identify pupils with learning difficulties.

II) METHODOLOGY

Research data concerning pupils' skills and knowledge in Mathematics when they entered primary school constitutes of two elements. First, a teacher completed checklist including an assessment of social and emotional development and attainment in Mathematics was designed to build on good observational assessment Teachers were asked to rate pupils as "developing competence", "competent" or

"above average" for each section. The checklist is accompanied by a comprehensive teacher's handbook which provides guidance on each section. Watson (1997) argues that the development of criteria for informal assessment and the attention to documentation of unplanned observations are important but not enough to ensure teacher assessment is valid. Thus, a performance test was designed to assess knowledge and skills in Mathematics identified in the Cyprus' Pre-Primary Curriculum. Pupils were asked by the researcher to complete at least two different tasks related to the purposes of teaching Mathematics to pre-primary pupils. It has been shown that the baseline items are appropriate in difficulty for the typical Cypriot pupil entering primary school but are also able to allow the more able pupils to demonstrate their attainment (Kyriakides in press). In addition to their baseline attainment, information was collected on four further pupil background factors: pupil's age when s/he entered primary school, pupil's sex, and type and length of pre-primary school provision. Pupil's age was converted into months and expressed as deviations from the grand mean for all pupils. Finally, external and internal methods of assessment were used to measure pupils' attainment in Mathematics when they were at the end of year 2. Teachers were asked to complete a checklist for each pupil indicating whether the child had acquired each of the skills included in the Mathematics Curriculum of year 2, and a written test was administered by the researcher to assess pupils' knowledge and skills identified in the curriculum of year 2. Data were available for 1664 pupils who completed both baseline assessment in October 1996 and the written test for year 2 pupils in June 1998.

The stratified technique was used to select 48 schools out of the 242 Cypriot primary schools. All the first year pupils from each class of the school sample were chosen. It is important to note that the chi-square test did not reveal any statistically significant difference between the research sample and the population in terms of sex, type and place of school and size of class. It may be claimed that the pupils who took part in the research were representative of Cypriot pupils entering primary school in 1996 in terms of the above characteristics.

The reliability of the findings was measured by calculating the relevant values of Cronbach Alpha for the scales used to measure pupils' knowledge in Mathematics. The values of Cronbach Alpha for the scales used to measure pupils' responses in the performance test and in the written test were higher than 0.80. Similarly, the values of Cronbach Alpha for the scales used in teachers' checklists were higher than 0.82. Thus, we can be confident about the reliability of the measures used. Moreover, the use of two different methods (internal and external) of baseline assessment and assessment of pupils' attainment at the end of year 2 provide us with useful information about the internal validity of the research. Significant correlations ($p<.05$) between the way teachers assessed each skill of their pupils and the way the pupils responded to the assessment tasks of the relevant test have been identified. Although this finding does not necessarily imply that the validity of the research is

high since it is possible that they are both invalid, the use of both internal and external ways of assessment provides a basis for triangulation of data.

III) FINDINGS

A) Predictive validity of baseline assessment

Table 1 shows the multiple correlations between the baseline attainment and attainment at the end of year 2 of primary school. The multiple correlation of 0.63 between the average baseline assessment score and the average year 2 score provides a satisfactory starting point for value-added analysis. It is of interest that the combination of teacher-completed checklist and the performance test provided the best indicator of pupil's subsequent attainment, better than either type of assessment in isolation.

Table 1: Correlations between baseline attainment measures and attainment measures at the end of year 2

Outcome	Predictor/s	Multiple Correlation
Year 2 average test score	Performance Test	0.58
	Teacher Assessment	0.54
	Performance Test + Teacher Assessment	0.63
Year 2 written test score	Performance Test	0.56
	Teacher Assessment	0.53
	Performance Test + Teacher Assessment	0.62
Year 2 teacher's Assessment score	Performance Test	0.57
	Teacher Assessment	0.51
	Performance Test + Teacher Assessment	0.60

B) Pupil Factors

Pupil factors and attainment when they entered primary school (average age 5.72 decimal years)

The first two columns of Table 2 give the results for the analysis of baseline scores. The multilevel model compares the effect of each factor against a reference group which, in this case, is girls of average age with one or less year of public pre-primary education. All the measured pupil background factors but the type of pre-primary education were significantly related to pupil's attainment on the baseline assessment. Older pupils' attainment was significantly higher than younger pupils' attainment. Sex differences were marked with boys having significantly higher attainment than girls. Age and length of pre-primary education covaried, with older pupils experienced more pre-primary education than younger pupils. The confounding of these two factors might be overlooked when assessing the effects of pre-primary education. However, the multilevel model allows the influence of early education to

be assessed whilst simultaneously controlling for age and all other measured background factors. Thus, it was found that pupils with more than three years of pre-primary education and those with more than one but less than three years of pre-primary education, both had higher attainment than those with one or less than one year of pre-primary education.

Pupil factors and attainment when they were at the end of year 2 (average age 7.29)

The third and fourth columns give the results for the analysis of pupils' attainment at the end of year 2. Again younger pupils had lower scores than older pupils and boys had higher attainment than girls. Finally, pupils with three or more years of pre-primary education had higher attainment than those with one or less than one year of pre-primary education.

Table 2: Fixed effects of pupil background on baseline attainment, year 2 attainment and progress during the first two years of primary education

Factor	Baseline Attainment		Attainment at Year 2		Progress (from 5 – 7)	
	Estimate	Std. Error	Estimate	Std. Error	Estimate	Std. Error
Pupil level						
CONS (Intercept)	18.482*	1.913	2.012*	0.122	1.623*	0.238
Baseline Score	--	--	--	--	0.048*	0.001
Age**	0.838*	0.082	0.031*	0.003	0.004	0.003

*= Coefficients significant at p<.05, ** = Variable centred on grand mean

Pupil factors and progress during the first two years of primary school

The following observations arise from the figures of the last two columns of Table 2 which show the effect of pupils' baseline score on pupils' progress. First, baseline score was the most important factor in relation to pupils' progress. Second, boys made more progress than girls. This implies that the gender gap becomes even larger during the two years of primary education. Third, amount of pre-primary education was not significantly related to pupils' progress during the first two years of primary education. However, the positive effect of three or more years of pre-primary education on baseline and year 2 results, mentioned above, suggests that the benefits of early education persisted during the first two years of primary education.

Since a wide disparity in pupils' responses to the baseline tests was identified (Kyriakides in press), a further analysis was conducted in order to compare the progress of different ability groups of pupils. The following five homogeneous

groups of pupils according to the way in which they responded to the activities in the baseline tests derived from cluster analysis: a) "Pupils with identified needs for remedial help", b) "Pupils with needs for extended mathematical activity", c) "Pupils who are typical for their age", d) "Formal knowledge possessors", and e) "Skills possessors". Thus, the variable "group 1" compares the progress of pupils who did not have any background in Mathematics when they entered primary school (group 1) with the progress of pupils who are typical for their age (group 3). Similarly, the variable "group 2" compares the progress of pupils who had completed correctly almost all the activities in the baseline tests with the progress of pupils of group 3. The figures of the last two columns of Table 2 reveal that pupils who did not have any background in Mathematics when they entered primary school and those with a very good background, both made less progress than those who were typical in their age when they entered primary school. Thus, the ability gap between the group of pupils who did not have any background in Mathematics and the group of pupils who are typical for their age becomes larger during the two years of primary education.

C) Differences between schools

School effects on pupils' progress were explored through three multilevel regression models. The first model (null model) included only the intercept term and indicates "raw" differences between schools in their year 2 results. The second model explores the effect of adding information on pupils' background including their baseline score, sex, age and type and length of pre-primary school provision. The third model explores the effect of including variables at the school level, especially the average baseline score, the percentage of girls and the mean of the age of their pupils. These factors are all aggregated from the pupil level data. The analysis of the data revealed that knowledge about pupil's prior attainment and background explains a good deal of the pupil variation in year 2 results (34%), but very little of the school-level variation (4%). It was also found that baseline score was the most significant of the pupil background factor since it reduced the pupil variation in year 2 scores by 29%. Including the school compositional factor in the third model explained no more of the pupil-level variation but significantly reduced the school level variation by 38%. A substantial amount of the difference between schools in pupils' progress between baseline and the end of year 2 was explained by the overall composition of the school intake. However, substantial differences between schools remained. The third model revealed that about 10% of variation in pupils' scores was attributable to schools. Having controlled for both pupil factors and school contextual factors, the results show that there were still substantial differences in the performance of schools.

IV) Discussion

The evidence presented above can be discussed in terms of its implications for the development of curriculum policy in Cyprus. First, it is important to examine

assessment policy in terms of policy on classroom organisation. The fact that some school entrants had either achieved most of the aims of teaching Mathematics or had not achieved any one of them implies that it is not possible to organise teaching Mathematics without taking into account the different Mathematical background of school entrants. Spending most of teaching time working as a whole class, as is the case in Cyprus (Kyriakides 1996), is not an appropriate way of teaching Mathematics to first year pupils. It can be argued that baseline assessment provides teachers with information which could help them to respond to the learning needs of each pupil, or more realistically of groups of pupils organised by previous attainment However, Cypriot teachers did not systematically assess their pupils when they entered primary school (Kyraikides 1997). Moreover, Cypriot pupils with special needs (either for remedial help or for extended activities) made less progress than pupils who are typical in their age. This implies that Cypriot teachers respond mainly to the needs of pupils who are typical in their age. An issue that needs to be examined is whether the development of a policy on baseline assessment may encourage Cypriot teachers to give more thought to the best way in which to respond to individual learning needs.

Second, significant sex differences favouring boys have been identified. Thus, in terms of equal opportunities across the first two years of primary school the lower rate of progress of girls in Mathematics suggests that equal opportunities issues remain highly relevant in considering whether differences in the nature of primary school experiences of the two sexes may play a part. A conclusion by no means unique to Cyprus (Frempong 1998).

Third, the findings of this study reveal that the school a Cypriot pupil attends does make a difference to his/her educational progress, since schools with intakes of similar attainment and of similar composition can and do achieve different results. It can be claimed that even if 15% of pupils did not respond correctly to the tasks assessing pupils' attainment and are likely to turn out to have cognitive problems, the school effect on the progress of this group of pupils should be examined. Although baseline assessment can be used to identify pupils who need extra help, value-added analysis is also needed to provide information about school effectiveness in teaching Mathematics to pupils with learning difficulties.

It can be finally argued that while the value added analysis shows that there are differences between schools in the progress made by their pupils, further research is needed to identify what it is that schools do that makes this difference. Nevertheless, the analysis of baseline assessment in relation to year 2 results to provide indicators of variations in school effectiveness in Mathematics offers schools valuable additional information for the purposes of self-evaluation and review. The value-added feedback may be used to encourage schools to identify apparent areas of strengths and weakness to formulate provisional hypotheses about the factors which may have influenced pupil performance in specific areas of Mathematics. Thus, the importance of linking school effectiveness and school improvement work in

Mathematics should be raised. An approach of curriculum improvement in which the targets set would arise from school-focused needs, defined at the school level by the school staff, would be more likely to generate authentic reform and to raise standards in Mathematics.

Learning pre-calculus with complex calculators: mediation and instrumental genesis

Jean-baptiste LAGRANGE
Institut universitaire de formation des maîtres
153, rue de St Malo 35043 Rennes Cedex FRANCE
Email: lagrange@univ-rennes1.fr

Abstract

University and older school students following scientific courses soon will use complex calculators with graphical, numerical and *symbolic capabilities. This paper is based on the experience of the design and the experimentation of an 11th grade pre-calculus course. The first part is a study of this new context, stressing the role of mediation of the calculators and the development of schemes of use in an 'instrumental genesis'. From this study, the paper looks at tasks and techniques to help students to develop an appropriate instrumental genesis for algebra and functions, and to prepare for calculus. Then it focuses on the potential of the calculator for connecting enactive representations and theoretical calculus and on strategies to help students to experiment with symbolic concepts in calculus.*

Introduction

New hand held complex calculators offer, to some extent, a synthesis of computer software and calculators. Like computers they have the powerful applications: computer algebra systems, geometric software and spreadsheet. From calculators they inherit ergonomic characteristics (small, disposable) and numerical and graphical utilities important to the study of functions.

This paper is based on an experience of integration of these powerful calculators into the teaching of pre-calculus[1]. It provides reflection, based on theory and practice, on the changes that these calculators may bring into the teaching and learning of mathematics, and a search for efficient means to use them.

This experience was a continuation of an earlier research looking at the integration of DERIVE into the study of algebra and calculus in France. An important limitation of this DERIVE experiment was that students generally lacked the familiarity with this technology necessary to really use it to support their mathematical activities and learning. So, when complex calculators became available we saw the potential for easier student access to computer algebra technology which might affect their

1 This study was done by a team of five. Michele Artigue was the leader, Badre Defouad and the author participated with the teachers, Michele Duperrier and Guy Juge, to the definition of the sessions and did classroom observations and interviews. A report on the project can be obtained from DIDIREM Université Paris VII 75251 Paris Cedex 05, France. The project was founded by the French ministry of Education (DISTEN B 2).

everyday mathematical practices, and that we would be able to observe more substantial changes. For this reason, we did a pilot project, designing and experimenting lessons/activities in four classes of the ordinary French scientific upper secondary level (11th grade) where every student had a TI-92[2]. This project forced us to conceptualise the changes in the mathematical activity of students using this complex calculator. We had also to think about the help that the various multilevel capabilities of this calculator can bring to teach a specific subject like pre-calculus.

The evolution of approaches to the use of computer technology in the learning of mathematics

From constructivist approaches to mediation

When computers became available many hopes were placed on the autonomous cognitive activity that a learner could develop when faced with specific tasks (Artigue, 1996). The general frame was a Piagetian approach: acting in adequately problematic settings, the learner meets insufficiency or inconsistency of his/her knowledge. Introducing computer environment could help to create settings of this kind. More recently Noss and Hoyles (1996) stressed that a computer application may operate as a linguistic tool, and they emphasise programming as a tool for expressing and articulating ideas. Therefore, Noss and Hoyles introduced mediation as a major role for the computer in the student's process of abstraction.

This idea of mediation is useful in our project because a purely constructivist view of the use of computers is insufficient to analyse the interaction between the user, his/her instrument and the objects in the settings. A constructivist view assumes that the computer settings will provide the means for a predictable and meaningful interaction. What actually happened when we observed the use of DERIVE was different: students' reactions and reflections did not have the meaning that the teacher expected because their perception of the feedback was influenced by the operation of the software (Lagrange, 1996).

The role of the instrumental schemes

Moreover, when the user is learning new capabilities, s/he does not distinguish the internal capabilities and the features of the interface. In this phase, the calculator is better seen as a complex instrument like those existing in the area of professional working, rather than as addition of a neutral interface and an internal algebraic language. For this reason, I use the theoretical approach of those instruments by psychologists like Verillon and Rabardel (1995). They stress that a human creation,

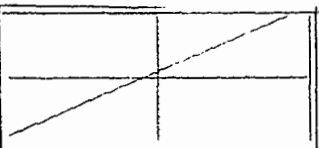
---

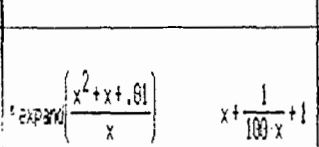
[2] At the time of the experiment, the relatively expensive Texas Instrument TI-92 was the only hand held calculator with symbolic capabilities. New student affordable calculators like the TI-89 and the Casio GRAPH 80 now offer symbolic capabilities.

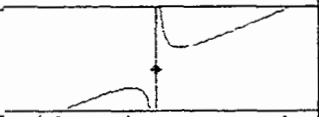
an 'artefact', is not immediately an instrument. A human being who wants to use an artefact builds up his/her relation with the artefact in two directions: externally s/he develops uses of the artefact and internally, s/he builds 'instrument utilisation schemes' to control these uses. This process is the 'instrumental genesis'.

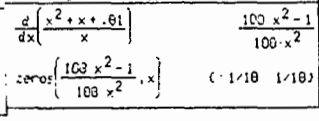
Schemes in calculus using a complex calculator

As an example of this approach, the figure 1 displays various schemes, calculator oriented or not, algebraic, graphic or symbolic that a user of a TI-92 can use to search for the variations of a function like $\frac{x^2+x+0.01}{x}$.









Nature of scheme	TI-92 output	Decisional dimension	Pragmatic dimension	Interpretative dimension
Graphic, TI-92		Graphing in the standard window is a good approach	Consider the graph of the function in the standard window	Function is increasing. Graph is a straight line
Algebraic, criticism	none	Graphical evidence must be compared to algebraic aspects	Consider the algebraic definition of the function	$f(x)$ is not a linear function
Analytic, TI-92		Expanding an expression helps the interpretation of the graph	Consider another algebraic expression of the function	There is something special near $x=0$
Graphic, TI-92		Graphic display will confirm analytic ideas	Zoom in around $x=0$ and $y=0$ until something appears	There are two turning points near zero
Calculus, TI-92		Use the derivative to find the turning points	Find the zeros of the derivative	Position of the turning points is confirmed

Figure 1: Schemes in a search for the variations of a function

The first scheme (graphing in the standard window) is prevalent among most students. In the initial stages of learning calculus very few students are able to produce critical interpretations like in the second scheme, even when they have the algebraic knowledge to do so. In contrast, more able students develop schemes where graphical action is linked with algebraic and analytic interpretation: they see, in the graph, properties that they anticipate from an algebraic analysis of the function.

Transforming the expression of the function like in the third scheme is not a spontaneous action to beginners. More advanced students choose the transformation randomly among the TI-92 capabilities rather than from rational reflection. Teaching can help to develop this reflection. Switching back to the graph window, as in the

BEST COPY AVAILABLE

fourth scheme, is quite natural. Able students anticipate immediately the required zooming, while others take considerable time over this decision. Students may have learnt the calculus approach in the fifth scheme as a method. As a scheme, it is often limited, because students are not able to activate it when the function is not a standard rational function considered in the teaching.

From this brief description of features of schemes appearing in a calculus task, and their apprehension by students, questions arise on the genesis of these schemes in an educational context. What is the link between the development of utilisation schemes by students and the development of their mathematical knowledge? How is teaching to be oriented to help the development of suitable schemes, their generalisation and their co-ordination?

An approach of teaching with instruments

Schemes for building knowledge

In Vergnaud's (1990) approach, schemes play a key role in conceptualisation: they organise the behaviour of a person in a class of problems and situations representative of a field of concepts, and they are a basis for knowledge in this field. When a person learns mathematics with an instrument, his/her schemes organise behaviours related to the use of the instrument as well as more general conducts. So the potential of complex calculators is to be searched in the many possible schemes that a user is able to build for its use. However, this potential will be effective only in situations where utilisation schemes are productive of adequate knowledge and mathematical meaning.

This is not all situations when we consider, for instance, the limit of a rational expression at a finite or infinite point. In an ordinary 'non computer' context, students may apply infinitesimal reasoning or methods, possibly rich in meanings. In contrast, with a calculator like the TI-92 or algebraic software like DERIVE, students are able to associate the idea of limit with a single scheme: pressing the 'limit' key of the calculator and reading the output on the screen. This scheme is effective for the task but, as Monaghan et al. (1994) observed, it may result in giving students a narrow understanding of the notion of limit.

So, depending on their co-operation with other schemes or meanings, schemes of use of the TI-92 or DERIVE are productive or not. Therefore, for the support of the technology to be effective teachers must control students' development of utilisation schemes and their co-ordination with the advancement of mathematical knowledge.

The role of tasks and techniques in the use of a complex calculator

Techniques and their relationship with the instrumental genesis are a key point in the use of technology to teach and learn calculus. Authors and teachers assume that the symbolic capabilities in this technology are means to lessen the stress on techniques

which, they consider, restrain students' reflection on concepts. This view was clearly present in teachers' expectations in the French DERIVE experiment, and I could establish the limits of this excessively conceptual approach (Lagrange, 1996). Of course, techniques without schemes are ineffective because they are not likely to evolve and cannot produce knowledge. However, classroom discussion on techniques is essential to help students to develop suitable schemes and enhance the reflective part of these[3].

Unlike the paper/pencil techniques, TI-92 techniques rationalise schemes of use of an instrument, and, according with Rabardel and Vérillon, these schemes develop in an instrumental genesis. A consequence is that the organisation of the tasks and associated techniques must comply with the constraints of that genesis and direct it in a productive way: schemes cannot develop arbitrary and not all combinations of schemes are able to produce mathematical meaning. Below we look more closely at these constraints and their implications in terms of tasks and techniques in the specific subject of pre-calculus.

Teaching pre-calculus with complex calculators

Tasks and techniques to develop an appropriate instrumental genesis for algebra and functions

At the beginning, the student tries to bring the schemes s/he built for his/her familiar graphing calculator into use. Tasks and techniques are thus to be organised to help him/her learn that, in the default mode, the TI-92 simplifies radicals and rational numbers symbolically and the difference between this 'exact' mode and the various decimal approximations. Then schemes of use of the algebraic capabilities are essential. A key point is the notion of equivalence of expressions and the need for awareness of the different equivalent forms of an expression. A student must learn to consciously use the items of the algebra menu, to decide whether expressions are equivalent as well as anticipate the output of a given transformation on a given expression. This work has to be continued when new expressions, like trigonometric functions, are introduced.

Like many calculators, the TI-92 offers a graphical window and a numerical table with a wide range of capabilities. Therefore, it may enhance early functional thinking because graphical and numerical schemes are essential for the growth of the function concept. As seen above, figure 1, notions like the variations of a function implies the co-ordination of algebraic and graphico-numerical utilisation schemes. A relevant task for developing these schemes is the study of functions whose properties are not obvious in a standard graph (for examples see Figure 1, and Trouche, 1994).

---

[3] For a more comprehensive study of the role of techniques in the use of CAS, in relation with Chevallard's (1992) theoretical approach, see (Lagrange, 1997).

Helping students to develop flexible links between calculus concept representations

The use of the TI-92 in calculus is quite simple: a menu entry for the symbolic calculation of limits and a key for the calculation of derivatives. So, as a difference with algebra and functions, no specific instrumental learning will be necessary. However, we saw above, with limits, that this use tends to produce symbolic manipulative schemes, likely to generate a narrow understanding of these concepts if they are alone. This implies a deep reflection on how teaching can help the development of other schemes.

Tall (1996) stresses that there is not a single way to teach pre-calculus, but "a spectrum of possible approaches ... from real-word calculus ... through the numeric, symbolic and graphic representations in elementary calculus, and on the to the formal ... approach of analysis". Like many others he emphasises the need for helping students to move flexibly from one representation to another and to establish a balance between representations

Technology tends to toss the traditional balance about. For instance, in France, every student in the secondary level has now a graphic calculator. This situation clearly changes the balance of the numeric and graphical representations and of the symbolic view of the concepts of calculus. Students often prefer experimenting from the graph rather than analysing with symbolic methods. Trouche (1994) noticed this behaviour and he highlighted the need for developing students schemes to control the graphs and numbers they obtain on their calculators. Now, with the TI-92 and others, calculators are graphico-numeric *and* symbolic. Little is known of how this new feature will affect the students' balance and flexibility between representations[4].

In the everyday use the calculator, higher complexity of the instrument may change students' flexibility. With common graphing calculators, graphical and numerical schemes are instrumental when analytic schemes are associated with pencil and paper practices. In contrast, with the TI-92, co-ordinating analytic and graphico-numerical schemes implies controlled switches between windows. In those switches, a clear view of the organisation in the calculator is essential and teaching has to help students to build this view.

The balance of representations was a key point in the design of teaching modules for pre-calculus courses. Our team assumed first that easier symbolic calculation enlarges the possibility of linking enactive representations and theoretical calculus.

---

[4] Ruthven (1997) reviews a number of researches into CAS in mathematics education. The prevalent topic is the comparison of student performances between CAS and non CAS students. so, little is known of the impact of CAS in the everyday teaching.

and also that teaching must avoid the danger of too close an association between concepts and symbolic manipulative schemes, wiping out other representations.

Enactive representations (Tall, 1996) exist in the prior differential knowledge of students. For instance, most students have a sense of the tangential behaviour of curves from their geometrical experience. It seems important to use this knowledge as a basis for the theoretical concept of derivative, because differentiation is an analytic answer to the question of the tangent line for a curve defined by a function. However, in the ordinary context of paper and pencil calculations, students cannot really question their enactive differential notions because they would have to consider, and give sense to, expressions which are beyond their abilities. In our experiment, using symbolic computation helped students to work with these expressions and to understand their meaning. A condition for this was the limitation of the cognitive complexity of the situation, in order that students could really reflect by themselves: an instrument like the TI-92 reduces time consuming calculations but not the difficulty of concepts. Also, students' development of algebraic instrumental schemes was essential to ensure the success of this work.

Our team was concerned that students may use the symbolic capabilities of the calculator for very simple limits or derivatives and see nothing more in those concepts than the manipulative aspects. As Monaghan et al. (1994) argue, symbolic computation may make manipulations effortless but tends to obscure other representations linked with infinitesimal approaches. For that reason, we preferred to introduce the TI-92 capabilities for limits and derivative only after students did considerable work on the concepts, linking enactive views with graphico-numerical approaches and symbolic forms.

For instance, in our experiment, the limit concept was introduced from an intuitive view that a function 'tends toward zero as x tends toward zero'. Students did a lot of graphic and numeric work, passing from '$f(x)$ is small when x is small' to '$f(x)$can be arbitrary small provided that x is small enough'. Then students had to study by the same means standard, as well as non regular, limits before the *limit* function of the TI-92 was introduced. After this it was time to consider the symbolic aspects of the concepts, namely the algebraic rules by which a person or a machine is able to obtain limits of expressions. Students could consider several examples on how the TI-92 computes limits and then learn to do those calculations by themselves. In this process the student had more self-reflection than in a formal approach where the teacher demonstrates the rules.

Conclusion

Comparing earlier approaches where mathematical knowledge is thought to be built from situations of personal interaction with the computer, the contribution of a complex calculator like the TI-92 appears different: the calculator acts as a mediator

for the action of students. In this mediation technology is by no means neutral: meeting new potentialities and constraints the students have to elaborate utilisation schemes, potentially rich in mathematical meanings. For this potential to be effective, attention is to be paid to the understanding that the students build in this genesis, and techniques of use of the calculator should be discussed in the classroom to improve students' schemes. In the learning of pre-calculus, teaching should help students to develop adequate algebraic knowledge and flexible connections of various representations of concepts. With respect to this aim, the analyse of the interaction of utilisation schemes is a key to design tasks and situations involving students' use of a complex calculator.

STORING A 3D IMAGE IN THE WORKING MEMORY

Lea Latner and Nitsa Movshovitz-Hadar
Technion - Israel Institute of Technology, Haifa, ISRAEL

Abstract

This paper elaborates on some lessons learned from observing high school graduates while performing tasks in 3D geometry. We observed difficulties, which we were able to attribute to a change in the original mental image of a solid, created by students who were presented with its 2D perspective drawing. Evidently, the original mental image changed unwillingly while performing the task. In some cases it was replaced by a different 3D image, and in other cases, by a 2D image. In some cases the student was aware of the change as it occurred, while in other cases the change happened unnoticed. Following the description of such observations, an attempt is made to explain them, applying theories regarding the storage of information in the working memory.

Background

Israel Matriculation exams results indicate that the percentage of students choosing to answer questions in Solid Geometry is lower then the percentage of students who chose to answer questions in any other mathematical area. Moreover, of those who chose to tackle such a problem, the percentage of those who complete it successfully, is significantly lower than the percentage of students answering correctly questions in any other area. We found this phenomenon intriguing and set ourselves to study the difficulties students face while performing tasks in solid geometry and in other related areas requiring spatial ability.

Although a consensus as to the components of spatial ability, has not as yet been reached, most researchers (e.g. Clements & Lean 1981, Bishop 1983, 1989 Lohman 1979, Yakimanskaya 1991, Battista & Clements 1988) point at some or all of the following as major ones:

a. The ability to create a mental image of a solid in 3D space;
b. The ability to retain this mental image;
c. The ability to manipulate a mental image;
d. The ability to "see" the relations among the various parts of a solid.

This paper is focused on the first two components. Using evidence collected in a series of interviews it demonstrates some phenomena which can be attributed to difficulties in storing a mental image of a 3D solid, created from its 2D representation provided on paper, and to difficulties in keeping the mental image intact, while attempting to perform the task.

Theoretical Framework: Working memory

Cognitive psychologists distinguish between long term memory (LTM) and short term memory (STM). Since the beginning of the 20th century, studies of STM focused primarily on the number of items stored, items that are not necessarily related to one another. Those studies concluded that STM is limited to an average of seven items. Atkinson & Shivering were (in Loggia 1991) the first who came up with a more complex model to STM that included the distinction of working memory. According to their model the main function of the working memory is to store information while engaging in a thinking process such as planing, or problem solving. Consequently, one should regard the working memory as a calculating area with operational abilities. While performing a complex task that requires many calculations, a need arises not only to store numerous mid-way results, but also to organize them in the working memory in a way that relates each of them to the work in progress. There is a distinct difference in capacity and content between the working memory and the short-term memory. Not only can the working memory store five to seven separate and unconnected items, it must include also pointers that connect the different items to one another.

Carpenter & Just (1989) claim that there is a mutual relationship between the capacity of the working memory and the two functions it performs: (i) as a storage area; (ii) as a calculating area. When a need arises to use one of these functions in an extensive manner, it overrides the other function. If calculations are carried out more or less automatically, there is more room in the storage area.

The study, parts of which are described in this paper, was based upon a set of tasks that required both functions of the working memory.

The Method

The study was based upon semi-structured interviews with high school graduates, each lasting a total of 5-8 hours in 2-3 meetings. A special instrument was designed to guide the interview. It consists of 26 tasks, all of which required a certain degree of spatial ability. Each interviewee was required to perform the tasks while "thinking out loud". The process was recorded. (A few sample tasks appear in the next section.)

Performing each task, required creation of a mental image of a 3D object represented by a 2D perspective drawing on paper, and manipulating it. In other words, all tasks required retaining the mental image of the object throughout the performance. The 2D drawing remained available to the interviewee, throughout the time of performance.

All the interviewees took advanced level math in high school Prior to the interview, each of them took ETS - a standard 3D exam, in order to determine their spatial abilities.

Observations

Three observations are documented below. They all indicate difficulties in maintaining the same mental image created by the interviewee when presented with the figure included in the task, throughout the period of time devoted to the task. Note that each task starts in a request to describe the configuration presented in the figure, followed by a request to operate upon it.

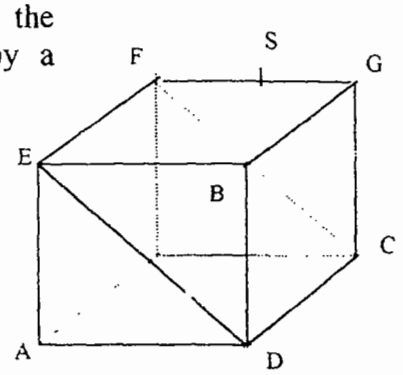

Figure 1

Observation no. 1
The task:

Consider a cube ABCDEFGH, and the plane EFCD (see Figure 1)

a. *Use your own words to describe the cube and the relative position of the plane.*
b. *S is the mid-point of FG. Find a symmetrical point to S, with respect to the plane FECD.*

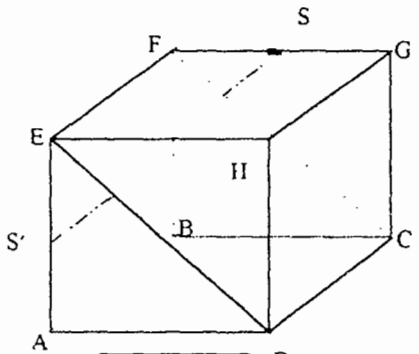

Figure 2

Ilana's answers

To part a: "It's a cube, it's a right cube, the plane crosses through the middle, inside the cube."

To part b: "Where do I drop the perpendicular to this plane? Perpendicular from S to the plane... oh.... I don't know where to drop it".

She drew the perpendicular from S to FC and extended it to the middle of EA. (Marked by------ in figure 2) and said: "I measure the distance by sight."

Observation no. 2
The task:

Consider a cube ABCDEFGH and the triangle GAD

a. *Using your own words describe the relative position of the triangle inside the cube.*
b. *Draw the angle between the triangle and the face EFGH.*

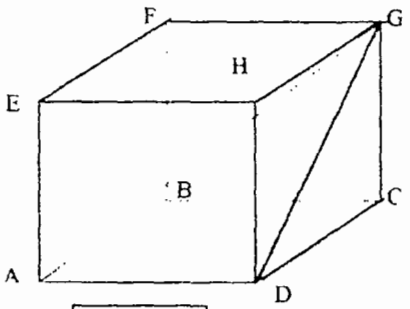

Figure 3

Hanna's answers

To part a: "The triangle (points to GAD) is slanted. No, actually it is not slanted. (She closes her eyes in an effort to visualize it, she uses her hands to draw in the air). "Yes, it is tilted, if it was from H it wouldn't be slanted."

To part b: "We need to drop a perpendicular to FG from triangle AGD. I don't know how to drop such a perpendicular. Wait ...., we extend DH... and then, create the perpendicular (marked by ------ in figure 4)..., DHEA is perpendicular to GHEF, I don't know, it can't be like that, I'm working in two dimensions....".

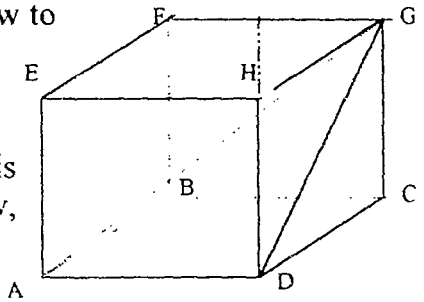

Figure 4

In the concluding part of the interview with Hanna, she tried to explain the phenomenon, as she perceived it: "When I concentrate more on the angles I switch to two dimensions. Because it is easier for me, because I understand the angles in two dimensions, the angles in 3D are different, they are not the same as in 2D."

Observation no. 3

The task:

Consider a right triangular prism ABCDEF, and a segment GA, where G is the mid-point of DF)

a. Using your own words describe the prism and the relative position of GA.

b. What angle is created between GA and AB?

Michael's answers

To part a: "Oops...I saw it a moment ago...oops, oops... I see it alright, but now it is different than I saw it earlier"

To part b: "GA with AB, oh, oh, oh.... Do you know what just happened to me? All of a sudden the prism turned outside-in. I'm trying to turn it back....how do you want me to see it, as a tent? No I didn't see it as a tent...I saw it... I can't get in to that now. I saw an oblique tent, but now I see a straight tent."

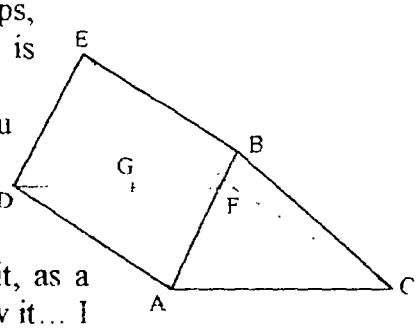

Figure 5

Observation analysis

Observation no. 1: The verbal description included in Ilana's answer to part a, indicates that she had created a 3D mental image of the cube and the plane inside it. In the first part of her answer to part b, the first mental image was still stored in her memory, while trying to drop the perpendicular from S to the plane. From her saying "how do I drop a perpendicular to the plane?" one can assume that she was familiar with the definition of symmetric points with respect to a plane. She knew she must drop a perpendicular. She also knew she must extend the perpendicular beyond the plane: "I measure the distance by sight", she said. However, she failed to execute it. A reasonable explanation for this gap is that the difficulty occurred because, while thinking about the process, the original 3D image of the object she created, was swapped with a 2D. Unaware of that switch, she created a new, flat image in which the lines FG and EA are on the same plane with the rectangle oblique plane. (See figure 6 as compared to Figure 2).

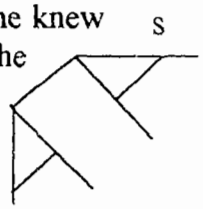

Figure 6

Observation no. 2: The first mental image created in Hanna's mind was most probably of a 3D object, as can be gathered from her reply to part a. However, due to her efforts to drop a perpendicular in the triangle plane, she lost her original 3D image and created a new 2D image of the object. In the new image DH, when extended, intersected with GF creating a straight angle: "Wait", she said, "... we'll continue DH and then create the perpendicular." At that point Hanna noticed she was working with a 2D image: "I was working in two dimensions", she noted, and reconstructed the cube image: "DHEA is vertical to GHEF". From that point Hanna managed to maintain a 3D image of the object. Unlike the interviewee in the first observation, in this case the interviewee was well aware of the fact that she was working in 2D, although she wasn't aware of the exact moment the image dimensional swap took place. Only after working a while in 2D did she realize it.

Observation no. 3: In the described event Michael was aware of the exact moment the image swapping took place, while examining the relations in the drawing. His awareness to the moment of the image swapping, enabled him to stop his work until he managed to concentrate and reconstruct his first 3D image. Due to the described circumstances this phenomenon is less serious than the previous one. Nevertheless, it may withhold the completion of the task due to the time necessary to concentrate and reconstruct the first image.

Discussion

The findings described above exemplify one phenomenon in three different levels, the phenomenon of change in the original mental image of a spatial configuration, while operating upon it. The 3D image stored in the working memory, goes through involuntary changes, while performing the task. In the first case the interviewee was not aware at all of the change, in the second case the interviewee was unaware of the exact moment the image swap occurs, although she became aware of it later on, while the third interviewee did notice it instantaneously. In the first two cases the change was from a 3D image to a 2D image and caused real difficulty in completing the task successfully. In the third case it was a matter of time and effort only, since the image twist was from one 3D to another one, as good as the first one.

The phenomenon described in the third observation is well known. Focusing continuously on some drawing, or attempting to examine the relations among different elements of a 3D object described in a 2D figure, may cause the first 3D image to modify. The back part of the object FD (see figure 7) "pops out" and creates the impression that the object turns inside-out or the other way around. This well-known phenomenon, especially related to cubes, is known in psychology literature as "Necker Cube phenomenon". This phenomenon occurs when the drawing of the object has a few stabled positions. One of the interpretations to this phenomenon is that the memory brain cells containing the object in one of its stabled forms wear down, and other brain cells take their place in storing the object, but this time in a different stabled form.

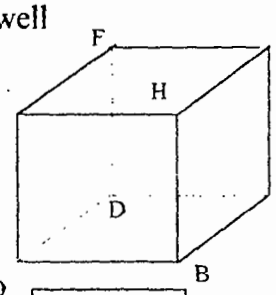

Figure 7

In our study we had many occurrences such as the third case. In all of them, except one, the original 3D image changed into another 3D image. In one case (which isn't mentioned in this paper) the 3D image changed involuntarily into a 2D image. This single event may indicate that the three observations described above are related to one another. The difference between the first two and the third one is whether or not the interviewee was aware to the moment the image swap occurred. Lack of awareness in the first two observations leads to unavoidable errors, while the in third one there was a temporary loss of concentration, not necessarily yielding an error. These findings are summarized in Figure 8.

In general, in many cases a 2D object requires a lot less room in the working memory than a 3D object both having the same 2D figure representation. For instance, a right angle in 2D drawing of a 2D configuration appears as such, while a right angle in a 3D configuration does not necessarily take the form of a right angle in a 2D drawing of that configuration. Consequently, it consumes more room in the working memory.

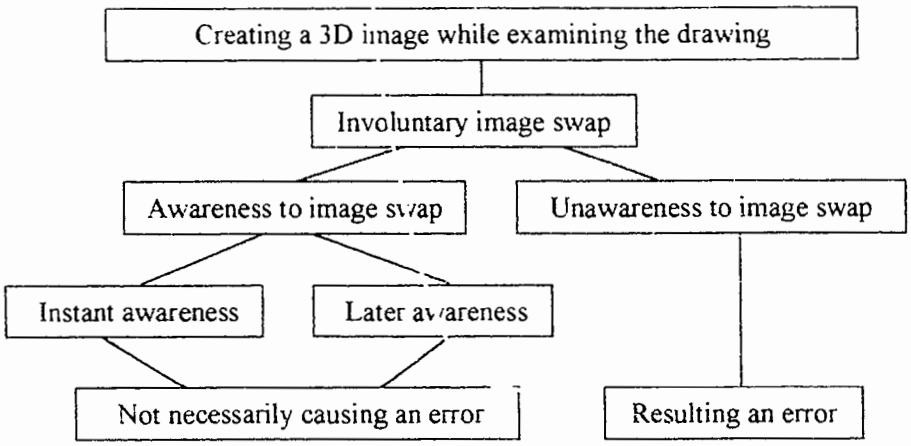

Figure 8

Observation no. 1, 2 may be explained as an overload in the working memory. As mentioned earlier, the working memory fulfills two functions, storing information and processing it. Each one of the two functions occupies memory space. Interviewees who spent a considerable amount of time in examining the relations within a drawing, had to store many details of the object's properties. We suggest that our first two observations can be explained by that storing and processing all the needed information, overloaded the interviewee's working memory. As a result some of the information, in particular information concerning the depth of the 3D image, was lost in the process. The 3D image changed into a 2D image as the 2D image occupies less space in the memory.

EXPLORING VAN HIELE LEVELS OF UNDERSTANDING USING A RASCH ANALYSIS

Christine Lawrie
Centre for Cognition Research in Learning and Teaching
University of New England, Armidale, Australia

This paper reports a study designed to explore the difficulties associated with the development of appropriate test questions suitable for determining van Hiele levels of understanding in geometry. Initially, a written test based on the Mayberry interview schedule was designed and given to 60 pre-service primary teachers. Analysis of the results by concept and by level led to the identification of strengths as well as inconsistencies in the items. The initial results for the items were then processed using the QUEST software application of the Rasch partial credit model provided by Masters, and analysed in depth. The purpose of the Rasch analysis was to provide a quantitative edge to what had been primarily a qualitative procedure. This paper presents the findings of the Rasch analysis.

Many difficulties are associated with the designing of appropriate test items for determining the van Hiele levels of understanding in students, and with the assessment of the students' responses to the test items. To make an assessment, there needs to be available a reliable diagnostic instrument. At the University of New England, Australia, a written test based on the Mayberry (1981) interview schedule was designed. The items tested for understanding in seven geometric concepts. Each question was designed to the operational definition of one of the van Hiele levels. Examination of the initial assessment of student responses indicated inconsistencies in the results (Lawrie 1997, 1998). To confirm the initial results and to explore further the strengths and weaknesses of the test items, the results were analysed using an application of the Rasch model. In this article, an analysis of the Rasch model results is presented. Before doing this, a brief background to the important ideas underpinning the study is presented.

Background

The van Hiele Theory

In the 1950s, Pierre van Hiele and Dina van Hiele-Geldof completed companion PhDs which had evolved from the difficulties they had experienced as teachers of Geometry in secondary schools. Whereas Dina van Hiele-Geldof explored the teaching phases necessary in order to assist students to move from one level of understanding to the next, Pierre van Hiele's work developed the theory involving

1006

five levels of insight. A brief description of the first four van Hiele levels, the ones commonly displayed by secondary students and most relevant to this study, is given:

Level 1 Perception is visual only. A figure is seen as a total entity and as a specific shape. Properties play no explicit part in the recognition of the shape.

Level 2 The figure is now identified by its geometric properties rather than by its overall shape. However, the properties are seen in isolation.

Level 3 The significance of the properties is seen. Properties are ordered logically and relationships between the properties are recognised.

Level 4 Logical reasoning is developed. Geometric proofs are constructed with meaning. Necessary and sufficient conditions are used with understanding.

The van Hieles (van Hiele 1986) saw their levels as forming a hierarchy of growth. A student can only achieve understanding at a level if he/she has mastered the previous level(s) They also saw (i) the levels as discontinuous, i.e., students do not move through the levels smoothly, (ii) the need for a student to reach a 'crisis of thinking' before proceeding to a new level, and (iii) students at different levels speaking a 'different language' and having a different mental organisation.

The Rasch scaling model

The Rasch partial credit model was first introduced for the analysis of dichotomously-scored responses in 1960. When data are fitted to the model, person parameters can be freed from the item difficulties and item parameters can be estimated independently of the calibrating sample. Masters (1982, p. 163-166) used a maximum likelihood procedure to estimate the parameters in the model. Means and standard deviations of the infit (weighted) and outfit (unweighted) statistics allow a check on how well the data fit the proposed mode. The advantage of the partial credit model over other models is that the parameters in the model are separable. This allows on a single scale, a measure of item difficulty, and of an individual student's ability to achieve success.

The QUEST Interactive Test Analysis System (Adams & Khoo 1993) which is based on Master's procedure, was used to process the data. This software includes the most recent developments in Rasch measurement theory for the analysis of test and questionnaire responses as well as traditional analysis procedures. Three measures are available to check on the suitability of the tests as a measure of geometric understanding. First, the item consistency is used to estimate the extent to which items reflect the same underlying construct. Second, the fit statistics for question estimates and student estimates can check whether the data compared favourably with the model. Third, the infit mean square map shows the level of

parameter fit in the model for each question. The estimates produced by QUEST are used to create a number of statistics which then allow analysis of various features of student performance and of the hierarchy of level used to code the questions.

Design

To investigate the difficulties associated with the assessment of van Hiele levels of reasoning, a detailed study of the geometric understanding of 60 pre-service primary teachers was carried out at the University of New England, Australia. The study aimed, in part, to provide a written test based on the Mayberry (1981) interview schedule in which each item was designed to the operational definition of one of the van Hiele levels. The items tested for understanding in van Hiele Levels 1 to 4, in seven geometric concepts, square, right triangle, isosceles triangle, circle, parallel lines, congruency and similarity. To accommodate time restrictions, the seven concepts were divided between two test papers, Papers I and II. Initially the responses of students to the written test were assessed using Mayberry's pass/fail scoring method of evaluation. Follow-up interviews were conducted with students to validate the levels of thinking as determined in the written test. When collating the results, inconsistencies in the assignment of van Hiele levels for some students emerged (Lawrie 1997). Interviews did not appear to clarify these inconsistencies. The QUEST program (which utilises the Rasch measurement theory) was applied to the results to confirm the initial assessment, to confirm patterns which emerged in the results, and to determine whether there were any other patterns not yet identified, i.e., the Rasch analysis was applied to give a sharper quantitative edge to what had been primarily a qualitative procedure.

Initial Results

Table 1

Highest level achieved by the Australian students for each concept (% of sample)

Concept	No Level	Level 1	Level 2	Level 3	Level 4
Square	0	3	84	7	7
Right triangle	3	19	55	19	3
Isosceles triangle	7	27	43	20	3
Circle	0	13	19	52	16
Parallel lines	0	17	80	0	3
Congruency	0	32	35	3	29
Similarity	0	43	40	10	7

The results of the initial assessment of the students' levels of understanding are summarised above in Table 1. When students failed to identify concepts, their results were recorded as No Level. All results are given as percentages, with the horizontal sums being (approximately) 100%.

The results show that the majority of students (77%) were assessed as having mastery of no greater than Level 2 understanding, i.e., they were comfortable recognising concepts and listing the associated properties, but did not understand the relationships between the properties.

The results (7.8%) of a few of the students showed inconsistencies in that the results did not validate the level hierarchy. One particular issue related to the inconsistencies was that some of the items did not appear to be measuring the van Hiele level for which they had been designed.

Results using the Rasch model

The QUEST software application (Adams and Khoo 1993) which utilises the Rasch measurement theory was applied to the results. A comparison drawn by the program between the relative degrees of difficulty of the question parts demonstrated patterns which support the van Hiele level structure, and produced an estimate of geometric understanding for each student. The reliability of estimates for both items and cases, and the internal consistency parameters were all close to 1, showing that there was good separation between the items and between the cases, and that the items came from the same underlying construct, i.e., geometric understanding. All the infit and outfit mean squares for item and case estimates were close to one, indicating that the data fit the Rasch model well.

The statistics from the QUEST application indicated the following patterns. For the infit mean square maps, the items with the largest values are those which have been answered correctly by a greater than expected number of weaker students, and incorrectly answered by a greater than expected number of better students. Almost all the items with largest values were found to be testing for understanding of van Hiele Level 1. This suggests that while the questions were clear to the weaker students, the better students may have had difficulty in interpreting the thrust of the Level 1 questions. Second, the item estimate maps showed that Level 2 question parts requiring the identification and naming of properties of sides of figures generally had lower difficulty thresholds than those requiring demonstration of knowledge of angle properties. This indicates that students were more confident with, and had a better awareness of properties of sides than properties of angles.

The calibration of the likelihood of students to answer items correctly in the item estimate maps showed that the average student was able to give a correct response to questions testing for understanding of van Hiele Levels 1 and 2, together with a very few of the questions testing for understanding of Level 3. The item estimate maps indicated also that the difficulty thresholds of some items supported the earlier observation that those items were unsuitable for measuring reasoning at the thought levels specified by Mayberry. In particular, difficulty thresholds for some Level 3 and Level 4 items suggested that the questions do not have sufficient complexity to measure the level for which each had been designed.

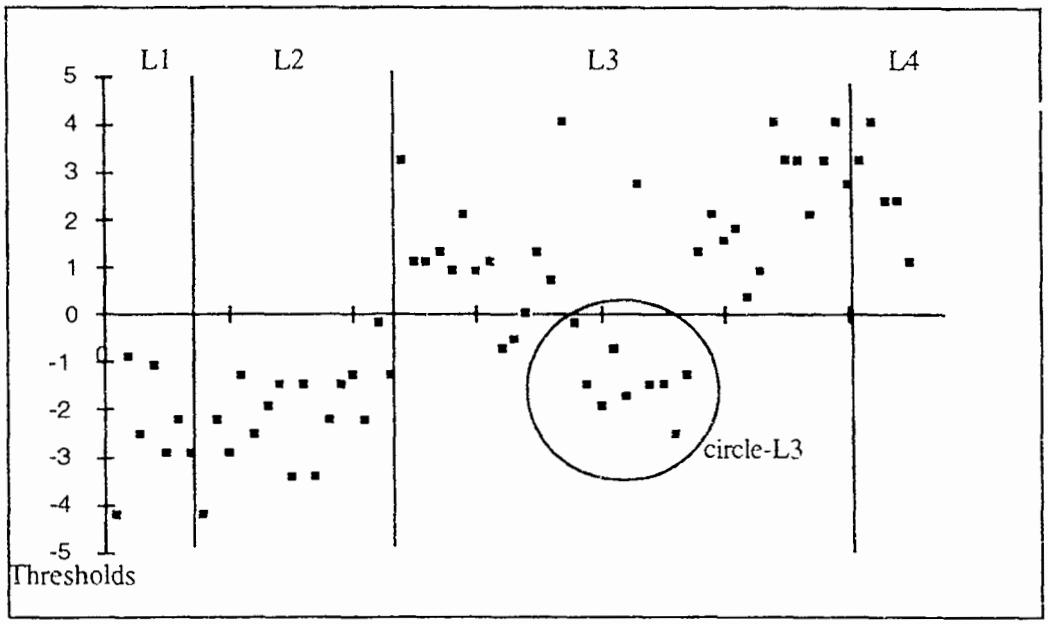
Analysis

To facilitate a deeper analysis of the results, the question parts were grouped by concept within each van Hiele level, then plotted against their difficulty thresholds. Any clusters appearing in the resultant graphs could indicate patterns worthy of analysis. The graphs are given in Figures 1 and 2. Each graph shows an increasing degree of difficulty from lower left to upper right, corresponding approximately with van Hiele Levels 1 to 4. However, the change in the degree of difficulty in both figures is much greater between Levels 2 and 3 than between the other levels. There is little discernible difference, and quite a degree of overlap between the degrees of difficulty for the questions set to test Levels 1 and 2, and, again, for Levels 3 and 4. This suggests that the students found the questions testing for understanding at Levels 1 and 2 to be similarly easy, while the questions testing for Levels 3 and 4 were found to be similarly difficult. Such an interpretation supports the results of the initial analysis, that the majority of the students were unable to demonstrate understanding for van Hiele levels higher than Level 2. The overlap between the levels suggests also that not all questions are testing for the van Hiele level for which they have been designed.

Figures 1 and 2 indicate that there is a greater range in the difficulty thresholds in Level 3 than in the other van Hiele levels. The item analysis gives the range as from -3.40 to +4.02. First, there are several items which have negative difficulty thresholds similar to the Level 2 items. This feature is discussed below. Examination of the items with positive difficulty thresholds led to the emergence of a further pattern. When the phrasing of questions was more generalised, the difficulty threshold of the questions was greater. Correspondingly, a lower difficulty threshold was associated with questions which used short direct sentences and which referred to or included diagrams. Thus, the larger than expected range

in the difficulty thresholds for the Level 3 items appears to result from the particularly wide variety of question types.

Figure 1
Thresholds of Items for Each van Hiele Level - Paper I



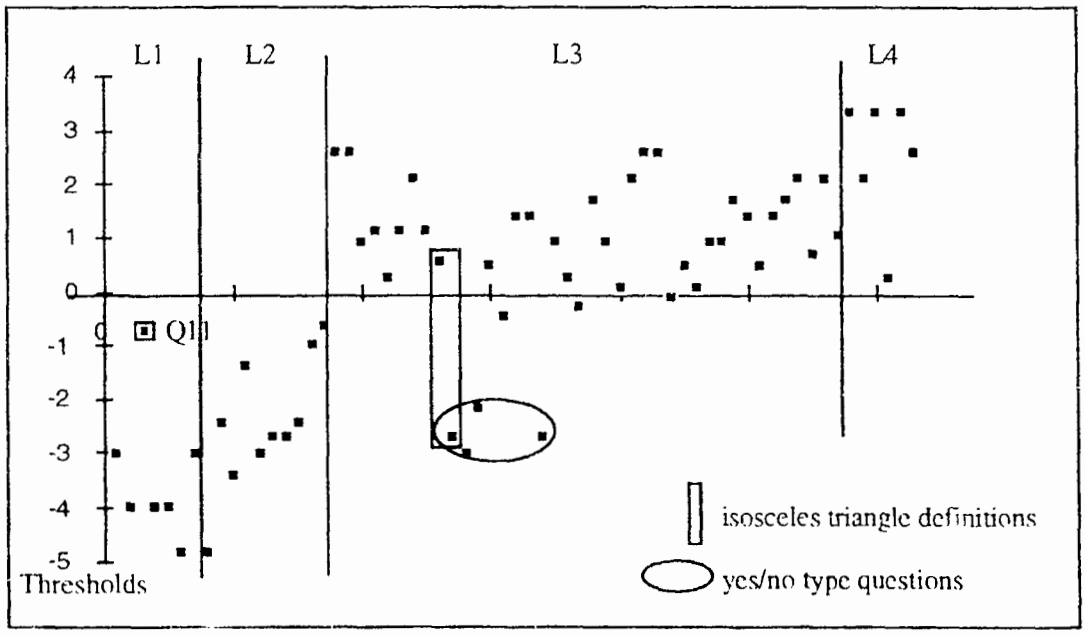


Figure 2
Thresholds of Items for Each van Hiele Level - Paper II

The four features highlighted in Figures 1 and 2 deserve comment. First, there is a cluster of nine items indicated by a circle in Figure 1. These question parts were all designed to measure for understanding of the circle at van Hiele Level 3. However, the graph indicates that the degree of difficulty of these nine question parts is similar to the degree of difficulty of the Level 2 items. This offers an explanation for the higher Level 3 success rate for the questions on the circle compared the results for other concepts, shown in Table 1. Second, Figure 2 shows a cluster of four items indicated by an ellipse. These question parts, which are across more than one concept, were also designed to test for Level 3 understanding. The four questions require either a simple yes/no response, or ask for recall of factual information. Their degree of difficulty is shown as being similar to that of the middle order Level 2 items, indicating that questions not requiring explanation of a student's answer do not necessarily provide insight into ability to reason at van Hiele Level 3.

Third, again in Figure 2, Q 11 is identified. The item was designed to test for Level 1 recognition of isosceles triangles. Its position in the graph and its threshold (-0.65) suggest that it is much more difficult than similar Level 1 questions. Examination of the item shows that a correct response requires identification of an equilateral triangle as an isosceles triangle, a Level 3 skill. Fourth, a rectangle in Figure 2 identifies two items showing noticeably different difficulty thresholds. Both questions test for awareness of necessary conditions in defining an isosceles triangle. However, Q 28 with the higher difficulty threshold (+1.41) probes for understanding of necessary conditions, while Q 29 (difficulty threshold of -2.72) asks for recall of a definition. This supports the above notion that questions requiring the recall of information without explanation of reasoning do not necessarily measure understanding greater than van Hiele Level 2.

Conclusion

The study employed a (relatively) new technique developed by ACER to provide a detailed quantitative analysis of the data. It involved use of the Rasch partial credit modelling process provided by Masters (1982). This allowed on a single scale, a measure of item difficulty, and of an individual student's ability to achieve success.

The purpose of the application of the Rasch model was to undertake a deeper analysis of the test items and the student responses than were available to Mayberry, and not previously undertaken in the area of geometry. Also, the analysis was designed to complement and extend the observations made in the initial results, by

giving a sharper quantitative edge to what had been primarily a qualitative procedure. Of significance are two features. These are:

1. The quantitative analysis confirmed the trends in the results which emerged in the initial analysis. These included confirmation that most students were able to demonstrate van Hiele Levels 1 and 2 understanding, but not higher levels of reasoning, and that not all questions were testing the level for which Mayberry had designed them.

2. Patterns in the responses which had not been perceived, or were not particularly clear in the initial analysis, emerged. Many of the Level 1 items showed the largest values in the infit mean square maps, indicating that higher performing students may have had difficulty in interpreting the thrust of these questions. A pattern made clearer in the QUEST analysis was that in the Level 3 questions, the more generalised the phrasing of, the greater was the degree of difficulty experienced by the students.

The focus of the analysis of the initial results on how students performed on a written test version of the Mayberry questions led to the identification of inconsistencies in the reasoning of some students. The QUEST analysis confirmed the occurrence of these inconsistencies.

RETURNING TO UNIVERSITY: MATHEMATICS AND THE MATURE AGE STUDENT[1]

Gilah C. Leder and Helen J. Forgasz
La Trobe University, Australia

Abstract

In this paper we examine what motivates mature-age students to commence mainstream tertiary mathematics courses and subsequently to persist, modify or drop-out of their courses. Our explorations were shaped by the model of academic choice proposed by Eccles (Parsons) et al. (1985). Earlier findings from the study were presented at a previous PME conference.

Introduction

In many countries more students than ever before are accessing higher education. Yet, there is growing international concern about enrolment profiles and waning interest in the study of advanced mathematics (Jensen, Niss, & Wedege, 1998). The changing emphasis in Australia for entry into higher education from school leavers to first time participants, irrespective of age, was an important impetus for the present study.

What are the factors that motivate mature-age students[2] to commence mainstream tertiary mathematics courses and to make subsequent course-related decisions to persist, modify or drop-out of their courses? How effective are older students in utilising the opportunities for participation in tertiary mainstream mathematics courses and how do institutions respond to their specific needs? These questions formed the framework for a three year semi-longitudinal study. The study is now in its second year and comprised four phases:

1. determining relevant factors to explore (through an extensive literature review)
2. determining enrolment patterns of mature-age mathematics students
3. a large scale quantitative survey across five universities
4. a longitudinal qualitative study, to allow in-depth exploration of affective and related factors, of a smaller sample of mature age mathematics/science students.

Results from the first three phases, and the methods used, have been reported elsewhere (e.g., Brew, 1998; Forgasz, 1998a, 1998b; Forgasz & Leder, 1998; Leder 1998; Leder & Forgasz, 1998). In this paper we focus primarily on data gathered as part of the fourth phase.

The *model of academic choice* proposed by Eccles (Parsons) et al. (1985) served as an initial framework for probing the data. The model has previously been used to explain subject choice decisions of students and is assumed to be sensitive to gender differences. The authors contend that:

> choice is influenced most directly by the students' values (both the utility value of math for attaining future goals and the attainment or interest value

[1] The financial support of the Australian Research Council and the research assistance of Chris Brew are acknowledged with thanks

[2] Students who are 21 or over on March 1 of the year in which University entry is sought

of ongoing math activities) and the students' expectancies for success at math. These variables, in turn, are assumed to be influenced by students' goals, and their concepts of both their own academic abilities and the tasks demands. Individual differences on these attitudinal variables are assumed to result from students' perceptions of the beliefs of major socializers, the students' interpretation of their own history of academic performance, and the students' perception of appropriate behaviors and goals. (pp. 97-98)

Research aims

Whether the variables identified by Eccles et al (1985) likewise shaped the attitudes and decisions of the mature age sample in selecting and continuing with university mathematics is discussed in this paper. Concentrating on two students also allowed us to contrast the survey data gathered as part of phase 3 of the study with the much richer information yielded by the qualitative methods used in phase 4.

Literature review

Previous Australian research has indicated that gender, socio-economic status [SES] and home location (urban/rural) influence school completion rates (e.g., Ministerial Council on Education, Employment, Training and Youth Affairs [MCEETYA], 1994).

Students' attitudes to tertiary studies, decisions to enrol in higher education courses, and level of achievement attained appear to be influenced by a range of social, cultural and affective factors, the desire to pursue academic interests and to gain entry into an attractive career (McInnis, James, & McNaught, 1995; Ramsay, Tranter, Sumner & Barrett, 1996). Course related factors, such as difficulty, pressures, expectations, poor teaching, and boredom can also contribute to students' decisions to drop out of university (Abbott-Chapman et al., 1992). Impersonal and large class sizes, an ineffective tutorial system, lack of support, assistance and encouragement, and poor facilities were critical learning environment factors cited by withdrawing students. Pedagogical approaches, curricular content, the ethos of a mathematics department, and perceptions of discrimination have been given by mathematics students as reasons for their withdrawal (Forgasz, 1998a; Rogers, 1990; Taylor, 1990).

Australian studies (e.g., Hore & West, 1980) found that mature age students are typically from lower SES origins than younger students and that parental expectations for daughters to pursue tertiary education were often low. Forgasz (1996) and Pierce (1995) repoted mature age students to be highly motivated and success-oriented.

Overview of the project's instruments

Five data gathering tools were used: a survey questionnaire, interviews, regular e-mail (or snail-mail) correspondence, 'tag for a day', and the *Experience Sampling Method* (Csikszentmihalyi, Rathunde, & Whalen, 1993) or 'beeper-activated' schedule. A summary of the methods, with sample items, is shown on Table 1.

Table 1. Summary of data gathering methods

Method/Contents	Selected Sample items
Survey computer	1a. Do you regularly speak a language other than English at home?

Method/Contents	Selected Sample items
scorable and open-ended items. Four main clusters: 1. biographical/ background details 2. enrolment issues 3. affective dimensions 4. perceptions of mathematics learning environment	(Yes/No) b. Parents' educational backgrounds (open) 2a. What degree/s are you studying? (open) b. Why are you studying mathematics? (check boxes from list provided) 3a. How good are you at mathematics? (1-5 rating) b. Do you enjoy university mathematics? (Yes/No/Sometimes) 4. Re: University mathematics: • well taught (5-point Likert: SA-SD) • lecturers approachable (SA-SD) • assessment is fair (SA-SD)
Interviews: semi-structured interview protocol (same issues as for survey)	• Tell me about your life pathway that has lead you to being enrolled in your current course. • Comment on university teaching: e.g., quality/ approachability of lecturers/tutors, level of support
E-mail/Snail-mail: monthly communications. Varied formats included open and closed items.	**May message**: How have you usually felt during lectures over the past month? (Mark with an "X" as many words that apply): interested; relaxed; worried; successful; confused; clever; happy; bored; rushed; panicky. Write one or more words of your own. **October message**: What are your reactions to your studies at university this semester? [content of courses, lectures, tutorials, assignments, pressures on your life etc.]
"Tag": spend time with student on campus. Observations recorded in field notes.	Observations of: • learning environment (to compare with student's views) • behaviour in lectures, with other students etc. Keep notes on conversation details
"Beeper": for six consecutive days, students were 'beeped' six times daily They recorded what they were doing and feeling at these times on prepared *Experience Sampling Forms* [ESF]. Study, as well as other activities, were thus captured.	**As you were 'beeped':** • Where were you? ..... • What were you doing? ..... *On 5-point scales* (not at all - completely/very much) • Were you living up to your own expectations? • Was this activity important to you? • Were you satisfied with how you were doing? **Mood**: (semantic differential type; 5-point scale) irritable - cheerful; competitive - cooperative

The participants

Mature age students (99 students out of a total sample of 815) who completed the survey questionnaire were invited to participate in later stages of the study. Of those who volunteered, 26 were interviewed. Not all chose to participate in all qualitative data gathering phases. A summary of the sample sizes for each phase of the study to date is shown on Table 2.

Table 2. Summary of number of participants in each stage of the study to date

Survey	Interviews	E-mail	"Tag"	"Beeper"
99	26	19	9	21

The two students for whom we present data in this paper are Caitlin and Boyd (pseudonyms). Both were enrolled at the same university which, according to the large scale survey findings, was highly ranked on many of the tertiary mathematics learning environment variables tapped (see Forgasz & Leder, 1998).

Results and discussion: What the data say about Boyd and Caitlin

The survey data

Survey responses from Boyd and Caitlin revealed that they had similar English-speaking home backgrounds. They could be considered to come from low socio-economic [SES] circumstances, as indicated by their parents' educational levels (no tertiary education) and occupations (working class), and the school type (government) they attended. Neither Boyd nor Caitlin was in a permanent relationship and both lived in rental accommodation.

Both Boyd and Caitlin were enrolled as part-time students - Boyd in a mathematics and computer science diploma course and Caitlin in an Arts degree, majoring in mathematics. Neither received government financial assistance to study. Boyd had previously completed a degree course. At different times, Caitlin had begun, then dropped out of two university courses. Dissatisfied with her current situation, Caitlin wanted to enhance her career prospects and finally live up to family expectations. She chose mathematics because she had been successful at it in school. General curiosity and an interest in quantum mechanics (and later possibly in research) were Boyd's main reasons for studying mathematics. Both had enjoyed school mathematics but Boyd's school mathematics background was stronger than Caitlin's.

Both also enjoyed their mathematical studies at university. Boyd felt that he was excellent at mathematics and expected to achieve highly. Caitlin believed she was good at mathematics and also expected to excel. They did not think they were likely to drop out of a mathematics subject during the year. They found university mathematics to be fairly easy but challenging, believed they understood the work and were confident of passing. They considered that the subject was well taught, lectures were not boring, sufficient individual help was available, lecturers were approachable, and assessment and the work load were fair. Both indicated that they had neither perceived nor experienced any form of discrimination within the mathematics department.

From the survey data responses, Boyd and Caitlin appear to be similar. Much more was learnt about Boyd and Caitlin from the in-depth qualitative data.

Qualitative data sources

Interviews. Interviews were conducted early in the second year of the study. Summaries, including selected quotations, of the students' perceptions of themselves as mathematics students and of the learning environment are shown on Table 4.

Table 4. Summary of interview data for Caitlin and Boyd

Boyd	Caitlin
Past experiences and affective issues	
• failed maths "spectacularly" at school -	• excelled in mathematics at school

did not like it; returned to do grade 12 mathematics in 1996 - now has genuine interest in the subject. • 1st time at university: began BSc - transferred and completed BA • works in health-related job; felt he was burning out and also feared redundancy • studying now because of interest in quantum mechanics and philosophy; chose "mathematics rather than physics because I don't like laboratory classes... never get experiments to work" • finds 2nd year demanding; uncertain how far he will go	• parents: high expectations despite no-one in family with tertiary qualifications • 1st attempt at tertiary study: very poor, got involved in other things, dropped out • 2nd attempt: part-time: financial and personal crises, dropped out again • Now has different attitude - no parental pressure; "most important thing is to... get this degree after all the torment that it's caused me". "The greatest thing I've had to overcome is the confidence... to come back and give it another shot and succeed". • believes male mature age students have clearer vocational goals for studying mathematics than she has. Wants to work in a field that uses mathematics; thinks this unrealistic. Mixes mainly with male mature age students; sees female mature age students as sitting alone and fairly quiet. • derives pleasure out of "stretching my mind"
Perceptions of learning environment	
• noticed enormous gender imbalance: "This year is a less macho environment as the macho ones simply did not pass the first year". • expected staff to be intimidating but found mathematics tutors helpful.	• staff approachable, "only complaint... sometimes finding people talking down to me because I don't know as much about their field as they do".

E-mail correspondence. Both Caitlin and Boyd replied to all four e-mail/snail mail messages (May, July, September & October, 1998). Relevant responses to items probing their past experiences, tapping affective issues with respect to mathematics and views of the tertiary learning environment are summarised on Table 5.

Table 5. Summary of e-mail/snail mail correspondence from Caitlin and Boyd

Boyd	Caitlin
Affective factors	
May: Busy with university politics. Pain from old injury "disruptive enough to cause me to fall behind". "Enchanted" with one of his two mathematics subjects; "humoured" and "entertained" by lectures; "challenged" by tutorials. *July*: "Confident" in one mathematics subject; "worried" about the other. *Sept.*: "Apathetic & lethargic" about studies this semester. Has "a major motivational slump... towards studying the course material". Spending much time on mathematics unrelated to course: "In a way I can actually achieve my goals without even completing the course". *Oct.*: depressed and very stressed about	*From May & July.* Part-time job change: "I'm not sure whether this affected my exam performance but it was not an ideal way to study & I felt very stressed". "Not as well prepared [for examination] as I would have liked... [performed] very well... made two mistakes... very frustrating". *Sept.* Pleased with previous semester grade (A+); This semester even better: Enjoying studies, would like to be full-time: "I feel very confident and comfortable with the maths department and with my abilities". Work less stressful, has more money; "studying more... doing well" *Oct.*: Motivated "...by doing well .. [and] by interest in the subject". "I am amazed at how good a student I am nowadays... still afraid of the fall...". Friends (other mature age students) who study mathematics

employment and family Believes he failed one mathematics examination; did not take the other - opposite to initial intentions.	are "great for keeping up enthusiasm...". Expects to perform well, "doing better than expected"
Mathematics learning environment	
May: Lectures: "I think the lecturers in mathematics are very dedicated to the students". Tutorials: ". . best if answers are explained in far greater detail... many mature age students have a sketchy background in maths and are unfamiliar with assumed knowledge"; comments on own inadequate school level background. *July*: "tutor could learn a few teaching skills... treats us [as would] a primary teacher". Assignments: insufficient worked examples in text book to "serve as a guide" Examination: "Felt sufficiently prepared] but "didn't perform as well as I thought for [one subject] but I was pleasantly surprised [for other]". Applied for special consideration on medical grounds *Sept* no relevant comments *Oct.* spoke to mathematics lecturer before deciding not to sit for the examination.	*July*: Lectures: "I'd like... clear overview of what the subject is covering and quick summaries along the way". Had fruitful discussion with lecturers. Tutorials: "no improvement needed". Assignments: "... expectations & relevance clear and the time allowed reasonable... especially useful... Easy to be lazy... in tutorials". Exam.: Unfair - "I wanted the exam to test my understanding of topics, not just how to practice the methods of solving problems". *Sept.*: thinks "courses are administered well... feel very OK to approach staff... with questions". *Oct*: "always look forward to classes and enjoy diversity of format". High-point - tutorials "I love them, working through questions.. either alone of with someone else. It's great to speak maths, to iron out bad techniques, to see how my peers approach problems and get very personal direction" Low point - practice classes "[I] feel very isolated Most of the class are young men and they tend to congregate and be very rowdy. I feel self-conscious, sitting alone and being so quiet. I wonder what they think of me...".

"Tag" and "beeper" data. Boyd and Caitlin were 'tagged' for about two hours on the days they were handed the beepers. Serendipitously, both were 'tagged' by the same researcher, on the same week day, at the same time of day, one week apart (Caitlin first). Both students were enrolled in the same second year mathematics unit. The researcher accompanied them to lectures. Field notes revealed that they behaved differently during the lecture. Caitlin concentrated and summarised the lecturer's notes. Boyd was less focussed and copied the notes verbatim. However, the researcher and both students concurred on the high quality of the lecturer.

Experience sampling forms.

Space constraints do not allow a detailed discussion of the data gathered in this way. Briefly, Caitlin's and Boyd's responses to the ESF prompts confirmed the impressions gathered from the interviews and their e-mail responses. For example, in his July e-mail message Boyd had commented on the lack of sufficient practice examples. When asked "What were you doing" when beeped, we learnt that Boyd used his travelling time on public transport to read a book about mathematicians and their work and to attempt some of the examples given. The beeper signal also caught him at a number of meetings of the environment collective, one aspect of his involvement with student politics. Caitlin told us in September that she felt confident and expected to do well in mathematics. When we compared Boyd's and Caitlin's descriptions of their mood for the times the beeper signals caught them during studying activities, Caitlin consistently revealed herself to be happier, more confident, more focussed, and clear. Interestingly, Boyd had found the 'beeper' activity very therapeutic and requested photocopies of

what he had written.

Concluding comments

The findings reported in this paper reveal that data gathered from a combination of quantitative and qualitative sources are both complementary and supplementary. From the survey data alone it could be concluded that Caitlin and Boyd were quite similar people. Even though the qualitative data were consistent with many of their survey responses, they also revealed ways in which the two individuals differed.

Our data suggest that the Eccles et al. (1985) *Model of academic choice* partially explains Caitlin's and Boyd's selection of mathematics as an academic pursuit. However, there were other factors associated with their personal lives and psychological well-being, as well as aspects of the learning environment, that appear not to taken into account by the model. These factors may be critical in the students' decisions to persist with mathematics into next year. As yet, we are very uncertain about Boyd's future at university and more generally.

The findings also raise a number of questions to be explored further:

- How do the lives of mature age students with and without families differ?
- Is mature age study only open to those who are financially secure?
- Do all mature age mathematics and science students return to study to compensate for educational mistakes made on leaving school?
- Do all mature age students cope with inadequacies in their learning environments?
- How critical is the role of the institution and staff of the mathematics departments in which students are enrolled?
- Do all mature age students share the same strong initial motivation to succeed?
- Is there a pattern of difference in the roles and expectations of male and female students?
- Are the perceptions of university courses and the daily routines and pressures that may affect studies the same or different for mature age students from overseas and from different ethnic backgrounds?

ELEMENTARY SCHOOL TEACHERS' UNDERSTANDING OF KNOWLEDGE OF STUDENTS' COGNITION IN FRACTIONS

Yuh-Chyn Leu
National Taipei Teachers College, Taiwan, R.O.C

Abstract

This study was aimed to investigate elementary school teachers' understanding of knowledge of students' cognition in fractions. Instrument used was developed based on the theories of hierarchy of mathematics understanding in two stages. First, the results of elementary school students' fractions understanding was analyzed. Furthermore, the assessment instrument was developed based on these students' understanding.

136 subjects took the paper and pencil test. 33 were selected for interview. The findings: Elementary school teachers could be classified into three levels on their understandings of students' cognition in fractions. 18% of the elementary school teachers could be identified as excellent level.

Introduction

"Understanding the knowledge of students' cognition in mathematics" is one important component of the knowledge of mathematics teachers (Fennema et al, 1992; Markovits et al, 1994; Even et al, 1996). Research results supported the finding that having more or less of this type of knowledge effects teaching (Carpenter et al, 1989).

Fractions is closely connected to decimals, percentage, ratio and division. All of these concepts not only play important roles in mathematics but also occupy mass of the elementary mathematics materials. Students have many difficulties in learning fractions (Leu, 1991). Based on these reasons, this study wanted to investigate the elementary school teachers' understanding of the knowledge of students' cognition in fractions.

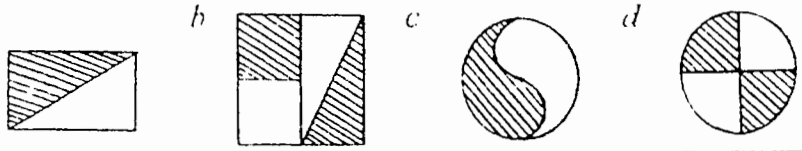
Because the coverage of the knowledge of students' fractions cognition is very broad, it's difficult to investigate all perspectives. This study only chose some important results of the theories of hierarchy of mathematics understanding, such as students' problem solving strategies, misconceptions and understanding levels etc. (Hart, 1981) as well as students' thinking tendency(Bruner, 1973). In this study, questionnaire and interview were used as research methods.

Sample and Assessment Instrument

Sample

A convenient sample of 136 elementary school teachers who took in-service summer school program in National Taipei Teachers College took the paper and pencil test in this study. Among these 136 subjects, 33 were selected according to the proportion of gender, teaching experiences and teaching grade from the 136 subject sample for semi-structured interview in one to one manner. It takes about 15 minutes to interview. To have the in-service training, these teachers had to pass a qualified exam. Based on their enthusiasm for learning and their capability, their performance on my research questions should be generally better than the average teachers.

Assessment Instrument



The paper and pencil test and the interview questions have developed on the understanding of students' fractions learning. Therefore, the tasks were developed in two stages. At the first stage, the information of elementary school students' fraction understanding was established. Tasks for elementary students were either designed by the researcher or from Yong(1987). At the second stage, five tasks for teachers were developed based on this information from the first stage. Each task has two forms. Students' tasks were firstly presented. Then the elementary school teachers were required to answer the difficulties students might have, the problems-solving strategies students might take or the reasons why students made those mistakes...etc. How the tasks were designed will be illustrated by following two examples.

Task 1: types of thinking tendency

The younger the children, the more often they use the intuitive thinking to solve problems(Bruner, 1973). In task 1, besides evaluating whether the elementary school teachers know that students will use the intuitive thinking to judge about equal partition, this study also want to know whether the elementary school teachers do know the difficulties students might encounter when they learn equivalent fraction and the figures of same-size irregular-shapes.

In the following figures, judge which shaded areas of them are one half of the whole areas. If the answer is Yes, please mark ✓ ; otherwise, please mark ×.

a *b* *c* *d*

(1)Please make a judgement about the order of difficulties

which might be encountered by the 2nd, 3rd, 4th grade students.
The order of difficulties (Please mark with a, b, c, d)

Easier:____ easy:____ hard:____ harder:____

(2)Please write down the reason why you make such a judgement.

The 4 items in this task were answered by about 660 students in 2nd, 3rd and 4th grades. The order of the difficulties of them is a, c, d, b. There is few percentage difference between the rates of correct answers in a (98%) and c (95%). The difference between c and d is around 30%; the difference between d and b is around 20%. a with c, d, and b should be belonged to different 3 understanding levels. To judge item c, according to the interview data, students compared the shaded area with the blank area, they used intuitive thinking to decide whether the shapes of figures are equal. Therefore, the rate of correct answer in c is pretty high. Although students can use intuitive thinking or analytic thinking to judge those 4 parts of d are equal, they thought the shaded area of d is 2/4 of the whole. They need to use analytic thinking to judge 2/4 equal to 1/2, so d is more difficult than c.

Task2: problem-solving strategies.

The students of Taiwan also have their own problem-solving strategies, but not for those who have learned the rules of algorithm. Those students still choose the rules of algorithm to solve problems unless they were encouraged to use alternative strategies. Students' performances in this task were from Yong(1987). They (around 260 students) had never learned the division of the fraction at school.

" Fraction divides fraction" is the mathematics material for the 6th grade. The rate of correct answers for the two following questions were the results of the survey which randomly investigated students of 5th grade in Taipei.

a. calculation:.3/4 ÷1 8 = (rate of correct answer is 15%)
b. applied question: In a relay race, each contestant has to run 1.8 kilometers, if there is a relay race of 3/4 kilometers, how many contestants will be needed? (rate of correct answer is 43%)

(1) Do you think the students' rates of correct answers for these two questions are reasonable or not? Please write down your reason.

(2) In solving question of b, besides using 3/4 ÷1 8, what were other

possible strategies you think that students might use? (strategies must be reasonable and can get correct answer)

In task2, this researcher told the elementary school teachers that "fraction divides fraction" is the mathematics material for the 6th grade and the students in the task were 5th grade. Teachers were reminded that the 5th grade students did not learn "fraction divides fraction" yet.

Result

This study also took task1 and task2 as examples to explore elementary school teachers' performances on understanding the knowledge of students' cognition in fractions. This study will show some of the teachers' answers as examples; T= is used to represent one subject's answer in the task.

Task1: types of thinking tendency

Question a appears frequently in learning materials as one half, so teachers know that it is the easiest for students.

- 27% of the teachers got order from easy to difficult as: a, c, d, b.
  T116:when dealing with questions a and c, students can use intuitive thinking to make a judgement. But d is 2/4 = 1/2, students must have the concept of simplification. b is much more difficult than d for students to explore.
- 38% of the teachers got order from easy to difficult as : a, d, c, b.
  T229: 1/2 is half of the whole area; so it is much easier to tell the figures of a, d and c. (d : The students will automatically switch the above shaded area with the below blank one; c: they will also switch the two small half circle to make up for the one large half circle.)
- 25% of the teachers got order from easy to difficult as: a, d, b, c.
  T417: a: students can immediately tell that 1/2 is half of the whole. d : divided into 4 equal parts, two of which are the shaded areas. It is also easier for students to tell 1/2. b: It can be divided into left and right two parts , the shaded area of each part is 1/2. c: students must draw the diameter of a circle, but most of them can't do this.
- 10% of teachers got other answers.

According to the above data, 27% of the teachers understood students' thinking tendency and the order of difficulty. From easy to hard, the order is : a: two equal parts , d: equivalent fraction, b: the figures of same-size irregular shapes. 63% of teachers don't understand students' thinking tendency but understand the order of difficulty. 10% of teachers neither know students'

thinking tendency nor understand the order of difficulty.

If the elementary school teachers don't know or don't accept that intuitive thinking is one of students' thinking types. It seems that:

- teachers' selection of instructional materials and sequences would not match with students' learning sequences.

  T414: for example, in order to divide a circle into a half, we must know what a diameter is, and the diameter must be across the center of the circle; then, we can get two equal halves of the circle. I don't think a 2nd grade child can answer such a question. Diameter and radius are teaching materials for the 4th grade students.

- elementary school teachers will adopt the way of analytic thinking to teach and the way they use to evaluate students' work might be based on absolute precision but not an visual and operational based precision.

  T414: such as dividing the chocolate bar, cutting it into a half, I doubt that student only did it by probable judgement. For our teacher to solve the same problem, we also need to measure the length, then, divide it by 2 and cut it.

Task2: problem-solving strategies.

- 14% of teachers were aware of the diversity of students' problem-solving strategies and can specify students' problem -solving strategies.

  T105: (a) The correct rates are reasonable. "How many contestants will be needed" is asked in the applied question. The answer can't be a fraction. Students will get an integer as answer by all means.

  (b) using $\frac{3}{4}=\frac{6}{8}$, $\frac{6}{8}$ *is six one-eights*

- 34% of teachers either were aware of the diversity of students' problem-solving strategies or can specify students' problem -solving strategies.

  T218: (a) The correct rates are reasonable. Students can reason out each question when solving the applied questions but couldn't solve calculated question if they forgot the rules of algorithm.

  (b) (no answer)

- 52% of teachers neither were aware of the diversity of students' problem-solving strategies nor can specify students' problem -solving strategies.

  T230: calculation is the foundation for the applied question;

BEST COPY AVAILABLE

only15% got correct answer in solving simple question of calculation. But in solving applied question, both adroit calculation and consideration are required. It seems not reasonable that 43% of the students got correct answer in solving such a complicated question.

Conclusion

According to elementary school teachers' performance on answering those 5 tasks, three levels of understanding of knowledge of students' cognition in fractions was found as table 1.

Table1: three levels of understanding of knowledge of students' cognition in fractions.

task	Knowledge of students' cognition in fractions	excellent	Mediocre	unsatisfied
1	Understanding students' thinking tendency and the order of difficulty of various figures	○ ○ ○ or (a)○ ○ ◑ or ○ ○ ●	○ ◑ ◑ or ◑ ◑ ◑ or ◑ ◑ ◑	○ ● ● or ◑ ● ● or ● ● ●
2	Be aware of and be able to specify students' problem-solving strategies.			
3	Be able to evaluate students by considering the learning difficulties of fractions			
Task 1~3 are paper and pencil questions.		10% (b)	73%	18%
4	Be able to explain the reason why students make certain misconceptions	○ ○	○ ◑ or ◑ ◑	○ ● or ◑ ● or ● ●
5	(c)Understanding that assembly ability will influence students' performance on solving equivalent fractions			
Task 4~5 are interview questions		18%	70%	12%

(a) The answers of each task can be stratified into three levels: excellent, mediocre, and unsatisfied.○, ◑ and ● are represented respectively as three levels.○○◑ means that teachers get one mediocre answer in task 1 or task2 or task 3 but get two excellent answers in the others. It isn't represented in the question order.

(b) 10% means the percentage of excellent performance in the paper and pencil tasks.

(c) Assembly ability means that students can divide unit into several parts, deal with each part correctly and then, assemble each part into the required fractions of unit. Students who lack such an ability can deal with each divided part but can not assemble each part into the required fractions of unit

If elementary school teachers do not understand their students' learning of fractions, there could be some important effects on their teaching and students' learning.

1.Teachers' selection of teaching material and sequences do not match with students' learning.

Students could use intuitive thinking approach to solve problems. However, teachers think students tended to use analytical thinking approach

to solve problems just like themselves. So they select their teaching materials and arrange their teaching sequence according to the cognitive demand and task analysis hierarchy. These two approaches will not match well. For example, teachers think 4th graders can divide a circle to two equal halves only after they have learned the concepts of diameter and radius. But most students already can divide a circle to halves when they are in 2nd grade. They do it intuitively, i.e., through visual or by actually folding it into two equal halves.

2. Teaching and evaluation do not match with students' learning.

Teachers conduct their teaching according to the analytical thinking approach. However, students adopt intuitive thinking approach while they solve problem.

Teachers may think that they should teach students' the rules of algorithm, then ask students to apply those rules to solve applied problems. But what's accepted by students should be put on these mathematics contents in a meaningful and interesting context, then start from students' problem-solving strategies and gradually link them to more abstract, formal mathematics algorithm.

Teachers might take the criterion of absolute precision to teach and to evaluate students, but students might take a visual and operational based precision to learn or solve problems. For example: a teacher might use a ruler to measure the length of a stripe of paper; then, he or she will use the division to calculate the length of each part. In contract, a student might divide the paper stripe through intuitive observation.

3. Teachers can't identify students' misconception and will overestimate or underestimate the difficulties students encountered while solving problems.

A BUDDHISTIC VALUE IN AN ELEMENTARY MATHEMATICS CLASSROOM

Abstract

The purpose of this study is to investigate the value an elementary school mathematics teacher emphasized in her class. Participatory observation was adopted as the main research method. We found the mathematics teacher is a devout Buddhist. She pretty much emphasized the importance to reinstate the original enlightenment. We identified it as the core value in her teaching.

Introduction

In recent years, studies of teachers' beliefs showed an apparent inconsistency between what a teacher thought and what a teacher taught (Anne, 1997;Chin, 1995;Thompson, 1984). Then, we would contend that this discrepancy is precisely the reason why values rather than beliefs need to be studied.

According to Raths, L.E., Harmin, M., and Simon, S.B (1987), formation of value contains three steps: choosing, prizing and acting. Those steps collectively define valuing. Results of this valuing process are called values. In order to determine the deeper factor that supports underpinning teachers' preferred decisions and actions, this research tries to investigate a teacher's values shown in an elementary mathematics classroom by the definition of values from Rath et al.

Methodology

We mainly adopted case study approach to find out the values transmitted in a mathematics classroom. An elementary school teacher, Ms. Tsen, was selected among teachers we have interviewed due to her recognized teaching expertise. She has 21 years teaching experiences. Besides being a classroom teacher of 40 fifth grade students, she was a mentor advising a student-teacher during our observation period.

The following procedures were carried out in order to collect data: observing Ms. Tsen's mathematics class, interviewing her, observing the student-teacher's mathematics classes and joining Ms. Tsen and the student-teacher's advising meeting; interviewing the student-teacher to check Ms. Tsen's values.

According to Rath's theory, acting, especially repeatedly acting, is an important indicator for core values. Therefore, when analyzing data, we focused on what Ms. Tsen repeatedly acted in classroom and what she considered as important and valuable.

When we came to a conjecture of Ms. Tsen's core values she was told and asked to clarify.

Results

Buddhism is one of the major religions in Taiwan. Ms. Tsen is a devout believer in Buddhism. The belief of it produces a great impact on her viewpoint toward education. In this paper, we presented one value which she agreed upon: The purpose of education is to reinstate the original enlightenment (本覺). To achieve the goal, she required students to calm themselves down and start self-reflection on their own. Following are some events indicating the evidence of the existence of this value. In the following excerpts, "I" stands for the interviewer; "Tsen" for Ms. Tsen, "Ts" for the student-teacher; "S" for Ms. Tsen's students, "C.O." for classroom observation, and "Int." for interview.

1. By way of "calming down" to reinstate the original enlightenment.

In mathematics teaching, Ms. Tsen was used to ask her students to repeat mathematics questions or strategies, and require them to listen and look attentively

BEST COPY AVAILABLE

frequently. This action reflected the "acting" component of values.

Tsen:"... There are 6 soaps in a box; we assign 5 boxes to 6 persons. How many boxes can each person get? ... Lee, repeat the question I just asked."(11.7.97.C.O.)

I:" What's your purpose of requiring students to repeat the question?"

Tsen: "My purpose is to let each student know what we are doing in the classroom; on the other hand, I remind the students who are not concentrated in class to listen attentively." (11.11. 97.Int)

Tsen: "You don't need to tell me the answer for this question; just tell me what the difference between this question and the prior one is?... Listen carefully! Some students still play with pencils. Put it down."(11.7.97.C.O.)

Why does Ms. Tsen emphasize students' being concentrated in class learning?
The answer was embedded in the following classroom observation.

Tsen:" I issue a warning to you against your not being concentrated. Ok, let's begin the next question: please use the method of filling the blank with the symbols of multiplication to write down the question. Some students are whispering. Once you calm down, you can solve this question."(97.11.28.C.O.)

Why does Ms. Tsen think "being concentrated" and "calming down" can enhance students' learning?

I: "In this forty-minute class, you have asked students to pay attention to what you said for more than 10 times. However, your students quite already paid attention on you, why you still keep asking them to be attentive to what you said?"

Tsen:" I found that once one is calm down, one can learn things much more efficiently. That is what I have learned from Buddhism. For example, I am able to integrate the subjects teaching pretty well. And the teaching pattern was less flexible than what I am doing now. I can notice the hazards that the students faced and try to

adjust my teaching style. (3.17.98. Int.)

I: " Besides requiring your students to be concentrated, what else would you ask them to do? Apparently, some students are very concentrated but they still can't get the point."

Tsen: "That is the point. (Researcher's note: Here we see the "prizing" component of values. When a person is concentrated, he is calm. Being able to calm down is an innate ability that can help people to observe things much more clearly. No matter what dumb or smart a person is, he/she can always show such ability."

I: "Those students who might be very concentrated in listening to the instructions, but... "

Tsen: " Right, a student probably can not understand some of the viewpoints. According to the terminology of Buddhism, it is a karmic obstruction (業障). Take "listening" as an example: for the same thing, some always look at the bright side of it but others always look at the dark side. It's regrettable that some persons always look at the dark side of events because they don't know the art of observing things. What I did is to teach my students how to observe a thing and how to detect everything around them. It's nothing but a root nature (根性) to which I pay close attention to. (Researcher's note: Here we see the "prizing" component of values.)... Generally speaking, Buddhism can be defined as one kind of education that can enlighten people's inborn wisdom and makes people understand the truths of the Universe and life. The basic purpose of Buddhism is to recover a person's original enlightenment, so Buddha means "enlightened being" (覺悟者). (12.2.97.Int.)

2. By the way of " self-reflection" to reinstate the original enlightenment

Ms. Tsen often warned students the mistakes occurred but seldom told them what their problems were.

Tsen: "This question requires you to write it down by the way of filling the blank. (Research's note: The correct answer is 13÷9=( )) Some of you write it down in this way; let's take the first reaction as an example... Come over here, S9, how did you write down this question by the way of filling the blank? "

S9: " 13÷9=1 and 4/9"

Tsen: "OK, 13÷9=1 and 4/9, if this is your answer, can you tell me what your problem is? "(11.14.97.C.O.)

When students made mistakes in the mathematics class, Ms. Tsen didn't tell her students what their problems were, only reminding them that they make mistakes. The reasons explained by Ms. Tsen were as follows:

I: "When a child made a mistake, apparently you would tell him he was wrong and ask him to reflect on what the mistake was. Why did you choose this way to ask him?"

Tsen: "When you make a mistake, you should be aware of the mistake by yourself. If a child couldn't find his own mistake, I would help him to discover it. This is for improving his nature of enlightenment (覺性). If he knows what his mistake is, he may find out how to debug it. ... During the process of discussion, I never tell them directly where the mistakes are and what should be improved."

I: "Will you first ask him what the mistake is when you found it?"

Tsen: "I won't tell him where his mistake is directly. This will put a damper on his awareness."

I: "What you emphasized is student's self-awareness. Do you think self-awareness is very important in learning?"

Tsen: "Self-awareness is very important not only in learning but also over the whole human life. (Researcher's note: Here we see the component of "prizing" in values.) That's your own feeling and awareness for yourself. Everyone has such ability but not every one can sense it. What I did is to guide my students to find their

BEST COPY AVAILABLE

own mistakes out and restore the awareness. Therefore, it is not necessary for us to tell students where the problems are. No sooner have they become calm, than they will keep sober-minded and find the truths gradually." (11.18.97. Int.)

Ms. Tsen's requiring students to do self-reflection was also detected and found by the student-teacher.

Ts: "... Generally speaking, most teachers might punish or award their students for their performances. But I strongly feel that Ms. Tsen has done something more for her students. To have her students to do self-reflection, she asked several questions, such as:' Are your behaviors only for others to observe, not for yourself?' 'Do you know your behavior is right or wrong?'(3.26. 98.Int.)

Ms. Tsen's apprehension of Buddhism makes her choose such an education goal, reflection. In addition, following paragraphs can show us that this education goal is formed through "choosing", another one important component in the processes of valuing.

Tsen: "The core of elementary education is life education. The reason why there are so many problems in our society is because we put too much emphasis on subject learning and ignore life education. ... It's just for teaching convenience, so school subjects are classified into Language Art, Mathematics...etc.(Ms. Tsen thinks teaching implementation of each subject should origin from life education.)" (3.17.98 Int.)

Tsen: "Every thing is a Sura. I would require my students to observe deliberately the environments around them." (3.24.98 Int.)

Tsen: "... Traditional Confucianism only consult about this life of ours; in contrast, Buddhism clearly points out the past, the present and the future. My responsibility is to make my students reinstate their original enlightenment. I don't believe the knowledge we have learned in school are sufficiently to help us to break away from hardships... " (1.6.98. Int.)

According to Ms. Tsen, the purpose of education is to help students to break away from hardships and suffering. To reinstate student's original enlightenment can help reach this goal, which, however, can not be achieved only through subject learning. Therefore, life education should be more highly emphasized than subject learning.

Discussions

Buddhism is one of the major religions in Taiwan. Tzu-Chi is one of the important Buddhist organization. It publishes a series of books, such as: The world of Tzu Chi · The garden plot of Chin-Si (silent-thought) · Chin-Si-Yu (words for silent thought), etc. These books disseminate Buddhistic concepts and pass on the principles of how to get along with people and deal with things properly in society. In addition, in the northern area of Taiwan, there are 16 teacher sodalities. These sodalities in total have more than ten thousand members. They are from different levels of public and private schools, and various academic institutes. They weld the content of Chin-Si-Yu into their curriculum. Therefore, in Taiwan, it is not unusual that Buddhism influences teachers' teaching in elementary schools.

How do we define "values" and how do we claim that "this is Ms. Tsen's value?" These still remain disputable. We followed Rath et al.'s definition, even though his definition is more close to value clarification than value identification. We have identified the value of Ms. Tsen, to reinstate the original enlightenment, through the process of seeking the three components of values: choosing, prizing, and acting. Yet, it does not mean that all candidate values should be examined and pass the above mentioned criterion. Such kind of operational definition of values is adopted in this study in order to get started with the investigation of values. Better description of properties of values are needed.

We found Ms Tsen not only prized and cherished her emphasis of enlightenment, but also combined the thought with the trend of constructivistic teaching in mathematics. We were convinced that under such circumstance, it is easy and

comfortable for Ms. Tsen to express her thought in public. On the other hand, we were concerned that what if a teacher's core value is against the mainstream values in the society? Can we have chance to detect it with ease?

CHILDREN'S CULTURAL ACTIVITIES AND THEIR PARTICIPATION

Pi-Jen Lin Wen-Huan Tsai
Hsin-Chu Teachers College, Taiwan
linpj@nhctc.edu.tw Tsai@nhctc.edu.tw

ABSTRACT

The study aimed to explore what children's cultural activities are and to understand the ways of their participation. Forty third graders selected from elementary schools of Taiwan were interviewed with four main questions, and their responses were classified. The socialization and mathematical skills needed in an activity and the amount of learning opportunities offered by adults were the indicators used in deciding the degree of children's participation. It is proposed that the conflict between cultural cognition and school mathematics might be a factor of school mathematics being disconnected from everyday mathematics.

Introduction

The purpose of this study was to investigate the mathematical concepts that occur in daily life, that children bring into school, and to explore the social contexts of such mathematics.

There has been a considerable number of studies that link "school mathematics" with "everyday mathematics" (Saxe, 1991; Petitto, 1982; Bishop & Abreu, 1991). The focus of school learning on formal mathematics is cited as one critical reason why children seem incapable of applying "school mathematics" to solve daily mathematics problems. Further reasons are weak connections between problem situations and inner representations (Hiebert & Carpenter, 1992), context-bound school mathematics (Bransford, et al., 1986), and the fact that school mathematics is learned away from social contexts. These are all possible explanations of the disconnection between "school mathematics" with "everyday mathematics".

Some researchers agree that the strategies of solving daily problems created by children are preliminary to learn school mathematics (Carraher et al., 1985; Bishop & Abreu, 1991). Madell (1985) claims that informal methods of solving daily problems are as often efficient as formal methods of solving school mathematics problems. Formal methods learned in school are initiated with informal methods of solving daily problems. If a concept to be learned seems relevant to the informal methods that have been used, children are more likely to learn it naturally. Thus to link knowledge gained from out-of-school with school mathematics, we should accept children's natural thinking. The design of "school mathematics" curricula should start with "everyday mathematics", since informal methods are originated with everyday mathematics.

According to Vygotsky's socio-historical perspective, the child is historical, social, and cultural. (Minick, 1989). Bruner (1990) emphasized that the cognition of human beings should focus on sense making of the world. He remarked that human

beings seem to have an innate tendency to make sense of the world in narrative forms and that narrative forms are distinct by cultures. This theory is supported by findings in our ongoing research project, where we have found children growing up in farm family learning the knowledge of farming and children living around harbor learning the knowledge of weaving fishnets and learning fishing skills. Similarly, planting mushrooms and cutting bamboo are viewed as natural skills for aboriginal children.

Brown et al. (1989) claim that learning situations should be embedded in authentic problem situations that makes sense to learners. Learning should naturally occur in real social contexts, but this does not mean that learning outcomes are universal to learners even in the same contexts. The assistance of adults, including parents, teachers, or peers in one important influence on learning. With Lave and Wenger's (1991) Legitimate Peripheral Participation (LPP) theory, apprentices learn to think, act, and interact in increasingly knowledgeable ways with people who do something well, by taking part in legitimate peripheral participation. Learning as participation treats the relationship among persons, their actions, and the world as a continuously evolving set of relations. The participation is at first peripheral but increases gradually in complexity to kernel participation. Situated learning theorists stress that the interpretation of learning behaviors should concentrate on the meaning and the content of learning in an authentic situation which learners interact with surrounding persons and the environment, rather than having focus on individual cognition.

In our research study, we are in the first year of a three year project, intended to explore children's authentic activities in daily life which have embedded mathematics contents. There are currently three research questions: a) What kind of cultural activities are children engaged in? b) What are structures of cultural activities? and c) How do children participate in cultural activities? The cultural activities that children participate in most frequently in the first year of the project will be the basis of the second year's study. The second year of the research project will focus on how to bring children's cultural activities involving mathematics concepts into classroom.

Method

This investigation was carried out in Hsin-Chu, a city of Taiwan. The participants were forty third graders in eight elementary schools, five children selected from each school.

To collect notes about children's cultural activities, each child was interviewed with four main questions: Who are in your family? What are they? What do you do after school or on weekend? Which festivals do you like best, why, and how do you celebrate the festivals? The two questions were to gather data on the interaction of the learner with their family, and the latter two questions were to collect information on children's out-of-school activities; especially, celebrations of conventional festivals.

Each subject was interviewed individually. Audiotapes of the interviews were

transcribed and coded. Four social contexts with mathematical activity embedded emerged: running a business, shopping alone, shopping with adults, and celebration of conventional festivals. Children had a distinct degree of participation in different contexts, and different involvement affected children's mathematical cognition and socialization significantly. The socialization and mathematical skills needed in an activity and the amount of learning opportunities offered by adults were the indicators used in deciding the degree of children's participation.

Results

Only some results appear below. We found that aboriginal children have a specific life style that typically includes activities such as planting mushrooms and jumping rope. They also have no cramming school, incomplete school homework, and no money for buying toys and computers. Doing assignments, biking, doing exercises and playing games in the arena of the temple are suburban children's regular out of school activities. Other activities include doing homework, attending cramming school, doing housework, playing with toys, and sports.

Some activities have mathematical structures. The structured activities which children were engaged in included pokers games, jump rope, chess, playhouse, hopscotch, and monopoly.

Each of these activities has mathematical content. When participating in a structured activity such as "Playhouse", children are becoming socialized but they also acquire mathematical knowledge. For instance, as Lily pretended to go shopping in a store with her cousin, she said:

> "... playing a cart game with my younger sister, using my aunt's room as a store. Two dolls, one is a man, the other is woman. They came to the door of the store to buy fish and a can and put it in the cart. After that they approached the cashier and paid. My sister served as a server, putting money in a drawer, changing money, and paying back the customer. They paid NT$500 for buying a can and fish NT$100 altogether, then the server gave them NT$400 change. They also bought pets in a pet store. A dog is NT$5000, A kitten is NT$3000, it is cheaper than the price of a dog. A bird is NT$7000, it is the most expensive. We made several pieces of rectangle paper and wrote the number on them as fake money for too dolls."

Fake money as currency, using room as a store, two dolls as shoppers. a younger sister to serve as a cashier, receiving and changing money—the role-play imitates a real shopping context. Lily's imagination and recognition of professional roles have been developing in the playhouse context. In play, Lily also learns to recognize the price per item, to compare the price of the items, to sum up, and to give change. Consequently, Lily's arithmetic algorithm of multiple units and comparing of big numbers have been developed naturally in the context of role-play, even though she

has not learned them in school yet.

We found that suburban and aboriginal children frequently help parents in buying general merchandise, such as salt, sugar, soy sauce, wine, cigarettes, etc. In order to verify the emergent mathematical goals in shopping context, they were asked to describe some of the routine activities they do.

We identified five forms of participation (no, partial, incomplete, complete, and kernel) that were unequally distributed in various contexts. For example, three learning processes were identified in the "shopping with parents" context — "no participation", "partial participation", and "complete participation".

Each level of participation was tabled against different activities. For example, children's "no participation" presented in four different contexts: shopping alone for parents, shopping with parents, family running a business, and Chinese New Year.

(1) No participation

We distinguished the structure of shopping activities in which children were engaged in shopping alone from that of shopping with adults. The structure of shopping in store can be described in three phases: preparing money to buy merchandise, buying merchandise, and checking the change. Children were involved in the three phases at different levels of engagement. For example, Ludan was asked to buy soy sauce and salt for her mother.

Case: Ludan, a policeman's daughter

Interviewer	Ludan
Were you able to help your mother to buy something?	Yes.
What did you buy?	Soy sauce and salt
How much does a bottle of soy sauce cost?	NT$50
How about salt?	NT$15
How much were you given by your mother?	NT$100
Before paying to sellers, did you count money?	My Mom told me I need to pay NT$65, the sellers will give me NT$35 change, and I need to check if it is correct.

Ludan did not need to solve any mathematics problems during the three phases, since her mother had prepared her for them. Thus we characterized Ludan's learning process as "no participation".

"No participation" was also identified in contexts of shopping with parents where children did not pay attention to the price of each item, or where a mathematical goal was not present in children's activity because they were bidden to follow their parents. Similarly in conjunction with a family business there were examples where children

had no participation. For instance, Weily, a son of a seafood restaurant owner seldom presents in the restaurant, so he does not know the price of each course. When he was asked to solve the problem: "Each bowl of fish soup costs NT$60, how much do 3 bowels of fish soup cost?", he had no confidence in answering and said "Likely NT$70". Weily had not been given any opportunity to learn the mathematical ideas embedded in the real context.

Susan enjoyed Chinese New Year, since she got lucky money as well, but she did not know the amount of money in all. Her mother was afraid of errors in calculating the sum. Susan said: "My mom helped me adding them up and she saved it in a bank". Susan was deprived of opportunities to learn mathematics in the natural context. Susan's learning process in this context was classified as "no participation".

(2) Partial participation

Most of children's learning in selling contexts was identified as "partial participation". Jen's home is next to a harbor, and her mother owns a seafood restaurant. Passing courses over and setting up bowls and chopsticks are Jen's jobs. She receives money from customers occasionally and is told by her mother the amount of change to give customers. She described helping in the restaurant passively. She said: "Mom told me which place was busier then I moved to there to help. If she told me she needed a hand here, then I came back here to help her." Jen's learning process was identified as a "partial participation", because the mathematical thinking was generally done by her mother. She did not know the price of each course, and her mother did not provide her with opportunities for adding customer's accounts. However, she had a chance to change money for customers, and can calculate change (e.g. NT$80 when NT$120 is deduced from NT$200, and NT$400 when NT$600 is subtracted from NT$1000).

(3) Incomplete participation

Running a store or producing farming products is a source of financial support for a family. Parents do not arrange the store intentionally to educate children, but children learn counting and changing money in the authentic contexts. We found that children whose families run a large businesses, such those selling ironwork and electric products, are seldom involved in their own store's activities. However, children whose families run small stores, such as those selling Chinese chewing gum (Ceg, a seed of a plant) or farming products, had more opportunities to do business.

Hong's father builds houses and his mother sells Ceg in a small store. He said that

he helps in selling Ceg in his mother's store every day after school. He knew the price of a package of Ceg and was able to count the sum NT$100 for two packages.

Mei is growing up on a farm family. Her parents produce and sell fruits in a farmers' market. The following episode describes her participation in a selling context. Note that both Mei and Hong (her older sister) learn mathematical ideas that are embedded in selling situations and interact with their customers actively.

Case: Mei (Note: NT$: Taiwanese dollars. US$1 = NT$33. kg = kilogram)

Interviewer	Interviewed
You just said you help selling fruits in a farmers' market?	Yes; otherwise, I worked in a mountain on weekend.
Did what?	Planting bamboo, cutting old branches of bamboo and firing them.
Were you able to help getting money from customers or did you tell customers the unit price?	NT$35 for each kg, NT$100 for each 3 kg
How much did you need to give the change when a customer gave you NT$100 for buying one kg?	NT$35 and paying NT$65 back to the customer.
Who received money from customers and who gave the change for customers?	Elder sister received money and I gave the change.
Before you gave the change, do you calculate the amount by yourself or were you told?	I did by myself I was watching the weight needed for a customer. My elder sister received money first, followed by my calculation and my change. Consequently, I passed over the money to my older sister and paid back to the customer.
How much does it cost, if a customer need 4 kg	NT$135
If he paid NT$150, how much do you need to give as change?	NT$15

The difference between these two cases is the assistance received from Mei's elder sister. Hong was offered a complete learning process in selling Ceg. His mother did not interfere. Hong learned not only mathematical ideas but also the social ability in the real social context. Nevertheless, Hong is unable to manage the store without his mother's presence in the store simultaneously, so Hong's learning process in selling context was identified as an "incomplete participation" rather than a kernel participation. When interacting with customers, Mei's elder sister sponsored her social actions such as receiving money and paying money back to customers. Her knowledge of mathematics involved in selling fruits is developing, such as adding sum up, counting, and changing, but Mei's learning process was classified as an "incomplete participation".

(4) Complete participation

Case: Linda, a pharmacy's daughter

Interviewer	Linda
[Linda stated that she helped her mother buying merchandise]	
If you buy a bottle of soy sauce and a package of salt, how much do you need to pay?	NT$65
How much were you given?	NT$100. I get it by myself from mother's purse.
How did you know it is NT$100?	A bill is NT$100.
Before paying to sellers, did you count the money?	I gave it to sellers directly.
How did you know the change was correct?	I counted it and it was checked while I gave it to Mom.

Looking at Linda we verify that the structure of the activity is similar to Ludan's (described previously), but the interactions with their parents in phase one and three seem to be rather different. Linda coped independently with situations where she needed to use mathematics. Linda's learning process as "complete participation".

(5) Kernel participation

Children engaged in the context of shopping for themselves were classified as having "kernel participation". When buying something for himself without parents' involvement, a child needs to figure out which objects meet their needs and how to best buy according to the money they own. Children require higher social ability in the context of buying something for themselves than when shopping for parents. The emergent mathematical goal presented in both phase one and phase three.

With festivals, mathematical goals present significantly at Chinese New Year. Large amounts of currency such as NT$500 and NT$1000 are used and addition of multiple units is embedded in the social cultural context. For instance, Mary said that she got NT$7500 in a red envelope as lucky money from her relatives and parents' friends: NT$500 from Daddy, NT$500 from her grandfather, NT$500 from two aunts, NT$500 from two uncles, and her grand mother's NT$500. When counting, Mary uses a strategy of multiplying four times 500 and adding 500 and then 5000, the sum being NT$7500. In nature, the counting of money here did not involve social aspects so we identified Mary's interaction as "kernel participation".

Discussion and conclusion

It is clear from results of our project to date that mathematics is embedded in children's cultural activities. Children learned addition and subtraction of numbers (and other ideas such as recognition of geometrical shapes) in authentic contexts where children interact with surrounding people. The more involvement in activities, the better the opportunities for learning. The degree of children's participation in various contexts depends on the opportunities offered by parents or elder peers.

As previous literature described, weak connections between problem situations and inner representations, context-bound school mathematics, and school mathematics learning deviate from social contexts, and result in school mathematics that is disconnected from everyday mathematics. The conflict of cultural cognition with school mathematics presented in the study might also be a possible explanation. School mathematics does not recognize complexities such as the target of "less profit means more sales" — an essential strategy in the trade culture. Efficient strategies invented by children such as Mei for solving sale problems in order to give customers not only a correct but also a fast answer, are not recognized, leading to cognitive conflict between everyday experience and school mathematics.

The question of how to optimize children's cultural activities into their mathematics classroom learning is worth further investigation, and will be a focus in the next stage of our research.

Making sense of informally learnt advanced mathematical concepts

Zlatan Magajna

University of Ljubljana, Slovenia
University of Leeds, UK

This paper considers the understandings of six vocational school students and two experienced constructors of splines (piecewise polynomial parametric curves used in Computer Aided Design (CAD) systems). All of the participants' knowledge of splines was learnt only in relation to CAD practice, i.e. informally, how to use the command for drawing splines. The constructors and some students related splines to their mathematical knowledge while other students, in making sense of splines, relied on the activity in which they occurred, machine design. Saxe's (1991) model is the basic vehicle for analysis but consideration of the role of intuition and expertise are also taken into account in the discussion.

Introduction

This paper is about the interplay between geometric reasoning in various practices. The post-modern view of mathematics has given rise to a conceptual distinction between mathematics and mathematical activities in various practices (Brown, 1994). Mathematics in no longer seen only as a decontextualized body of knowledge which is 'naturally transferable' to other contexts. New paradigms view mathematical knowledge as situated and linked to the various practices in which they occur. Whether the mathematical knowledge in various practices is the same or not obviously depends on the considered perspective on knowledge application (Ernest, 1998). In general, connecting the knowledge of various practices is no longer seen as something obvious, in fact, several researches (e.g. Lave, 1988, Nunes, Schliemann, Carraher, 1993, Saxe, 1991) have pointed to a marked discontinuity between the mathematics rooted in different practices. Yet even if the problem is considered from a situated standpoint one has to consider the interplay between mathematical knowledge linked to various practices. Saxe (1991), for example, in considering the mathematical practices of Brazilian candy sellers has observed some interplay between the abysmally divided school learnt mathematics and the mathematics of candy selling practice. Similar results have been recorded by Nunes, Schliemann, Carraher (1993).

The interplay between knowledge linked to various practices is not easy to observe and research. Most work in this area has been related to elementary topics (simple arithmetic and geometry). The absence of advanced topics is easy to explain. First, most advanced mathematical knowledge is very rarely used in everyday contexts. Second, most advanced mathematical knowledge is learnt first in mathematical

classes and is only later eventually linked to other contexts (e.g. other school subjects, workplace, etc.). The fact that a topic has been considered formally in mathematics classes obfuscates the observation of the process of generation of mathematics related meanings in a context.

Some important insights into the relation between school and out of school mathematics has been obtained via the meaning-making process of elementary mathematical concepts in a context by considering instances of mathematical knowledge acquired informally (not in institutionalised learning of mathematics, see Nunes, 1993; Saxe, 1991). I have researched a similar instance (see also Magajna & Monaghan, 1998) which involves more advanced mathematical ideas. I have found that Saxe's 4-parameter approach (i.e. interpreting the data in terms of activity structure, previous knowledge, social relations and artefacts used) explains well, though not completely, the meaning-making process in a context.

Splines - an example of informally learnt advanced mathematical knowledge

I begin with the observation that, at least apparently, cases of informally learnt advanced mathematical ideas are rare – students usually learn about relevant advanced mathematical ideas first formally, in the mathematics classes. Though they may use these ideas later, informally, in other settings (and may even re-learn them), such cases are never clear-cut and we can hardly speak of advanced mathematical concepts which are clearly informally learnt. Splines – mathematical objects encountered in CAD courses and drafting practices – are an interesting exception. Since splines are mathematical objects which are not widely known I shall explain this concept in very simple terms (see Boehm, Farin, Kahmann, 1984, for details).

Splines are curves used in most CAD systems to draw 'free' forms. On a computer a spline is usually defined by pointing to a sequence of points, called *control points*, along (resp. near) the imagined curve, and the computer draws a curve which can usually be interactively modified by moving the control points. This may appear as magic but there is a mathematical model behind this. The constructed curve is made of pieces, each piece being a parametric polynomial function, usually of 3rd degree. The end of each piece coincides with the start of the next piece not only in terms of the endpoints but also in terms of the derivatives (usually up to the second degree), which gives the impression of smoothness of the curve. There are many significantly different ways to relate the control points to a sequence of 'smoothly' connected pieces of parametric polynomial curves. In most applications a variant of

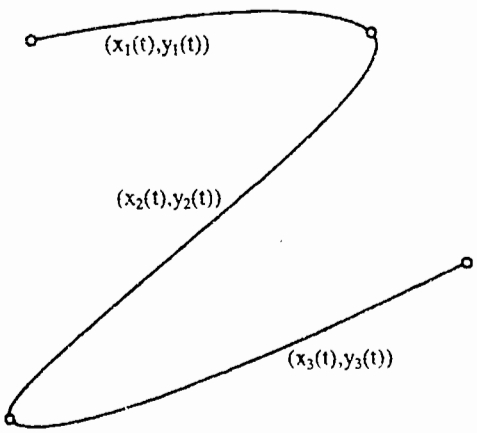

Figure 1. A simple interpolatory spline curve consisting of three polynomial 'pieces'.

non-interpolatory splines are generated (i.e. the resulting curve does not interpolate the control points, see Fig. 2). Only in specific situations are constructions of interpolatory splines preferred. Note that in any case, given the control points, the construction of the polynomial pieces is not unique: thus, to convey the shape of a spline the whole piecewise polynomial structure has to be considered.

Figure 2 depicts a cubic spline defined by 4 control points (joined to a *control polygon,* for easier visualisation), which may serve as a prototypical example of non-interpolatory spline. I just list (without argumentation) some general features of non-interpolatory spline curves: 1. they start at the first control point and end at the last one; 2. the first and last line segments of the control polygon are tangent to the spline at the endpoints; 3. the construction of a spline from the control points is affinely independent - in practice this means that symmetric control polygons give rise to symmetric splines, that the mirrored image of a spline is the spline constructed from the mirrored control points, etc.

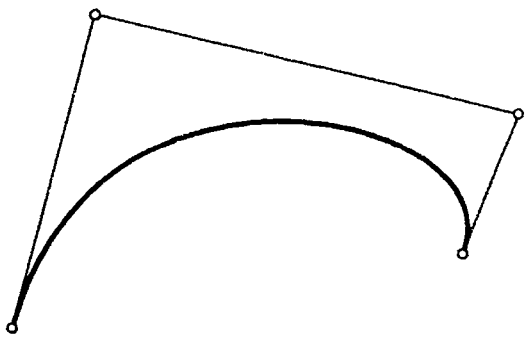

Figure 2. A non-interpolatory cubic spline defined by 4 control points joined in a control polygon

I consider splines as a case of informally learnt advanced mathematical knowledge for the following reasons:

- splines are rather complex mathematical objects, not included in vocational-school mathematics curriculum (in Slovenia) and well beyond the reach of vocational schools mathematics;
- mathematics teachers of vocational schools and students' parents usually do not know anything about splines;
- splines are common in (machining) CAD drafting, but the students and practitioners on CAD courses or elsewhere just learn how to use them, i.e. without any allusion to mathematics.

My main point of interest is how do users of CAD systems understand splines and where/what are the roots of their understandings.

The method

The aim of the study was to find cases of qualitatively different ways of making sense of mathematical objects that are used in a practice. Since this paper forms a self-contained part of a larger study concerning interrelations between geometric reasoning in workplace and school settings, the participants selected were those that took part in the larger study. Part of the research took place in a small factory in Slovenia that produces moulds for the glass industry. The work of six practitioners

1043

working on CAD systems, all with vocational school training for machine technicians, was studied for three weeks using several techniques (interviews, observations, scheduled observations, document analysis, protocol analysis related to given problems). Among these two practitioners, who most often used splines in designing complex shapes, were selected for this study. Another part of the study took place in a vocational school for machine technicians in Slovenia. The participants were selected from a class of 22 students, aged 18, that recently finished a CAD-drafting course (lasting several months, two hours per week - a similar course was observed as part of the research). Six participants were selected on the basis of their attitude regarding the use of advanced mathematical ideas in CAD context (using a special test that served as a filter). As it turned out, two of the six selected students were inclined to use, in CAD context, the geometric ideas learnt in mathematics classes (they will be referred as GEO-oriented students), while four of them avoided this (and will be referred as CAD-oriented students).

Participants' ideas about splines were elicited using a semi-structured interview (Robson, 1993). The participants were interviewed in front of a computer while using the CAD software they normally used. They were asked to talk (for about 40 minutes) about splines in various contexts, to explain their ideas by making hand-drawings on paper, and, toward the end of the interview, to draw simple drawings using splines and to comment on them. The table below illustrates the kind of information which was sought in the interview and how it was obtained.

	tacit knowledge	**explicit knowledge**
knowledge about the spline command	observation during the interview	explicit questions about the spline command
relating splines to CAD; relating splines to mathematics	emerged during questions (e.g. 'How to convey the shape of a spline via the phone? Does the shape of a spline depend on the software used?)	'Did you learn something related to splines in mathematics/CAD class...' 'informal' talk at cooling down
knowledge about the shape and properties of splines (tangents, overall shape, smoothness, symmetry)	4 hand-made drawings given 4 control points each drawing spectacles' frames on the computer using only splines	asked to explain how to draw a spline given four control points explicit questions about the construction of symmetric glass frames
representation of a spline **the 'structure' of a spline**	'Does the shape of a spline (given control points) depend on the display, plotter, software, hardware?' 'Imagine you are looking at your mental image of a spline through a microscope. What do you see?' 'How would you convey the shape of a spline to another constructor by phone?' 'Do splines have length? What is meant by the length of a spline?' 'Assume the spline (or circle) command broke. Can you still draw splines (circular arcs) using just the command for drawing circular arcs (splines)?' 'Is it possible to draw with the spline command the shape of a bandy (and vice versa)?'	

All sentences of participants' answers were coded (often a statement was assigned several codes) and a large concept matrix with 50 entries for each of the eight participants was built. The matrix showed a marked distinction between the three groups (CAD-oriented and GEO-oriented students, experienced constructors) and rather consistent understandings of each participant. Below I present the main findings that emerged from this analysis.

Tacit and intuitive knowledge about splines

In working with splines all the participants relied to some extent on intuition (see Fishbein, 1987 for a treatment of the topic). It appeared that all the participants used intuition to complement their experience. They were very confident that splines have the properties they would like them to have. All CAD-oriented students, for example, have learnt only about non-interpolatory splines and have occasionally used only such types of splines - yet they convincingly, systematically and explicitly hand-drew all splines as interpolatory curves. All students also firmly, consistently and explicitly related the symmetry/mirroring of the control polygon to the symmetry/mirroring of the resulting spline. Only some students used this property in their work (e.g. when constructing a pair of spectacles).

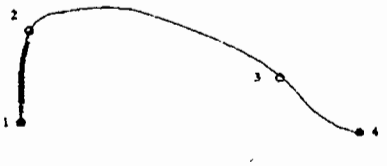

Figure 3. Andrej, a CAD-oriented student, drew the spline defined by four given control points as an interpolatory curve. Note the strange direction of the curve at point 4.

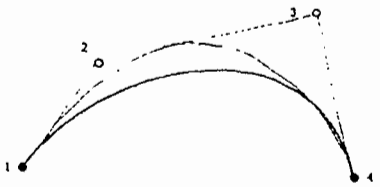

Figure 4. Branko, an experienced constructor, given four control points, drew the related spline (middle curve) quite accurately compared to the exact one (the lowest curve, added later for reference).

Experienced constructors were quite adept at drawing the shape of the spline by hand, given its 4 control points, but part of this knowledge was clearly tacit . One of them, for example, consistently drew the correct direction of the spline at the endpoints but did not mention this feature when he was asked to describe the shape of a spline curve. The experienced users also related the symmetries/mirroring of the spline and its control polygon and quite often used this in their work. However, they were much more cautious in using 'intuitively obvious properties'. Franci, an experienced practitioner, for example, when asked whether a mirrored couple of control polygons determines a mirrored couple of splines reasoned:

> **Franci:** *Ahm. I could try it now. I often try such things if I do not know how they work. Now. I would get the shape. It seems to me I would get the same*

1050

shape. Except if it depends from which side you subdivide (i.e. of the orientation of the control polygon). For if you mirror this (the control polygon) it goes in the other direction. Does this matter? Anyway you subdivide the same curve (control polygon) but in different directions. I have not tried yet this.

Participants' ideas about the nature of splines

All the participants learnt how to use the spline command on CAD software in a CAD courses or from manuals. The command is rather easy to use: one just picks the control points and the computer draws a curve which can be interactively modified by moving the control points. Though the participants have not received any explanation about the properties or the structure of the spline curve - they had quite precise ideas about its the nature.

The CAD-oriented students (i.e. the students that avoid using advanced mathematics in CAD environment) understood splines as interpolatory curves which consists of a sequence of circular arcs (or line segments), each arc being tangent to the its adjacent arcs. Note that it is a standard practice in machine hand-drafting to approximate various curves with circular arcs (which can be drawn with a compass). As is easily seen the construction is not unique. Consequently, according to these students, the shape of the spline curve is not uniquely defined and depends on the software used. In conveying the shape of a spline, according to these students, one has to consider the data of all the circles of the particular construction. One of the four CAD-oriented students claimed that though there are many 'smooth' curves made of circular arcs and interpolating the given control points, the shape of the splines (given the control points) does not depend on the software used because all CAD system use a standardised way (standards are common in machining) of arranging the circular arcs.

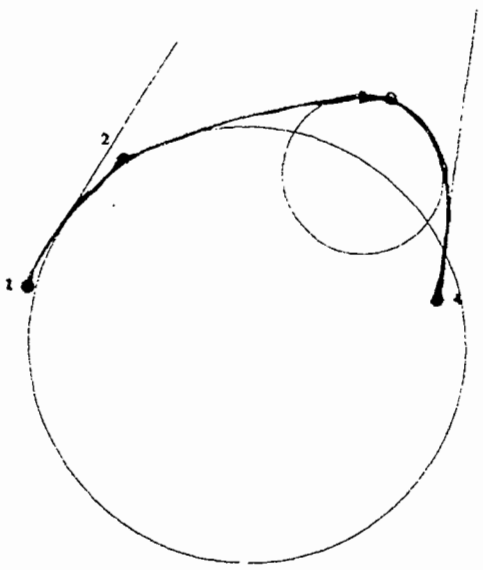

Figure 5. The analysis of a spline curve, drawn by Andrej, a CAD-oriented student, based on his explanation during the interview.

The GEO-oriented students consistently claimed that splines are mathematically defined curves (like parabolas or sine curves). They ignored how they are defined, but they were certain that there is a uniquely defined mathematical procedure to calculate the points on the spline curve. If they knew the procedure, they said, they could find out the properties of the curve, e.g. whether a spline can exactly match a

BEST COPY AVAILABLE

circular arc. Consequently, the shape of the spline curve depends only on the control points and not, in any way, on the software used. Thus, to convey the shape of a spline curve, according to them, it is certainly enough to just state the positions of the control points.

The expert constructors also viewed splines as mathematically defined objects, but they have developed interesting idiosyncratic ideas about them. Because of the mathematical nature of the splines, they claimed, the shape of a spline depends only on the position of the control points (and not on the software used). Nevertheless, if they had to convey the shape of the spline to another constructor by phone, though it depends only on control points, they would send as much data as possible about the curve, since they have to be absolutely sure that the shapes match.

The mathematical nature of splines was also reflected in the participants' interior representation of splines. The two GEO-oriented students and, to a great extent, both constructors viewed splines as mathematical objects. Their 'mental spline', for example, was infinitely thin and they did not bother about the irregularities of a displayed spline (due to resolution of the display). On the other hand the CAD-oriented students, though they obviously distinguished between the spline curve and its representation on the display, when they were talking about splines they often referred to their representation on the display (e.g. the shape of the spline, given the same control points, depends on the display). Apparently lacking a firm link between splines and mathematics they relied on visual appearance. A CAD-oriented students compared circles in CAD and circles in mathematics class:

> **MihaK:** *In CAD the circles are simplified, they are made of fewer segments, so that they take less place in memory. You can see sometimes how a circle is made of few straight segments, a hexagon or something like that. There is a command to increase the number of segments. In maths, I don't know, I think it is rather similar, you also have there the radius, the formula for the circumference is the same, the pi. I don't know, I would say it is much the same.*

Saxe's model

I view Saxe's 4 parameter model (Saxe, 1991) as a useful framework for understanding these observed phenomena. Splines, as objects in CAD activity, are not 'understood' by the students/practitioners who use them, they are simply told how and when to use them. I would say that the students/practitioners appropriate the form (how to use the spline command), attaching to it a non-cognitive function (e.g. denoting a section with a curved line). I have found that at least three of the four Saxe's parameters were involved in constructing the meaning of the spline curves. Some participants sought for the meaning of splines in the **activity structure** by relying the splines to standard approximation procedure of curves used in hand-drafting. What is most important, in my view, is that not all of the participants were

trying to make sense of the splines in the activity context. Some of them, the GEO-oriented ones, related splines to mathematical curves, i.e. to their **prior knowledge** of mathematics. Thus, though the procedure (form) for using splines was learned in the activity, the basic understandings of splines (their representations, structure and basic properties) are derived from the activity as well as from participants' prior knowledge of mathematics.

The role of **social relations**, due to the method used, was not observed, while the role of **artefacts** and **conventions** is quite obvious, e.g. the implementation of the command for drawing splines on CAD systems. Perhaps it should be stressed I have observed two additional factors that influenced the understanding of splines: *intuition* and *expertness*. Intuition apparently helps in making sense of splines, mostly at the initial phase. For most students splines were what they wanted them to be, and they had properties they would like them to have - and they found them as obvious. Expertness, on the other hand, gives at least some indication about what can be expected in a new situation. Both expert constructors intuitively 'knew' about certain properties of splines (e.g. that they depend only on control points, that a spline can be mirrored by mirroring the control polygon), yet - by experience - they knew one cannot rely on such knowledge and they claimed that such things have to be carefully tested and checked.

AN ASPECT OF A LONG TERM RESEARCH ON ALGEBRA: THE SOLUTION OF VERBAL PROBLEMS

Nicolina A. MALARA - Department of Mathematics - University of Modena - Italy

We expose here some results of a research concerning the solution of verbal algebraic problems by 12/13-year-old pupils. This research was carried out within a wider study regarding an innovative approach to middle school algebra. It shows that if pupils are appropriately guided they can represent verbal relations in many ways, they can compose relations by substitution and get to the solution - without any specifically syntactic study - of complex problems at many unknowns and achieve the awareness of the need and importance of the autonomous study of algebraic expressions and equations.

Introduction

This report is about an activity concerning the solution of algebraic verbal problems and part of a wide research project of didactic innovation for the three grades of middle school. The research aimed at approaching algebra as a language for the production of thought (Malara & Iaderosa 1998a) and included syntactic and structural aspects of the discipline (Malara & Iaderosa 1998b), according to the theoretical model of algebra teaching/learning formulated by Arzarello & Al. (1995).

Our experience, together with the results of many classical researches in algebraic realm (Bell & Al. 1987, Chevallard 1989/90, Freudenthal 1974, Kuchemann 1981, Kieran 1992, Sfard 1991) make us believe that it is important to:

- teach the algebraic language in analogy to natural languages, trying not to face syntactical questions a priori and from an instructional point of view, but rather trying to suggest situations from which these questions arise as a natural consequence;
- make sure that the pupils get used to the plurality of representations of the same thing by creating didactic situations that make them aware of the fact that the choice of how to denote an object or express a relation influences the development of reasonings about them;
- highlight the passage from the procedural level to the structural level, so that the pupils acquire the awareness of the duplicity process-object, which is typical of the way mathematics develops and of the discipline itself.

From a general point of view, the working method we used in class was based on the systematic use of written verbalization, on the analysis of the working strategies enacted by the classmates so as to induce metacognition and on the collective discussion of the different results so that all conclusions drawn can be socially shared within the class.

In this research project, we do not study verbal algebraic problems separately from the rest, but we include it in such an activity that progressively develops all through the three years and concerns:

1054

- the (manifold) translation into mathematical language of information expressed in the verbal language;
- the interpretation of formal writings and the recognition of their possible equivalence;
- the study of relations that are expressed by equalities between two terms and their transformation into equivalent ones;
- the introduction of the literal calculus starting along the study of problem-situations in general terms, and focusing on the role of the properties of the arithmetical operations.

Our methodological hypothesis

Traditionally, the study of algebraic verbal problems is started after the introduction of linear equations at one unknown; usually, considering the age of the pupils, the problems that are presented are in most cases solvable by intuition or by resorting to the appropriate graphical representations. However, as underlined also by Bernardz & Janvier (1996), this procedure doesn't allow the pupils to appreciate the goodness of the algebraic method.

Our methodological hypothesis starts the study of complex verbal algebraic problems at two or more unknowns even before equations are formally introduced, so that pupils can see why they should be studied as a mathematical object according to the historical evolution as well as to our ministerial syllabuses. This way the pupils get trained to the "principle of economy" that suggests the study of schemes representing a plurality of situations and that is so typically mathematical.

What we wanted to test with this hypothesis is the pupils' behaviour in front of:

- the formal translation of the relations expressed in the verbal text;
- the transformation and elaboration of the relations in order to get to a resolutory equation;
- the naive study of the equations for determining the values of the unknowns and solving a problem.

On selecting the problems that we wanted the pupils to solve, we considered the main difficulties about which the researchers have written, and in particular:

- the order in which the information appear in the text of the problem: the sequential nature of verbal language leads the pupils to a procedural reading, but if the order in which the data should be dealt with is different from the one in the text, it is very easy for them to make errors (Mac Gregor 1991);
- relations like "... is bigger than ...", "... is x times more than ...": they must be converted into terms of equality whereas pupils often do a translation that interferes with their proper elaboration (Mac Gregor & Stacey, 1993);

We can summarize the specific aims of the activities with problems as follows:

- to provoke and refine the pupils' ability to grasp and translate relations into terms of equality;
- to use hypothetical thinking in order to formalize information (if an object costs k Liras, then another object that costs twice as much costs ... Liras);

- to manipulate formulas by using the principle of substitution and the properties of equality appropriately for getting to an equation with a single unknown that has to be elaborated for determining the value of the unknown;
- to guide the pupils towards more and more refined syntactical questions through the solution of the problems.

Since we have limited room here, we shall only show the main results obtained with a group of 22 second-grade pupils with reference to a few algebraic verbal problems at more unknowns, underline by analysing the protocols the different difficulties and behaviours arisen and eventually we shall point out possible tips for overcoming them.

A few problems

In Table 1 you can see some of the problems at more unknowns on which we have worked. These problems usually have a rather simple text, that generally requires a formal translation that is not particularly difficult. The number of unknowns ranges from two to four and the relations can be additive, multiplicative, or both.

The didactic path developed with the pupils is focused on the control of the plurality of the possible writings of the same relation. For instance, on studying the relation "the segment $\overline{AB}$ *is greater than the segment* $\overline{CD}$ *of 4 (cm)*" the pupils usually express the sentence in the following ways $\overline{CD} = \overline{AB} - 4$; $\overline{AB} = \overline{CD} + 4$; $\overline{AB} - \overline{CD} = 4$ and they analyse and choose among them the most convenient writing as to the problem in exam. The substitution method is presented as "the game of changing", to be applied one or more times until they obtain an equation at one unknown which must be then elaborated. Thanks to the properties of the arithmetical operations, as far as the problems we have considered go, such equation can be lead to the structure ax+b=c, with a, b and c as natural or rational numbers.

Table 1

Algebraic verbal problems with more than one unknown done in VII grade

1. Consider a triangle ABC leaning on side AB of which the following information is given: the perimeter measures 60 cm; side BC is 5 cm longer than the side AC; side AB is 10 cm longer than side AC. Calculate the measures of its sides. Could the triangle be a rectangle triangle? If yes, which would be the right angle and which the hypotenuse?
2. Determine the two numbers of which the major one is such that it is by 50 bigger than the triple of the minor, and the sum of which is 110.
3. In a courtyard there are 224 animals between dogs and cats. The cats are 6 times as much as the dogs. Calculate how many are the cats and how many are the dogs in the courtyard.
4. Massimo goes to the pizzeria and spends 83.000 Italian Liras for a pizza, a pudding and a coke. The pudding costs 15.000 Liras less than the pizza. The pizza costs 400 Liras more than twice the coke. Calculate the cost of the pizza, of the sweet and of the coca-cola.
5. The perimeter of a rectangle trapezium measures 96 cm. The measure of the greater base is 20 cm more the smaller base. The difference between the measure of the greater base and the one of the oblique side is 13 cm. The difference between the measure of the oblique side and the one of the height is 10 cm. Calculate the measures of the two bases, the height and the oblique side.

We present this method in a collective activity of guided solution, in which the teacher acts as a model and shows the best way of facing each meaningful step of the process.
Apart from the number of unknowns and the kind of relation in question, the main difficulties concern: i) the translation of relations into terms of equalities and their transformation; ii) dealing with the resolutory equation; iii) choosing the unknown through which the others are to be expressed.
This is the order in which we faced them, but it is not strictly sequential.
The first problem presents two additive relations which express the relationship of two numbers as to a third one. It is very important to find the right translating formulas to get to the resolutory equation. To tell the truth, we usually start with easier problems than this, where the relations are more easily linkable together.
The second problem is even more complicated, because it contains an additive and a multiplicative relationship and also because you have to convert the expressions "is bigger than" and "is triple of" into terms of equality.
The third problem is quite famous (Mac Gregor, 1991). We usually get to it after dealing with other ones, with the specific aim of testing whether and to what extent the pupils, after they have practised with formal translation, have the difficulties that Mac Gregor has highlighted (difficulties with translating multiplicative relations that linguistically are expressed in the inverse order than in translation o: confusing quantity with quality in using and interpreting letters).
The fourth problem, too, is faced after other problems. It contains an additive relation, a subtractive one, and an additive-multiplicative one. It is used for testing the pupil's ability to deal simultaneously with different pieces information to be translated, as well as their ability to elaborate the information obtained.
The fifth problem is a bit different: apart from the context, which is geometric, this problem contains four unknowns and it is linguistically complex. Of the four relations, two have the difference between two unknown quantities as subject.
You will find in the following paragraphs some protocols of the pupils' work which can help us understand what they were asked to face.

Analysis of the protocols

The protocols you see in Table 2 contain some difficulties the pupils had and the strategies that they enacted.
The first two protocols concern Problem 2. The first one shows a good ability in translating formally and elaborating the information, whereas the second contains a typical error for beginners: to indicate the two unknown numbers with the same letter. Although there seems to be a good "local" control of the relations, it lacks a global control of the situation and the ability to organize the information into a formal translation.
The protocols about Problem 3 testify the difficulties concerning the syntactic aspect of dealing with the resolutory equation. In the first one, Annalisa can't interpret and elaborate correctly the writing "C + Cx6 = 224", but she understands

that her simplifying it into Cx6 = 224 is wrong. (Just like the researches have demonstrated, this error was quite frequent during our activity).
In the second protocol, Chiara works in parallel with two different encodings of the problem and makes a good and immediate translation of the relations expressed in the text. Still, she makes a very rough mistake on transforming, which reveals her procedural reading of the formal encoding of a relation (the expression "dogs+ dogsx6 = 224" is transformed into "dogs·2·6 = 224") and shows difficulty in controlling the meaning in the correct reading and elaboration of the equations she obtains.

Table 2

Examples from the pupils' work

From the protocols on Problem 2

Silvia: A = Bx3 + 50 ; A + B = 110 ; B + (Bx3 + 50) = 110 ; Bx4 + 50 = 110 ; 110 - 50 = 60 ;
60 : 4 = 15 B = 15 ; 15x3 + 50 = 45 + 50 = 95 ; A = 95.

Anna: maj. 1st number is bigger by X + 50 → sum 110; 2nd number triple X·3; minor number 110:3=(X·3)+50=X major number

From the protocols on Problem 3

Annalisa: G = Cx6, C = G:6, C + (Cx6) = 224; 224:6 = it doesn't work

Chiara: dogs + cats = 224 ;

dogs x 6 = cats ;	cats: 6 = dogs;
dogs + dogsx6 = 224 ;	cats + cats: 6 = 224
dogs·2·6 = 224	cats·2:6 = 224
224:6 = 3	224x6 = 1344 ; 1344: = 672; cats 672; dogs 672:6 = 112.

From the protocols on Problem 4

Chiara B.: 8.300 = Pizza + sweet + coke ; pizza A , Coca = B , sweet = C.
A = sweet + 1500/cokex2 + 400. B = pizza - 440:2 No. B = pizza:2 - 400
C = pizza - 500/cokex2 + 400 - 1500. 8300 = A + B + C = A + A:2 - 400 ; A·3:2 - 1900 = 8300 ; 8300 + 1900 = ; A + B + C = Bx2 + 400 + B + Bx2 + 400 - 1500 ; B·5 + 800 - 1500 = 8300 ; 9800 - 800 = 9000 ; 9000:5 = 1800 coke ; pizza = 1800x2 + 400 = 3600 + 400 = 4000; sweet = 4000 - 1500 = 2500.

Eleonora: P pizza, C = coke, D = sweet. P + C + D = 8300 ; D = P - 1500 £; P = D + 1500 C = P:2 + 400 NO CP = C + 400x2 NO C = Px2 + 400 ; P = C:2 - 400. The following part appears erased: P + P - 1500 + P;2 + 400 = 8300 3P - 1500:2 + 400 = 8300; 8300 - 400x2 + 1500:3 = 900x2 + 1500:3 1800 + 1500:3; 3300:3 = 100

From the protocols on Problem 5

Eleonora: 2p = 96 cm = AB + BC + CD + DA;
BC = AB-13 , AB = BC+13 ; BC = CH-10 ,
CH = BC+10 ; AB = DC+20 , DC = AB-20
AB + + AB - 13 + BC - 10 = AB + AB - 13 + AB - 20 + AB - 13 - 10 = 96 ; 4AB - 13 - 20 - 13 - 10 = 96 ; (96 + 13 + 20 + 13):4 = 119 + 20 + 13:4 = 139 + 13:4 = 152:4 = 38 ; AB = 38 ; CD = 38 - 20 = 18 ; BC = 38 - 13 = 25; DA = 25 - 10 = 15.

Alberto: AB - CD = 20 cm ; AB - BC = 13 cm ; BC - CH = 10 cm AB + BC + CD + DA AB-CH = 23 ; 96 = AB + AB - 20 + AB - 13 + AB - 23 ; 96+20+13+23 = 152 , 152:4=38=AB; AB = 38 cm; 38-13 = 25, 38-20 = 18 , 38-13 = 25; BC = 25 cm ; CD = 18 cm AD-CH = 15.

BEST COPY AVAILABLE

The protocol about Problem 4 reveals more difficulties in reading the formulas correctly so that they can be transformed. The young girl makes a mistake in explicating B from the relation A = B x 2 + 400 since she writes B = A:2 - 400 instead of (A-400):2. However, it is interesting to see that since she cannot elaborate the equation in unknown A in a way that she can manage, in the end she reconverts the relation of equality in function of the unknown B, which allows her to achieve the solution.

The two protocols regarding the last problem show two different ways of organizing the information for getting to the solution. Eleonora, who is not particularly brilliant, translates the information literally and gets to the fundamental equation at one unknown by operating subsequent changings. Alberto, on the other hand, is quite smart; he operates in a very original way. He expresses all the information in terms of difference between the unknowns and combining such differences he obtains a further relation of difference which he uses for eliminating one of the unknowns.

Generally speaking, as to the first problem, the "game of changings" turns out to be quite easy for almost all the pupils. As to the second one, on the contrary, the protocols are rather different. The best solutions revealed themselves to be a good model for the pupils who were a bit lost. As far as the third problem goes they generally give a good translation of the text. Only the 14% of the pupils make errors of this kind, but there is a widespread presence of mistakes and serious difficulties concerning the syntactic elaboration. One of the difficulties that we have detected in the pupils, for instance, is well known in didactic research (see Lopez Real 1998) and it is due to the fact that the pupils are working with natural numbers: they couldn't convert writings like g + g:6 into g + g/6, which is more expressive as to a correct transformation. The fourth problem was quite difficult for them owing to the variety of relations involved. The biggest obstacle seems to be managing the correct translation of the relation: "the pizza cost 400 liras more than twice the coke", which is tied to the correct interpretation of the linguistic expression "more than twice the". As to the fifth problem, beyond the number of relations involved, the pupils are negatively struck by the novelty that two of the four relations of the problem concern the difference between two of the unknowns.

The global analysis of the protocols tells that the solving strategy chosen by the pupils is "mixed": they begin by operating algebraically (they write down the single relations formally and by substitution they reach an equation with only one unknown), and once they get to the equation, since they lack appropriate algebraic knowledge, they study it "arithmetically" by dividing it into two steps; on the basis of the meaning of the equality of the two terms of the equation, they isolate and solve the numerical expression constituted by the known terms, then they lead the initial equation to one of the kind ax=b by summing the terms including the unknown and by substituting b with the result of the numerical expression they have elaborated. On manipulating the equation, the pupils have mainly syntactic difficulties, and in particular on doing the sum of the terms in x, especially when

some terms have fractionary coefficient, or when there's one term without numerical coefficient among the terms including the unknown (which makes them neglect it on doing the sum), or even when they have a bad management of the parentheses. Some protocols show very clearly that if by working on an unknown they reach an equation that they acknowledge to be difficult for them, they go back to the beginning and look for a different unknown which gives them a much easier equation. These protocols are rather useful for classroom discussions aimed at introducing 'forecast thinking' and 'choice economy'.

General considerations

This activity had a very strong impact on the pupils both for involvement and results achieved. Almost all of them understood that they were dealing with a general model for solving problems with unknown data, based on the translation into formulas of the information contained in the text, which allows to reach the solution thanks to the elaboration of the formulas obtained. As to their behaviour, we can divide them into two groups of the same size: the first one contains those pupils who adopted the algebraic method and were able to face syntactic elaboration on their own, according to the principle of economy; the second one contains the pupils who actually learned the principle of formal translation, but who never went beyond the models they had learned, which made them get stuck in front of new syntactic situations. Besides, a small group of very weak pupils didn't understand the spirit of the algebraic method and resorted to graphic solutions whenever they could. Nevertheless, we must say that with time almost all the pupils developed the skills for translating and organizing by substitution the relations contained in a text. Of the errors reported in research studies we didn't see neither the conjunction error that usually appears with additive and multiplicative relations (Mac Gregor & Stacey, 1994) nor any difficulty on passing from one to many unknowns (Radford, 1994).

As the protocols witness, the fact of having done algebraic problem solving before doing any algebra syntax implied of course that the pupils sometimes enacted wrong transformations - some of which had no justification, like those connected to the omission of the parentheses, or those which were due to lacks of thinking about the meanings of the writings.

Anyway, this method made the pupils approach syntactic questions in itself, outside any reference context, concentrating on the arithmetical properties. For example, on the basis of the difficulties arisen, at a certain point the teacher asked these questions: *If M is a number, what can I say about: M + 2M + M + M ; M + 2M + 7M - 4M; -7M + 7M*? and concentrated on the following answers for discussion: M + 2M + M + M is: 5·M (Eleonora); M·3 + 2·M (Jessica); M + M + M + M + M (Silvia) ; 2 + 4·M (Cristina). M + 2M + 7M - 4M is : (1+2+7-4)·M = 6M (Alberto) ; 5·M Vincenzo ; 10·M + -4·M (Salvatore) ; 3·M + 7 M - 4·M = 10·M + -4·M = 6M (Chiara). -7M + 7M is : $0 \cdot M^2$ or M·(-7 + 7) = M·0 (Sara) ; 2·M + 7 - 7 (Chiara) ; 0 + (M·M) (Cristina).

Some of these answers show that for many pupils the meaning of those expressions that the teachers consider easy and by no way ambiguous is not at all straightforward. This means we should spend more time than usual with problems like these, which are so important for the control of the meaning of literal expressions. We therefore resort to very simple problems of this kind, which unfortunately are not contained in our textbooks and are often considered banal by teachers, but can be found in foreign projects (e.g. Harper 1987).

These results make us suggest that in the future we should carry out more studies on this aspect, face equation solving beside problem solving, presenting them like hypothetical equalities between two expressions in the sense of Herscoviz & Linchevski (1992). These equations should be solved without resorting to ready-made techniques, but rather in different ways according to the features of the equation (through reasoned trials, through the weigh-model and using the law of cancellation, resorting to inverse operators, etc.), also for reducing to the minimum the difficulties connected to the different structures of the numerical realms in which they might operate.

Conjecturing and Proving in Problem-Solving situations

M.A. Mariotti & M. Maracci
Department of Mathematics - University of Pisa - Italy

Abstract *This paper reports on the first phase of a research project which aims to investigate conjecturing and proving processes in problem-solving situation. The analysis focuses on the relationship between the process of production of a conjecture and that of its justification: in particular, deductive proof is compared to argumentation supporting a conjecture. The paper discusses on the difficulties related to the passage from the production of a conjecture and the production of a proof.*

1.Introduction

Previous investigations (Shoenfeld, 1985) have provided evidence of the appearance of argumentative reasoning accompanying the solution of an open-ended problem, so as its relationship with the production of a proof (Boero, et al. 1995, 1996, Harel, 1998)

Despite the undeniable difference between "deductive organisation of thinking" and "argumentative organisation of thinking" (Duval, 1991), some aspects of argumentative activity were observed and described, in the production of conjectures so as of proofs (Boero et al. ,1996; Mariotti et al., 1997). The peculiarity of the teaching experiment, within which those aspects of continuity were observed put in question the generality of the observation and claimed for further investigations, in order to identify the relevance of the particular context and the role played by the specific 'didactic contract' set up in the classroom. Actually in the teaching experiments, which Boero et al. (1995) refer to, open-ended problems were commonly included within school activities with the explicit agreement that the solution should provide a conjecture as an "argumented choice"; the issue arises whether similar results could be found outside this special contract.

Despite the fact that problem solving activities have become very popular in mathematics education, so as in the school practice of some countries, this is not the case of Italy, where open-ended problem solving and investigation rarely appear among school activities, even less at the high school level. Consequently, a research project, still in progress, has been carried out with the aim of investigating on the solving processes of open-ended problems.

This paper reports on some results of that analysis, in particular the relationship between producing a conjecture and constructing a math proof of that conjecture.

The main hypothesis

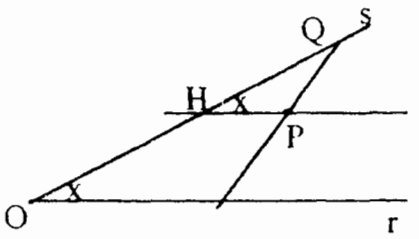
Mathematical proof is a complex idea dealing with many different aspects, concerning logic, epistemology and cognition (Mariotti et al., 1997). The facets that proof can assume in different institutional contexts depend mainly on the function attributed to proving process: as far as school mathematics is concerned, the most relevant functions are explaining and convincing, while that of

systematising a result within a theoretical framework represents a secondary function (Bell, 1976; de Villers, 1991). That seems consistent with the conclusions recently reached by Hoyles and Healy (1998) As the authors say "Students are unlikely to use deductive reasoning when constructing their own proof". (p. 42) and "An argument felt to convince or explain is more likely to be selected as a student's own approach than one that is not, and the likelihood increases still further if it does both"(p. 30).
That can be summarized in the following Hypothesis.

Hyp. Proving is providing logically enchained arguments referring to a theory, but at the same time proving is providing an explication which can remove doubts about the truth of a statement.

This twofold meaning of proof, which is unavoidable and pedagogically consistent (Hanna, 1990 quoted by Harel 1998), may cause difficulties and misunderstanding, when open-ended problems are concerned.
Open-ended problems appear to provide situations to introduce students to theorems (Boero, Mariotti et. al., 1997): arguments are mobilised in order to produce and support a conjecture, but for the same reason the need of justifying a conjecture and removing uncertainty can cause the aims of explaining and convincing to prevail. As a consequence, the resulting argument may be very successful in explaining an answer, but may be completely inadequate as a proof of a conjecture. What Harel states (1998) could be adapted as follows: "The proof schemes held by an individual are inseparable from his or her sense of *what means to solve an open-ended problem* ".
In Italy at the high school level a common task concerns the proof of a given statement, but according to a well established didactic contract (Brousseau, 1986), a proof must be clearly required: specific expressions are used to formulate the task "Prove that ..."
On the contrary when open-ended problems are concerned, no clear and established norms may be found: the process of solution seems to require a justification, but that is usually conceived as the explication of one's own 'reasoning'. That means that the solution must be accompanied by an argument which explains and justifies it.

The experimental design
Seventeen subjects were selected in different Scientific High Schools: according to school evaluation, all of them were high-attaining XI and XI' Grade students and generally speaking were considered brilliant students. Although they did not belong to the same class and not even to the same school they followed a deductive approach to Geometry. Four problems were selected and proposed to the students in an individual interview; during the solving process they were asked to think aloud and the whole problem-solving session was videotaped, then the transcripts of the interviews analysed (Maracci, 1998).



In this paper only one of the problems is considered: the text is the following.

Pb1. *A convex angle rOs is given , where the two rays r and s are not on the same straight line, and a point P internal to the angle, determine a line segment which has its ends on the arms of the angle and P as its midpoint.*

That is a construction problem; it presents some difficulties in the identification of the solution, but may be successfully approached by assuming the segment given and looking for some characterising properties.
The problem is not too difficult not too easy and for this reason provides a good test for our purpose. Students can undertake the solving process, but the solution does not come immediately: often successful, the solution comes after some investigation.

Argumentation supported by theorems and definitions
The analysis of the transcripts reveals a great variety in students' performances, but also interesting similarities.
It is difficult to separate the process of solution into different phases corresponding to an ideal sequence of producing, formulating and proving a conjecture. What occurs is more like to an intermingled combination of this phases. The process is clearly directed by the goal of attaining the solution together with the certitude of its correctness. The culture of theorems into which students have been introduced leads them to consider that for a reasoning to be correct it must refer to well known geometric properties and theorems.
The solving process results in a long and often tortuous discourse with arguments referring to the possibility of "applying theorems". But it is very difficult to isolate a statement which could be possibly recognized as the formumation of a conjecture, either in the hypothetical form "if ...then" or in any other form; similarly, it is very rare to find a final deductive argument which could be possibly recognised as a proof.
The following protocol can be considered an exemplar.

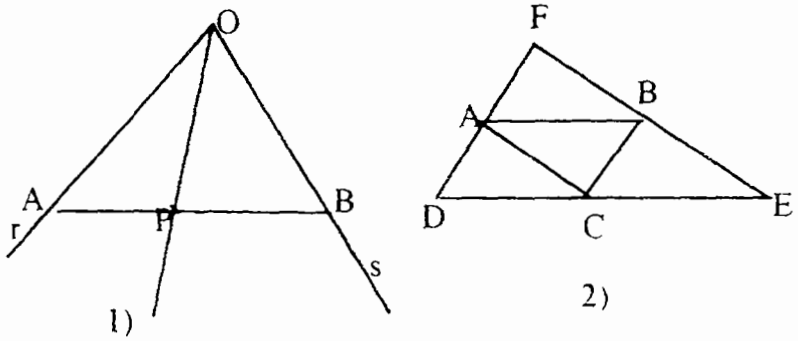
Gia 11th grade (Scientific high school) Pb1
Giacomo reads the text of the problem and after few attempts (drawing an angle and a tentative solution segment) seems to have an intuition
Gia. : let us draw the lines parallel to the arms of the angle and passing through P - *he draws the lines, then draws a new drawing (4) where he traces few segments passing through P; stressing one of them* -
Gia. Yeah, one can make the parallel to r pass through P - *he draws it on drawing 4* - at this point - *he marks the angles* - here, practically ... if I trace the segment through P - *he stresses the segment* - which should be practically one half, I should find that because of the similarity ... this is one half of this ... and then also the ratio of the other sides, that is - *he put the labels Q and H* - OQ and OH must be 2.

1064

Thus in order to find the segment one can do in that way - *he draws a new figure (5) and labelling* - given a point P one draws the parallel line to r - *he draws the line on figure 5* - after that - *he marks the intersection between the new line with the ray s* - one doubles ... I should obtain OH, let us consider a segment with the same length - *he marks the point Q on s* - and one make the segment pass and this is ... has the ends - *he marks the point R, intersection between r and the line QP* - on the arms of the angle and P is the midpoint.
I.: Have we finished that way?
Gia.: I think so; here we used the 'similarity' and we could use it because I had two triangles - *he comes back to drawing 4 and puts the label M on the end of the segment passing through P* - OQM and HQP similar because constituted by one equal angle and because I drew the parallel to the ray r - he points at it - I know, because of a theorem that I have already proved, a group of parallel lines which intersect a ray, divides it in ... a group of rays ... divides it into similar triangles; thus from the similarity I just pass to this ratio of sides which between QM and QP must be 2, but, in order to be 2 it must be 2 also the ratio of QH and QO, because we know that in two similar triangles the ratio must be constant and then I come to the end : given a point P one can draw the parallel line, in this case to r, but one could do the same with s, and consider the segment OH, double it in order to get another equal segment, pass the segment through Q and ...
I.: OK, I ask you only another question: if I were your teacher and she had given you that problem, at this point would you say "I finished" or would you do anything else?
Gia.: I would say that I finished, because I got the thesis that I wanted, I found the segment.

The production of the solution is accompanied by the explication of one's own 'reasoning '. The formal approach to which students have been exposed lead them to approach the problem 'theoretically', i.e. the segment must be "geometrically constructed" and for the argument to be correct it must refer to well known properties and theorems. Thus, since the beginning, Gia. refers to "tracing *parallels*" and to "apply *similarity* ". But the student seems not to feel the need of reorganising that reasoning in the form of a statement and its proof. The main objective of the argumentation remains that of explaining and convincing oneself and/or the hypothetical interlocutor, and the discourse does not assume the form of a Theorem (a statement and a proof within a theory, Mariotti at al. 1997).
After the question of the interviewer Gia takes up his argumentation and immediately points out that he used ("ho sfruttato") a geometric concept - similarity -; then he seems to undertake the first steps of a proof, although no statement has been clearly formulated and remains implicit in the description of the construction. What seems to me most interesting is that at the crucial point, when Gia is going to apply the theorem, he goes back to the indirect argument, used in the production of the solution: with the same words of his previous argument, he says:

thus from the similarity I pass to this ratio of sides which between QM and QP must be 2, but, in order to be 2 it must be 2 also the ratio of QH and QO.



In other terms, the inversion between hypothesis and thesis, typical of the change from 'analysis' to 'synthesis' and required by a deductive systematisation of the argument, did not occur.

Gia's reasoning explains in a narrative form both the genesis of the solution and its justification; that reasoning satisfies the student because it fulfill his needs in that situation: it accomplishes both the function of convincing and explaining, and the 'didactic agreement' that the support of a conjecture must be provided by theorems already known. Thus, despite the pressure of the interviewer the structure of the argumentation does not change and it does not even change after the explicit reference to the didactic contract "If I were your teacher ..."
Let us consider another example which presents some similarities, but also an interesting difference, with the preceding one.

Fra. 11th grade (Scientific high school) Pb1

Fra. reads the text and draws a first diagram. That gives him the idea of a theorem about midpoints in a triangle. Confronting the first drawing and a new one representing the theorem, Fra comes to the solution: at this point, he summarises his reasoning running through his previous arguments and concludes:

1. **Fra**. the figure is not precise ... because of the fact that ... now the figure is not well done, anyway these points here - *in the drawing 1 he changes the labels of the points images of O in the symmetry of centre A and B, he points at D,E and P* - they should be collinear.

2. **I**: D, E and P should be ... and so they are?
3. **Fra**: They are, I mean they are and also they are parallel to this line here - *he points at AB* - thus I got the end, if I drew a good drawing.
4. **I**: sorry, you are saying that D, P and E are collinear, ...
5. **Fra**: Yes, they are, because of this reason ... if I have this point - *C on the drawing 2 and P on the drawing 1* - which would be practically the midpoint on this side here - *he uses the pen to point at the segment to determine, but without drawing it* - I can use the relationship holding between the midpoints - *he points at the drawing 1, PB and r* - ... being that parallel - *BC in drawing 2* - I draw this parallel - *PB in drawing 1* - in order to find this - *point B in drawing 2* - then drawing the other one - *PA in drawing 1* - and finding this point - *A in drawing 2* - I know that this - *OA in drawing 2* - is equal to half that side - *he points at AD in drawing 1* - I do the same - *he points at drawing 1* - I take DE and that's all.
6. **I** : That seems a good idea, but it could be that I am not convinced that D,P and E are collinear.
7. **Fra**: ... but ... the theorem ... - *he points at drawing 2* - ... this theorem says that if I draw the lines through the midpoints of a triangle, for instance B and C, all the segments, the length of the segment between the midpoints is equal to half ..., in all the triangles, any triangle ... I mean I find this relationship ... I mean ...
8. **I**. In our problem, we have the point P and the angle, we draw the parallel lines to the arms of the angle, we find the point A, B; let us do the symmetry ...
9. **Fra**.: let us call them O' and O" - *he changes the labels in drawing 1*.
10. **I**.: ... you construct O' and O"
11. **Fra**.: now O'O" passes through P

1060

12. **I.:** I don't know that, I don't ... that O', P, O" are collinear, I don' see that so evident from that theorem, try to explain that better ... what does it mean that they are collinear?
13. **Fra.:** If I draw the straight line - *he points at a hypothetical straight line passing through O', P, O"* - they all are on the same straight line
14. **I.:** How can you prove it?
15. **Fra.** : One must prove that if I take the straight line O'O", P is on that line .
16. **I.** : ... It doesn't seem straightforward to me ... from that theorem
17. **Fra.** : ... let us suppose that P is not on that line, then there should be another point P', let us put it here - *he marks P,' separated from P', on O'O"* - such that ...
...
18. **Fra**: if I did a new drawing ... - *he draws the angle, the point P and the parallel lines* - P is here, I draw the parallel lines ... let be like that - *he draws a segment that does not pass through P* - it would exist a point P' which is the midpoint ...
...
19. **Fra.** : *the comes back on drawing 1* - then it should exist a point P' on O'O" ... a point P' which would be the midpoint of the side ...
...

Similarly to Gia., the first justification produced by Fra (5) is a summary of his previous arguments centred on the reference to the "midpoints theorem"; also the following attempt remains confused and vague. At this point the interviewer intervenes: he reformulates the solution, and directly asks to *prove that* P belongs to this segment and is its midpoint. After the direct request of proof Fra begins a proof by contradiction, which is then completed .
It is interesting to remark that in order to accomplish that proof Fra needs
1. to detach himself from the previous reasoning through the drawing of a new figure, where the statement to be proved is clearly expressed (18).
2. to come back to the first drawing (19), where the first conjecture was produced, in order to resume his reasoning and the relationships among the elements involved (an example of cognitive unity, Garuti et al., 1996) .
Similarly to the previous example (Gia), after the intuition of the solution, there is neither spontaneous reorganisation of the reasoning in a deductive form, nor the formulation of a clear conjecture. The student is able to provide a proof, only in response of a direct request (14) of the interviewer.

Discussion

Open-ended problems confirm themselves as catalysts of argumentative activity: the feeling of uncertainty that accompanies the solving process provide a good stimulus for the production of arguments. It is also clear that the need of a Geometric support for those arguments has overcome the status of a norm of the didactic contract and has evolved in an epistemic need.
Never the less, the main objective of students' argumentation remains that of convincing oneself and/or the hypothetical interlocutor, and the discourse does not assume the form of a theorem. In other terms, students seem unaware of the distiction between the process of constructing arguments, i. e. "proving", and the deductive systematisation of those arguments in a "proof" (Douek, 1998).
But in this case speaking of a cognitive rupture between these two aspects (Duval: 1991) would be misleading. Rather, our hypothesis about the presence of

different functions of proving, which coexist and guide the organisation of the argumentation, provides an interpretation for both the examples. In the former example (Gia.) there is a prevalence of one function on the other and the absence of the correct formulation of a deductive proof. In the latter example (Fra), a direct request of proving may cause the shift from the function of explaining and convincing to the function of validating a statement. The example of Fra shows that the necessity of reorganising the arguments in a proof can be understandable, although not immediate. Actually, some difficulties must be overcome: as the protocol shows it is after the mediation of the interviewer that the student understands what he was required to do. Spontaneously he would never think of doing that.

Although, proving as part of the solution of an open-ended problem seems similar to proving as response to a "proof task", between these two processes there is a great cognitive difference. As far as the proof task is concerned, the statement and the request of its proof are directly posed to the student from outside. On the opposite, when an open-ended problem is concerned, the production of a proof must be the response to a self-imposed task, encapsulated within the solving process, and strictly dependent on the production of a conjecture. Thus, within the solution of an open-ended problem the functions of explaining and convincing may completely prevail over the other. This effect may be amplified in the particular situation of the interview: the request of thinking aloud and making one's own reasoning explicit to the interlocutor naturally leads the student to shift to the functions of explaining and convincing.

The peculiarity of a construction task

As a final remark I want to focus on the particular task selected for the interview: a construction task.

When a construction task is concerned the solution requires to describe the constructing operations, and then to validate it in a Theorem (Mariotti et al., 1997). That means to formulate a statement, expressing the geometric relations among given and new elements, and prove it; but summarising in a 'hypothesis' all the relationships stated by construction may be too difficult to be done. That could explain why in our protocols it is almost impossible to find any formulation of a conjecture, and when it occurs the conjecture is never expressed in a hypothetical form. On the other hand, the absence of a statement may obstacle pupils to assimilate the situation to the familiar situation of a 'proof task' and hinder the production of a proof. On the contrary, the formulation of a clear statement could direct the students towards the idea of proving and facilitate the correct construction of a proof.

Conclusions and didactic implications

The pervious analysis shows of the continuity between the arguments used both in producing and justifying a conjecture and its potentialities, but makes also clear

that the relationship between the process of constructing a conjecture and that of constructing its proof presents a complexity which must not be underevaluated.
In particular, the delicate didactic problem concerning the relationship between the different functions of proving must be directly addressed because of its effect on the process of constructing a mathematical proof.
A suggestion comes from our analysis: teaching intervention could foster students to reconstruct their arguments into a Theorem, i. e. a statement and a proof within a theory. Moreover, according to our results, a basic point seems to concern the formulation of a conjecture in a clear and precise statement.
It is true that most of the solutions provided by our students appear very close to mathematicians' practice of doing mathematics, but the obvious difference between mathematicians and students cannot be forgotten. Mathematicians can afford (take the liberty of) informal arguments, in fact beneath an incomplete and informal discourse they maintain the epistemological control of what is going on, of what can and/or should be proved On the contrary, as far as students are concerned, the control of the different functions of proving is not expected and the balance between them is not immediate. As Hanna wrote: "what needs to be conveyed to students is the importance of careful reasoning and of building arguments that can be scrutinised and revised" (1989, p. 23).
As any characteristic feature of mathematicians attitude, the complementarity between different forms of argumentative activity, could be the result of a slow and complex appropriation process: an explicit educational goal.
That is not simply to comply with the standards of mathematical argumentation, but because, in our opinion, the appropriation of a productive relation between argumentation and proof may improve students' awareness of the functioning of mathematics.

FORMING RELATIONSHIPS IN THREE DIMENSIONAL GEOMETRY THROUGH DYNAMIC ENVIRONMENTS

Christos Markopoulos and Despina Potari

University of Patras, Greece

This study explores how children build relationships between geometrical solids and their properties and between the solids themselves while working with dynamic three dimensional models. The data used in this paper comes from a teaching experiment where two pairs of children, one of grade four and one of grade six work on the models which have been developed by the researchers. Issues that emerge from the study are the role of constructed environment in bridging the gap between intuitive and formal school knowledge, in encouraging the development of relationships between the two and the three dimensions and in supporting interactions between "concrete" and "abstract".

A number of research studies have focused on children's thinking about three dimensional geometrical solids. However, most of them explore children's conceptions on solids' representations on the plane (Bishop, 1979; Cooper and Sweller, 1989; Mitchelmore, 1980; Piaget and Inhelder, 1956). Even in cases where the solids themselves are considered, they have been examined through their plane representations either in static or in dynamic environments (Battista and Clements, 1996; Ben-Chaim, Lappan and Houang, 1989; Chiappini and Lemut, 1992; Gutierrez, 1996). In this study, children's geometrical thinking is investigated through models of geometrical objects which through dynamic transformations can take different forms. We accept Bauersfeld's position (1995) that the materials and their properties are not "self-speaking" but we consider that the dynamical manipulation of them may help children to construct and extend dynamic images and develop their geometrical thinking. This analogy can be seen in the work of Shepard and Cooper (1982). Kaput (1992) supports that in the case of geometrical objects this process is characterized by the recognition of the invariance of these objects and this can be encouraged by the variation of the objects.

The focus of the study

In this paper, we present a part of a research study which focuses on children's geometrical thinking about geometrical solids and their properties. In particular, we explore the role that the dynamic transformations of geometrical solids can play in the creation of a learning environment which encourages the development of children's ability to focus on the properties of each solid and build relationships between these properties and, based on these relationships, between different solids. This development can be seen within the model of the van Hieles' levels of spatial thinking

or within Presmeg's (1986) and Johnson's (1987) view of the development of mathematical reasoning and understanding through the transition from concrete images to more abstract and flexible images. The dynamic transformation of a geometrical solid is considered as a process where the solid changes its form through the variation of some of its elements and the conservation of others. Similar transformations have been studied in the case of two dimensional geometry and especially through the use of computers (Laborde, 1993; Markopoulos and Potari, 1996). However, the case of three dimensional geometry requires the development of more complex relationships as the properties are related both through the linear properties of the solids (e.g. the relationships between the edges) and through the properties of two dimensional geometrical figures (eg. the relationships between the faces).

The above transformations have been seen in three different contexts. The first is defined through children's manipulations of physical materials of three dimensional geometrical models. The second involves children's interactions in a computer based environment which simulates such geometrical models and their transformations. The last one is formed through children's involvement in imaginative situations where dynamic transformations of solids take place. The possibilities and the constraints of these three environments make possible the appearance of different aspects of children's conceptions of the solids. These contexts vary in the type of transformations which they require through children's actions. It seems that through these contexts the children move from physical to visual and finally to mental actions. Here, we can probably see a development from concrete to abstract considerations of the solids. The data used in this paper concerns the first context.

In this paper, we focus mainly on cognitive aspects of the learning environment by working with pairs of children. However, the research is concerned with the process where the role of the transformations is explored in a mathematics classroom environment. The focus is not only on the development of children's geometrical thinking about solids but also on the wider environment, such as the teacher's actions, the cooperation between teacher and researcher, the adaptation of the materials in the mathematics curriculum, the whole interaction between the teacher and the children and between the children themselves, which frames this development.

The process of the study

To explore children's constructions and how these are developed, we have used a "constructivist teaching experiment" where the researcher acts as a teacher who models children's constructions. The researcher, reflecting on his/her interactions with students, tries to explore children's actions and construct models of their mathematical understanding which throughout the teaching sessions are tested and revised. Based on current interpretations of children's actions, the researcher - teacher makes decisions concerning situations to create, critical questions to ask, and the types of learning to encourage. (Cobb & Steffe, 1983)

In this experiment we worked with two pairs of 10 and 12 year-old children. Each pair worked in three 45-minute sessions per week for 4 weeks. The sessions were videotaped and transcribed. The two pairs were selected from the forth-grade and the sixth-grade classroom of the same school according to their responses to a given task. Children were given three different solids and asked to write a description of each solid which would be given to one of their classmates. The description should be as accurate as possible, so that their classmate could identify the solids. The three solids were: a prism, a solid consisting of a cube and a pyramid and a cylindrical can . From the analysis of their responses, we identified two groups in each classroom according to the way they referred to the properties of each solid. Each pair consisted of one person from each group. We also took into account the gender (one boy and one girl for each pair) as well as the teachers' opinion about the personal relationships between the children.

Description of the materials

These are models of solids which were developed having some of their elements varied dynamically. In this experiment three models are mainly used by the children. The first dynamic model is a cube formed only by its 12 edges whose length could vary. The children could also vary its angles. In these transformations the degree of variation is constrained by the fact that the lengths can double in size while the angles can vary by up to thirty degrees. The second model is a cuboid where the length of its edges remain the same while its height varies from an initial length to zero when the solid "becomes" plane. The third one is a rectangular or a cylindrical transparent plastic solid filled two thirds with salt. The children can study the various forms that the salt takes. All these transformations which can be performed on these models are characterized mainly by the variation of the form of the solid and not only by the variation of its position.

The tasks used were based on our interpretations of children's actions. They varied from the free exploration of the models to more goal directed tasks where children were asked to transform an initial solid into a different one and study this transformation, considering, for example, the properties that have been changed. However the tasks have evolved throughout the sessions. Children were encouraged to face extreme cases, to anticipate and to generalize. In our analysis below, we exemplify more clearly the role of the tasks in the whole learning environment.

Emerging issues

From the analysis of the transcribed videotaped teaching sessions we exemplify below some points that indicate children's thinking in three dimensional geometry and its development.

Building relationships between the solid and its properties The children were asked to transform a given solid into a different one and compare the two solids to identify similarities and differences. This task encouraged the use of different comparison strategies which fall into three categories:

BEST COPY AVAILABLE

- comparisons based on the form of the solids
- comparisons based on the variations of the initial solid caused directly by the children
- comparisons based on the subsequent changes caused through the transformation

Throughout the teaching experiment all these three categories emerged and there was a development in children's strategies from the first category to the third. In the first category, the children considered the solids as whole entities. For example, in the case of transforming a cube into a cuboid by changing one dimension one pair of children (12 years old) initially saw the cuboid " like a cube but a little longer". Later on they started to consider them as separate solids with different properties " It (the cuboid) has these equal and those equal (the opposite faces) but it is not like the cube which has all equal". By moving from one form of the solid (the cuboid) to the original one (the cube) and vice versa, they start to become conscious of the underlying changes in the dimensions of the solids "its length has changed while its width has remained the same (of the cube)". This is an example of the second category where the children consider the change in the properties which was caused through their own actions in this dynamic situation. The problem becomes more complex when the children are asked to make another cube, different from the original one. In this case all the three dimensions should be changed properly. The children initially have not developed a particular strategy but they try different cuboids by changing the dimensions and finally approximate the cube while they start to realize that for a cube " we need to have equal sides".

In the third category, the children form more abstract relationships as the changes in the properties are not visible, for example the changes in the surface area or in the volume. Even in cases where these changes can be seen, for example in the case of the angles, they have not been caused directly by the children but are the result of the transformation. Through the researcher's encouragement the children started to consider these types of changes. We give an example below of how the children conceived the change in the volume when they made an oblique cuboid from a cube, keeping the same sides. Initially the children think that the volume becomes bigger "it becomes slanted and takes up more space". Through the discussion we realised that the children meant that the new solid does not fit easily into a cubic frame. Later on when they were asked to justify their opinion, they could not see any point in doing so as they thought that it was obvious. When the researcher asked them to find a way to calculate the volume of the two solids, they started to recall the "formal" school method of multiplying the dimensions in the case of the cube. They extended this method to the case of the oblique solid. Then they started to believe that the two solids had the same volume as they had the same edges. The whole problem changed to a manipulation of numbers, the lengths of the dimensions, while their intuitive conceptions of volume disappeared and the problem was transformed into the comparison of the two solids in terms of their surface area. The integration of intuitive and school knowledge took place when the researcher intervened and asked the

children to imagine what would have happened to the solid if they continuously made the cube more slanted. This led the children to see the effect of the height both on the surface area and on the volume, and doubt their previous belief. As a result they explained by using the variation of the height, that the volume of the solid will become smaller.

The development of these three comparison strategies is associated with the evolution of the task during the experiment (see figure 1). Students were asked to transform an initial solid into a different one and study this transformation from three different perspectives. These perspectives are characterized by different manipulations of the transformation. One was the transformation into a different solid (the result of children's free experimentation with the materials) where the varying properties had to be identified. The second was the transformation into a specific solid (e.g. the transformation of a cube into a different cube) where the properties of the two solids had to be taken into account in order to get a satisfactory result . The third was the transformation into a different solid through a specific variation of a property (e.g. the solids to have different volumes) of the original solid. In the last two perspectives the children are forced to take into account the properties of the solids and build relationships. So, we see the appearance of the most advanced comparison strategies (the last two categories). On the other hand, the first perspective encouraged the use of more holistic comparison strategies, although this was not exclusive.

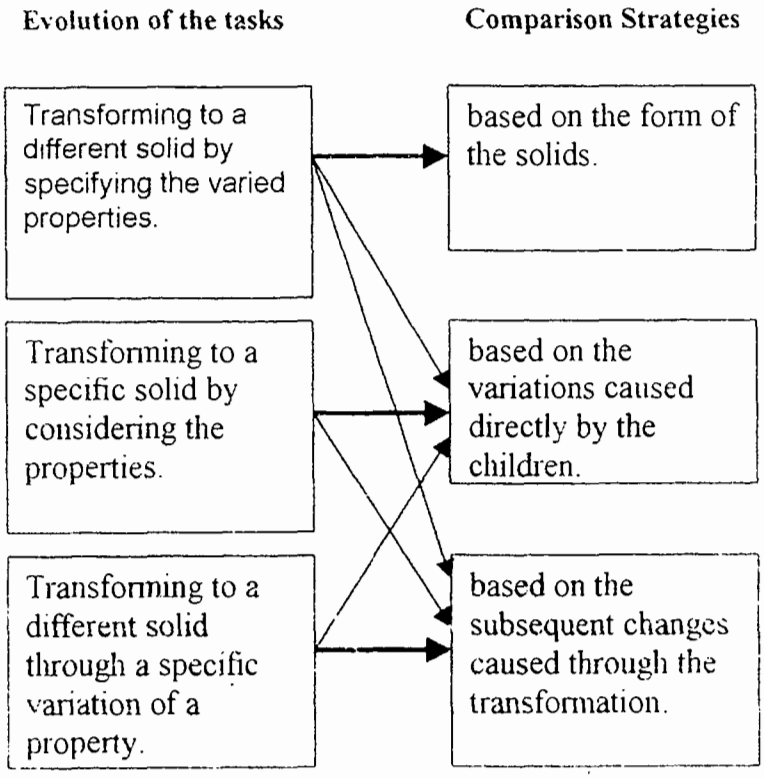

Figure 1 Associating the evolution of the tasks with the children's comparison strategies

Forming relationships between the solids The dynamic transformations of the solids allowed the children to experience through their own actions, different forms of the same type of solid and possibly overcome the prototype phenomenon (Hershkowitz, 1989). Even the younger pair of children (10 years old) could relate the cube and the cuboid and developed arguments to express and justify their relationships. For example, these children, in their attempt to make a cube different from the original, make a cuboid by making one dimension of the cube bigger. They recognize it as a cuboid and they explain that this is different from the cube as "it does not have all the edges equal".

Concrete and abstract Although the tasks involved the physical manipulations of solids, in the whole process we see the "concrete" and the "abstract" to be interwoven. By this, we mean that the children, through the evolution of the tasks, could go beyond a specific physical action to a generalization. This development was not linear as the specific and the general continuously interact mainly through the children's attempts to justify their opinions. We see below an example of such an interaction. The pair of twelve year-old children had made different solids by moving the salt in the cylindrical object and they came to the conclusion that all these solids (made of salt) had the same volume. The problem is extended to an imaginative situation when the children have to decide what would happen to the solid if the salt were in a bigger cylindrical object. In this problem the children actually consider a mathematical problem which is to examine what happens in a cylinder when its volume remains the same but its dimensions change. The boy in this pair used his dynamic images which have possibly been created through his involvement in the experiment to face this problem: "if the perimeter (the circumference of the circle) was the same, then it would occupy exactly the same space but if it was much bigger (the circumference) it would become very tiny (showing with his fingers the height of that cylinder)".Here, the children come to a rather general mathematical conclusion by referring to the specific context of the initial concrete situation. The children were often challenged to make generalizations through considering "extreme" cases.

Intuitive and school knowledge By "intuitive" knowledge, we refer to what Fischbein and Grossman (1997) define, to global, direct estimation based on some initial information, on some mental operation. By "school" knowledge, we refer to what the children had been taught in their mathematics lessons. The dynamic features of the materials and the type of interaction which was developed encouraged the children to anticipate, estimate and form hypotheses. These hypotheses were mainly justified either from the variations observed or from those imagined and were of an intuitive nature. The oldest pair of children tended to recall their school mathematical knowledge in their justifications. On the contrary, the youngest pair of children remained on the intuitive level as their school knowledge in this area was very limited. The mathematical knowledge was used for recognition of the objects, for the formulation of definitions and rules and for computation. In some cases it supported the whole activity and it obtained a meaning for the children and it was developed

further. For example, the oldest pair of children used the process taught in school, the transformation of a parallelogram into a rectangle by cutting and pasting the right-angled triangle formed by its height and the one side, to make an analogy in three dimensional geometry. They tried to compare, through the same model, the volume of a cube with an oblique cuboid which had edges equal to the cube's by cutting and pasting a prism. On the other hand, there were some incidents where the children's persistance in using mathematics prevented them from seeing other alternatives, even in cases where they did not have any clue as to how to face a situation.

Concluding remarks

Goldenberg (1995) supports the view that the use of dynamic geometry suggests new styles of reasoning. He also poses a number of questions open for research concerning the role of this geometry in mathematics education. In this paper, we attempted to approach some of these questions and show the possibilities of the dynamic transformations of three dimensional solids in helping children to form relationships. The issues that emerged indicate that it is possible to create an environment where the children build and extend mathematical investigations by interacting with the teacher and the developed materials. In this environment, through the continuous deformation of a geometrical solid, the children seem to realize the role of the properties in the solid's form and are led to make generalizations. They develop the ability to predict and anticipate the result of their physical actions. Moreover, this environment encouraged the children to think intuitively, in some cases overcoming the "lack" of mathematical school knowledge and in other cases developing an alternative meaning for this knowledge.

It is expected that the complete results from this project will extend the features and the possibilities of such an environment by taking into account the complexity of the mathematics classroom.

The major focus of this study is to trace the cognitive development of students throughout a mathematics course and to seek the qualitative differences between those of different levels of achievement. The aspect of the project described here concerns the use of ***concept maps*** *constructed by the students at intervals during the course. From these maps,* ***schematic diagrams*** *were constructed which strip the concept maps of detail and show only how they are successively built by keeping some old elements, reorganising, and introducing new elements. The more successful student added new elements to old in a structure that gradually increased in complexity and richness. The less successful had little constructive growth, building new maps on each occasion.*

Introduction

A *concept map* is a diagram representing the conceptual structure of a subject discipline as a graph in which nodes represent concepts and connections represent cognitive links between them. The use of concept maps in teaching and research has been widely used in science education (Novak, 1985, 1990; Moreira, 1979; Cliburn, 1990; Lambiotte and Dansereau, 1991; Wolfe & Lopez, 1993) and in mathematics education (Skemp, 1987; Laturno, 1993; Park & Travers, 1996; Lanier, 1997).

This study focuses on how concept maps develop over time. Students taking a sixteen-week algebra course using the function concept as an organising principle were asked to build concept maps of FUNCTION on three occasions at five-week intervals. In addition to qualitative analysis of the successive concept maps, we use a simple pictorial technique to document the changes.

Given a sequence of *concept maps*, a *schematic diagram* for the second and successive maps is an outline diagram for each distinguishing:

- items from the previous concept map remaining in the same position,
- items moved somewhere else, or recalled from an earlier map,
- new items.

Ausubel *et al* (1978) placed central emphasis on building meaningful new knowledge on relevant anchoring concepts familiar to the student. Using the schematic diagrams we investigate whether fundamental concepts persist in the development of successful students' concept maps and what happens to the less successful. This will be triangulated with other techniques of data collection and analysis. Given the extensive literature on the difference between those building a powerful conceptual structure and those remaining with inflexible procedures, we expect to find these differences reflected in the concept maps and schematic diagrams.

Concept maps and cognitive collages

The question as to whether a concept map actually *represents* the inner workings of the individual mind has long vexed the mathematics education community. Here we are not so much concerned with this issue as to how the individual *chooses* to represent his or her knowledge. It involves a wide range of technical, cognitive and aesthetic issues. Davis (1984, p. 54) used the term *cognitive collage* to describe the notion of an individual's conceptual framework in a given context. As one of us was for many years a professional artist and the other a practising musician, we warm to the rich inner meaning of the term "collage". For a child it may simply consist of a collection of pictures cut out of magazines and stuck on a piece of card, but for the artist it has a theme or inner sense that binds together distinct elements in a meaningful way. So it is with concept maps drawn by students. Some are seemingly arbitrary collections of items, others use all kinds of artistic and other devices to hold the ideas together. Figure 1, for instance, shows the first concept map of student MC drawn in the fourth week of term. The original is in colour, with colour coded inputs red and outputs representing links that are lost in a greyscale reproduction. By triangulating the development of these maps with students' written work and interview data we will explore how they provide a means of documenting cognitive growth over time.

Methodology

The subjects of the full study were twenty-six students enrolled at a suburban community college in a developmental Intermediate Algebra course. The curriculum used a process-oriented functional approach based on linear, quadratic and exponential functions supported by graphing calculators. Data was collected throughout the semester on every student including concept maps requested in weeks 4, 9 and 15 of the sixteen-week semester. Students were advised to use "post-it" notes to allow them to move items around before fixing the map. The maps were collected a week later, reviewed with each individual student to gain further information on the intended meaning, and then retained by the teacher so that at each stage the student was invited to draw a concept map anew.

Results of pre-and post-test questionnaires—together with results of the open-response final exam and departmental multiple-choice final exam—were used to rank the students. Two subgroups were selected, the four "most successful" and four "least successful" in the rankings, for more detailed profiling using follow-up interviews.

The concept maps of the eight selected students were analysed to document the processes by which they construct, organize, and reconstruct their knowledge. Schematic diagrams were constructed for the sequence of concept maps produced by each of them. The full analysis of the concept maps and schematic diagrams (McGowen, 1998) was triangulated with other data (Bannister et al, 1996 p. 147). Here we focus on two students, MC (in the most successful group) and SK (in the least successful).

Visual representations of students' cognitive collages

The second concept map of MC (figure 2) should be compared with the first (figure 1). Although the overall shapes change a little, the second is an expansion of the first. Some topics not studied in the interim (e.g. measures of central tendency and variability) remain unchanged, some are extended (representations, equations), and new items (finite differences) added.

The final concept map, created during week 15, was drawn on a very large piece of poster-board, too large to reproduce here. The topics included on the three maps followed the sequence of organization of the course and the connections shown are successively based on the main ideas of earlier maps. In his final interview, MC commented:

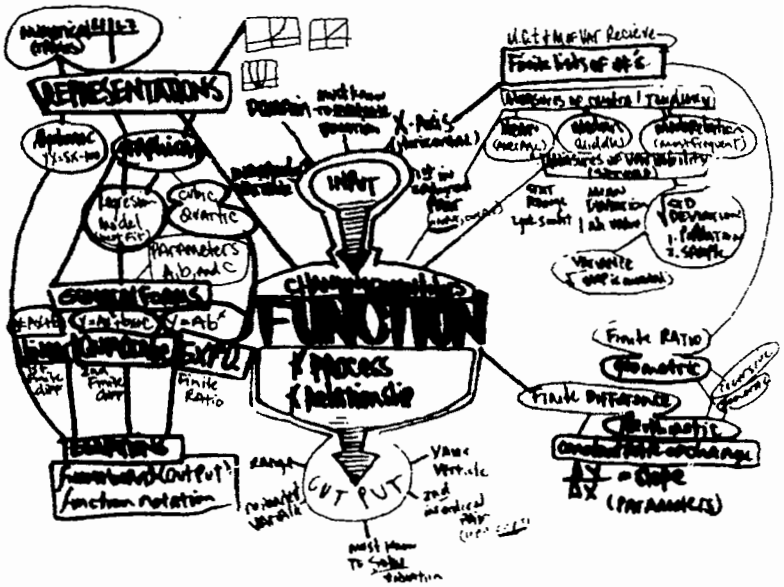

Figure 2: MC's second concept map, week 9

BEST COPY AVAILABLE

> While creating my [final] concept map on function, I was making strong connections in the area of representations. Specifically between algebraic models and the graphs they produce. I noticed how both can be used to determine the parameters, such as slope and the *y*-intercept. I also found a clear connection between the points on a graph and how they can be substituted into a general form to find a specific equation. Using the calculator to find an equation which best fits the graph is helpful in visualizing the connection between the two representations. I think it's interesting how we learned to find finite differences and finite ratios early on and then expanded on that knowledge to understand how to find appropriate algebraic models.

This final map is a rich collage, focusing on concepts and links between them, for instance, between graphic and algebraic representations, relating finding zeros in the first to factorising in the second.

The maps of SK provide a sharp contrast (figures 2, 3, 4). Week 4 includes definitions (in speech balloons). Week 9 is a bare skeleton with little in common with the earlier map. In week 15 the three basic function types (linear, quadratic, and exponential) become linked not to the central function concept but to *parameters*. The final map reveals procedural undertones by concentrating on routines (find slope, find constant common ratio, simplify, solve, evaluate, etc.).

Triangulating these concept maps with other data confirms that SK's knowledge is compartmentalized. She seems to have assembled some bits and pieces of knowledge appropriately, but others are missing, preventing her from building a cognitive collage with meaningful connections. When confronted with situations in which she is unclear what to do, she defaults to using remembered routines. She usually focuses initially on the numerical values stated in a problem. When confronted with a task for which she has no appropriate schema, she can only retrieve a previously learned routine. Her concept image of linear and exponential function on her week 15 concept map, for instance, is

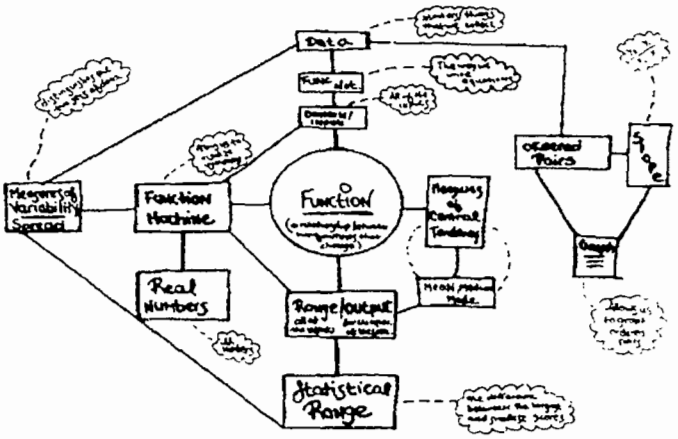

Figure 3: SK's concept map,week 4

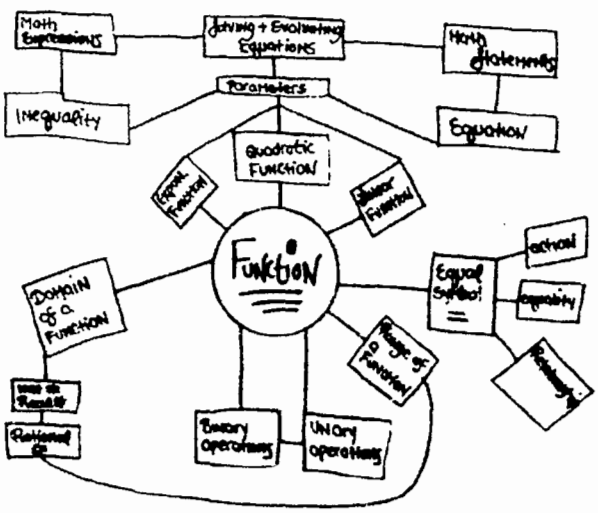

Figure 4: SK's concept map,week 9

BEST COPY AVAILABLE

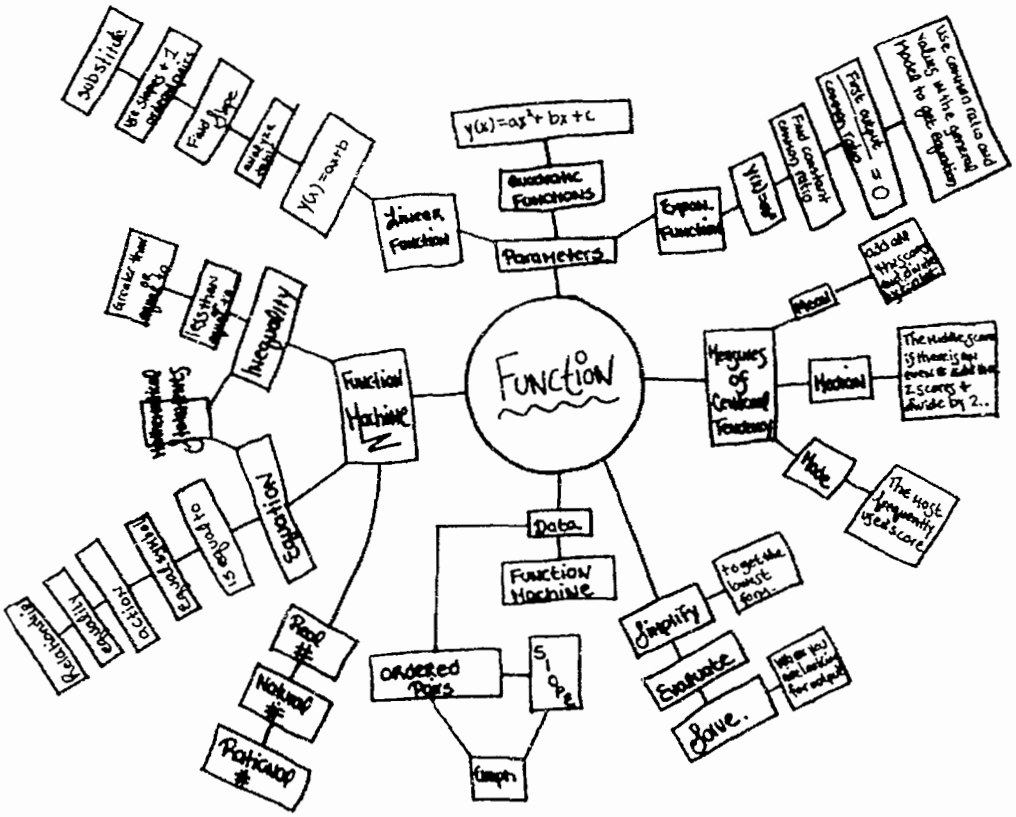

Figure 5: SK's concept map, week 15

limited to the computational procedures used to determine the parameters. Neither her classification schemes, nor her concept maps, reveal any interiority to these concepts or links to other concepts, to graphical representations or to alternative strategies for finding parameters. She demonstrated no ability to reverse a direct process in any context at any time in the semester. On at least two occasions, she retrieved and used two different approaches without realising her responses were inconsistent. She readily admits she is unable to distinguish between a linear, quadratic, and exponential function, even after sixteen weeks of investigation of these three function types. Confidence in the correctness of her answers decreased over the semester, and her attitude became increasingly negative.

The more successful student MC began with considerable lack of confidence in his algebraic skills. Despite this, he was able to select an appropriate alternative strategy when necessary, using the list, graphing, and table features of a graphing calculator. His ability to translate among representations is documented. His work suggests that he has formed mental connections linking the notions of zeros of the function, x-intercepts, general quadratic form and the specific algebraic model appropriate to the prob[illegible] situation. He relates new knowledge to his previously acquired knowledge, buildin[illegible] the cognitive collage he has already constructed. The interview data indicates that he was able to deal with both direct and reverse processes, and recognizes them as two distinct

BEST COPY AVAILABLE

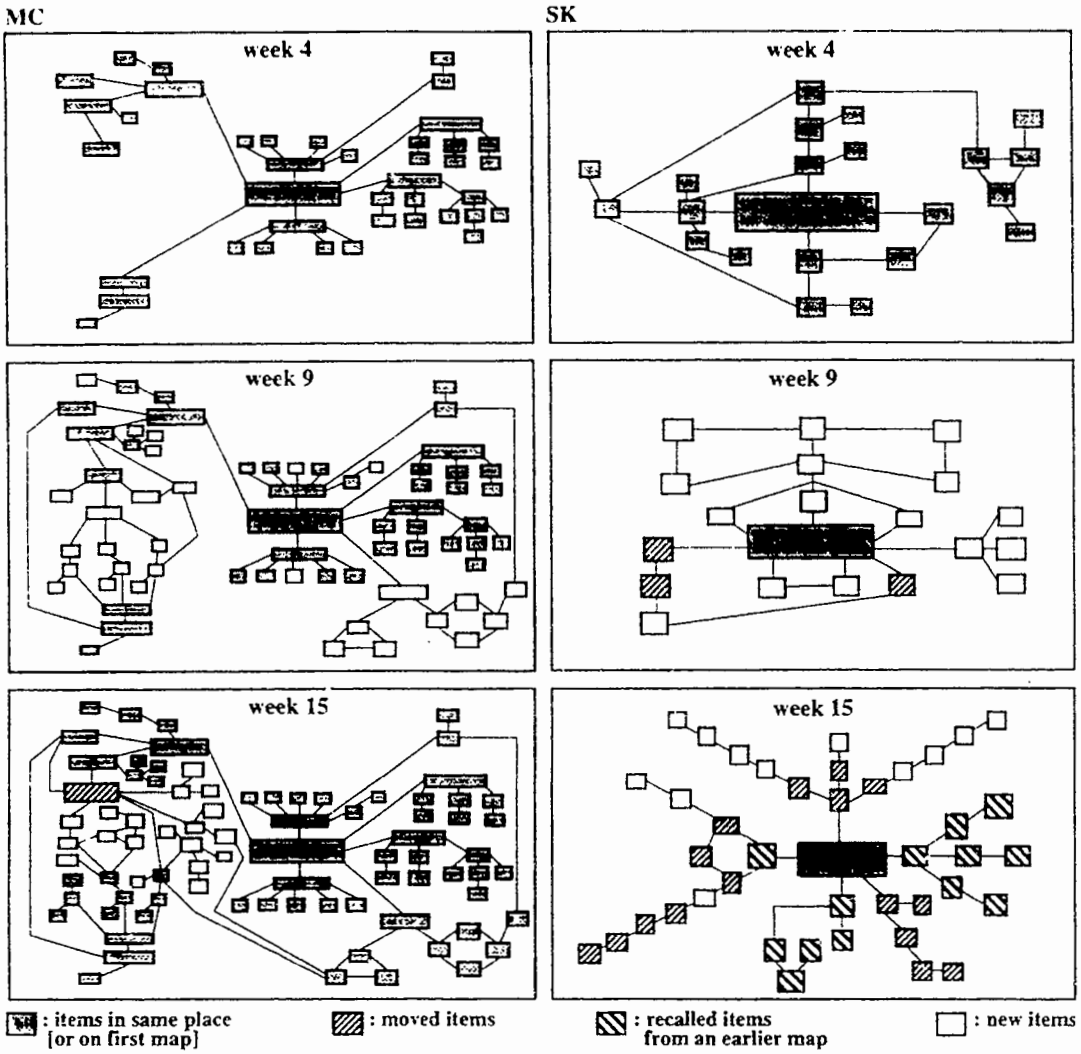

Figure 6: First concept map and successive schematic diagrams for MC and SK

but related processes. He was able to translate flexibly and consistently among various representational forms (tables, graphs, traditional symbolic forms, and functional forms). Confidence in the correctness of his answers increased over the course of the sixteen weeks. An examination of his work suggests that he initially focuses on the mathematical expression as an entity, then parses it as necessary, exhibiting the flexibility of process and concept necessary for more sophisticated study.

The use of schematic diagrams reveals these radically different developments (figure 6). It is immediately apparent that the basic structure of MC's first concept map is retained and extended in week 9 then further extended in week 15. However, the concept maps of SK seem to start almost anew each time, with few similarities and almost no basic structure that remains intact. Whilst MC builds from solid anchoring concepts, developing a strongly linked cognitive collage, SK builds on sand and each time the weak structure collapses only to be replaced by an equally transient structure.

Comparison with other students

Analysis of the other selected students reveals striking similarities among the schematic diagrams for each group. *Each student in the more successful group produced a sequence of concept diagrams whose schematic diagrams retained the basic structure of the first within a growing cognitive collage.* Each set of schematic diagrams for the least successful also exhibited a common characteristic: *a new structure replaced the previous structure in each subsequent map, with few, if any elements of the previous map retained in the new structure. No basic structure was retained throughout.*

Triangulating this information with other data reveals that the basic classification schemes used by both groups of extremes confirm the concept map and schematic diagram analyses. The more successful have processes of constructing, organizing, and restructuring knowledge that facilitate the building of increasingly complex cognitive structures with rich interiority. Their basic anchoring structures, are retained and remain relatively stable, providing a foundation on which to construct cognitive collages whose concept maps are enhanced by imaginative use of layout, colours, and shape.

The concept maps and schematic diagrams of the least successful reveal the fragmentary and sparse nature of their conceptual structures. No category appears on all three maps of any individual student, nor even was there a single category common to all four of these students. As new knowledge was acquired, new cognitive structures and new categories were formed, with few, if any, previous elements retained. Even those that were retained were reclassified and used in new categories with a different classification scheme.

Reflections

This study reports a wide divergence in the quality of thinking processes developed by remedial algebra students using graphing technology. High achievers can show a level of flexible thinking building rich cognitive collages on anchoring concepts that develop in sophistication and power. The lower achievers however reveal few stable concepts with cognitive collages that have few stable elements and leave the student with increasingly desperate efforts to use learned routines in inflexible and often inappropriate ways.

There remains the question of whether we are looking at these students through suitable lenses. Recent research offers new insights into the roles of perception and categorization (Rosch 1976), Lakoff (1987) which resonate with modern neuro-psychological theories of how the brain functions (e.g. Edelman, 1992) and how the evolution of the brain supports certain kinds of l ·in structure more than others (Dehaene, 1997). Within such wider frameworks we must ask "What if students like SK are organizing their knowledge according to a classification scheme which is not currently recognized or understood?" There exists the possibility that some students have different ways of knowing—ways of perceiving, categorizing, constructing, organizing, and restructuring knowledge—which those of us engaged in the teaching and learning of mathematics are unfamiliar with and have failed to consider. When one considers the significant improvement of the most successful students, the conundrum remains of how

and why students like SK—who claim to want to connect new knowledge to old—appear unable to integrate new knowledge into existing structures.

REINFORCING BELIEFS ON MODELLING: IN-SERVICE TEACHER EDUCATION

Maria do Carmo Domite Mendonça
University of São Paulo, São Paulo, Brasil

The aim of this paper is a comprehensive discussion on my role as a teacher educator in a course for mathematics in-service teachers, containing some analysis on aspects of three teachers' teaching and on problems of their students. The course was at State University of Campinas (UNICAMP) for experienced and qualified in-service middle and secondary school mathematics teachers. In this paper I draw upon my own notes as an adviser related to the discussions during the teachers' coursework, a classroom experience using an innovative method centered in "mathematics modelling".

Introduction

In recent years much research has been reported on the use of mathematical modelling for the enhancement of mathematical learning. The racionale for teaching mathematics through mathematical modelling has been described by Bassanezi (1987, 1994), Blum (1990), D'Ambrosio (1986), Skovsmose (1994), among others.

According to Bassanezi (1994), "the study of problems and real situations with the use of mathematics as its language for their comprehension, simplification, and solution, aiming at a possible revision or modification of the object under study, is part of a process that has been named mathematical modelling". In terms of teaching, the use of modelling leads to the learning of mathematics content involving a real problem solution.

Bassanezi has suggested that one important variable involved in the mathematical modelling process is a situation, as its starting point, that belongs to the "real world". Blum (1990) has also suggested for teaching through mathematical modelling "an open situation which belongs to the *real world* and for the solution of which some mathematics might be helpful". By "real world", both, Bassanezi and Blum, refer to the world outside mathematics - in Blum's words: "by real world I mean the 'rest of the world' outside mathematics, i. e. school or university subjects or disciplines different from mathematics, or everyday life and the world around us".

Indeed, by assumimg such ideas for teaching mathematics, the issue of concern here is whether and how, for three in-service teachers, the researcher could influence and help them to use mathematical modelling as a method for teaching mathematics. It was a goal to begin working with situations that belong to the *real world* in order to develop basic and general foundations to problem posing and teaching through mathematics modelling.

Actually, if this research group had to choose a psychological motive for leading students to mathematical modelling, it would be ideas from Vygotsky, used also by Bruner, "if one is arguing about social 'reality' like democracy or equity (...) the reality is not the thing, not in the head, but in the act of arguing and negotiating

1086

about the meaning of such concepts" (Bruner, 1989, p.122).

In order to analyse these researchers' role as an educator and the teachers attitudes, Ponte's ideas were followed, being that, even though the teacher absorbs understanding and information from an external force, he or she, decides on how to execute decisions – his/her movement/transformation is from the inside to the outside. (Ponte, 1998)

This paper is, then, a qualitative analysis on the author's role as a teacher educator in coursework for these in-service teachers. It also analyses the author's own learning from this experience and some aspects of the teachers' pedagogical practice through mathematical modelling.

Characteristics of the course: format and content

The coursework which is presented here is part of a larger program, entitled "Science, Arts and Pedagogic Practice", with duration of 360 hours (4 semesters), divided in eight classes of 45 hours (four of general themes and four of specific subject themes). All the participants in this program are required to take classes in each one of the following areas: Artistic Education, Physics and Mathematics. In each one of the semesters, the participants had to attend two classes, one from the general theme, and another related to the specific area they were involved in. The whole program was offered in a period of two afternoons a week, over two years. This first year the teachers attended required courses, and during the second year, they participated in *coursework* that consisted of *discuss and practice* form of inovation in their classrooms. The conditions and the description of the program coursework was given to the student-teachers on the first day.

Thirty students participated, in groups of 10, with an undergraduate degree in one of the following subjects: mathematics, science (physics or biology) and arts. All the participants in this program were experienced teachers of students aged 11 to 18. One of the objectives of this course was to provide a link among the public teachers' pedagogical practice, the academic education and the social/politcal questions about them. (A brief summary of the content of the courses appears in table 1)

At the begining of the second year, the student-teachers were introduced to a discussion/study about research in mathematics education. and moreover, about action research. The seconde year of the course stressed the importance of using cultural and social sources and personal experiences in the teaching of mathematics on one hand, and the steps the teacher has to follow/value in a mathematics education through the mathematical modelling process, on the other hand.

The results that I present in this paper correspond to the description/analysis on the changes a particular group of three in-service teachers - Gilberto, Maciel and Solange - went through during the course, and my own learning from this work.

Method

The selection of a qualitative method was quite natural since this work is a type of case study which includes an analysis of personal discussions with the three student-teachers, as well as, an analysis of teaching through mathematical modelling and the existing teaching/learning results.

First of all, before actually starting the classroom experience through mathematics modelling, the student-teachers and I discussed the following four papers: a) "Modelling as a Teaching-Learning Strategy" (Bassanezi: 1994); b) "Applications and Modelling in Mathematics Teaching-a Review of Arguments and Instructional Teaching" (Blum: 1990); c) "Investigation: Where to Now?" (Lerman:1989) and, d) "*Problematização: Um Caminho a ser percorrido em Educação Matemática*" (Mendonça :1993)[1]. It is important to stress that the discussion on Blum's paper led the student-teachers and I to decide that the analysis of their mathematics teaching through modelling should be made taking into account the "pro and con arguments". Blum presents, from several investigations and inquiries in many different countries, the obstacles and potential roles that arises in everyday teaching through mathematical modelling – the author's "pro and com arguments" were discussed from the student's point of view, from the teacher's point of view and from the point of view of instruction.

The teachers were asked to register some of their actions related to the innovation proposed for their pedagogical practice in the coursework. The objective of the registration/diary was mainly to begin some reflections about themselves as a modelling teacher, and at the same time, as a critic of his/her educational practice. We decided that their diaries might not be shown to me, but naturally it was a very important resource since it was, in part, from these notes that I obteained my data and the student-teachers wrote their monographes. (Seen is in appendix I)

[1] The papers by Bassanezi and Lerman were read in Portuguese translations.

BEST COPY AVAILABLE

Having read the articles, the teachers decided to work through *generative theme*, as a starting point of the modelling process. In other words, the teachers would invite their students to choose a situation/story/context from social reality – a theme – and then, would help them to observe and investigate the facts underlying this theme in order to pose/choose the problems that would be interpreted in a mathematical model. Surely, the choice would be oriented, never imposed, by the teacher, and naturally, it is important that the students were involved in that process and felt motivated by the topics and problems raised. Indeed, the teachers Gilberto, Maciel and Solange were prepared to develop, among their students, the following steps: a) electing the generative theme; b) motivating a problematization/discussion about the theme; c) asking the students a historical study about the theme; d) helping the students to pose one or more problems d) using mathematical language for the comprehension of the problem, which means to obtain/establish the mathematical model, and, e) critically interpreting the obtained solution within the considered reality.

In a general way, the teachers were led to link their conceptions of teaching to the basic purposes, among others:

- mathematical knowledge is a set of relationships built in the interaction of the active person with the others, by means of intellectual/physic/emotional actions, on facts and objects of the enviromnent and,
- the starting point of the school work would not be a mathematical content, but a problem - especially, a problem that emerges from social reality.

Teachers' ways in the classroom

Some details of Solange's modelling experience (Group of Senior High School students)

Generative themes: *fotografia* e *camisinha (*photography and condoms). A historical study of both subjects was made. Two main problems posed using the *photography theme were*: 1) "The relationship between the opening of the camera lens diaphragm and the clearness of the photo" and, 2) "The time the photo would be submerged in the fixator and the quality of its clearness". (Observation: Solange stimulated the first question much more because she antecipated that in the second case, they would not have a way to measure the clearness). Some of the mathematical models developed: setting up points in a Cartesian diagram/graph of the given data/calculations of roots/curve sketching/adjusting curves. Two main problems posed on *condoms theme*: 1) "What types of preservatives are much more used?"and, 2) "The relation of its use and people's ages". Several statistical contents were studied and many hypotheses were tested with the use of computational software.

Some results of Solange's experience - Solange pointed out that from the questions emerged, great part of the program was developed and there was an active participation of the student in the teaching-learning process. Almost all problematization emerged from the students. Solange observed that she never clearly proposed questions. She noted that her students were naturally grouped according to a common interest - one group, for instance, studied the history about the chosen

1083

theme, while the other group went to the research field to look for pieces of information which were, in general, collected through interviews or bibliography references. She said[2]: "my role was to make the process dynamic and to find a way of leading the students to solve their own problems, I mean to model the problem-situation. I actually worked, most of the time as a monitor... I would say that my work was to help them to interpret the collected data in mathematical language, that is to make the written mathematics meaningful". Solange concluded as follows: "The class was successful beyond my expectations... It nevertheless seemed that I, as a modelling teacher, merely scraped the surface of something much deeper... It is not that mathematical modelling can be, for instance, introduced in a High School classroom twice a week...the use of mathematical modelling, as a method of teaching is rather a philosophy of mathematics instruction, is related of higher order educational goals".

Some details of Gilberto's modelling experience (Group of 8th grade students)

- Generative theme: *futebol* (soccer). A historical study of *soccer was made*: the estudents studied the story/development of *soccer* with an expert, a doctoral student who has special knowledge about the theme. Problems posed by Gilberto leads to several mathematical models: area of different polygons, length of diagonal, trigonometric relationships, graph and formula of quadratic equation, among others.

Some results of Gilberto's experience - Gilberto pointed out that his greatest difficulty in adopting the modelling process in his classroom was to break the barrier posed by his 8th grade students, who possibly were influenced by the tradicional educational system, whose goal was to learn a sequence of prerequisits for the test they would have to attend at the end of the year. He said: "since my students showed a certain degree of resistence in posing a first question, I presented them a problem, a kind of story-problem related to the form and the measures of a playing field. I was afraid that the ready-made question could damage the process, but it didn't happen, they became extremely involved". His report reveals that this problem-situation, which was followed by some other ones, provided motivation to learn about the real situation - *soccer* - and about elementary geometry, measuring, linear and quadratic equations, elementary trigonometric relationships, proporcionality and graphs. As a final phase of this process, Gilberto tried to build a whole picture of the problem-situation, requiring a quadratic equation as a model, before getting to the analytical mathematical expression of this equation. Gilberto concluded as follows: "The theoretical readings, discussions and analysis were essencial elements in my development as a modelling teacher. My ideas changed... I would say that they were reinforced because I was already looking in this direction, but I didn't know how to apply them. I believe that the use of socio-cultural ideas of the students in a mathematics classroom is a very natural thing to do. However, for this result to be effective the undergraduate mathematical course must have courses according to modelling. It is like Blum says in his *pragmatic argument*: 'the ablility of students and teachers to master extra-mathematics situations does not result automatically

[2] All quotions from teachers come from interview data

BEST COPY AVAILABLE

from learning pure mathematics, but can only be achieved by dealing in mathematics instruction, with such real situations'. I also would say that the work started in this course needs to be wide and deep. The mathematical courses for teachers do not discuss/teach how to integrate mathematics with social problems and other forms of knowledge. That was the first time I was invited to use activities that are close to students'socio-cultural context. I like my results in spite of thinking, there is still a big gap between modelling and my experience here".

Author's reflections

I would say that this paper has presented the argument that mathematical modelling using problems generating from "real situations" involved the students much more than traditional mathematical instruction, based only on subject content. In fact, these preliminary data suggested that in some aspects mathematical modelling achieved pleasing outcomes with respect to our student-teachers' learning/changes and my role in this process.

Indeed, little more than one semester classroom practice through mathematical modelling, was too short a time to evaluate these teachers. This realization came about because the three teachers commenced the work with a great deal of interest and motivation –they demonstrated a willingness to help their students to learn mathematics from within their reality. This instructive model allowed me to better see our learning and changes much more than was expected.

In order to follow the student-teachers involvement with this innovation, and to accomplish my analysis as their adviser, use of categories, such as: a) through my orientation, the degree of the teachers' perception growth in reference to mathematics modelling; b) the degree of possibility that the innovative method could actually be accomplished and, c) mathematical concepts and models worked with based on problems which emerges from real situations.

In the first few weeks of the coursework I assumed a radical position, following Freire's ideas that "it is only parting from questions that one must look for answers" (Freire, 1986, p.46). He asks, what would it mean if there are no questions, there will be no lessons, there will be nothing to teach. However, after a while I started wondering if the teachers were not *wasting their time* trying to use a problem posed by the group, given the fact that many mathematics topics they already knew how to teach (from a ready made way or formula) in an interesting and dynamic way which captured the attention of their students. But, it is interesting to note that once the teachers' interest increased, especially Solange and Gilberto's, when problem posing, from the facts of social reality became the heart of their mathematics instruction, my doubts quickly disappeared. After two weeks of classroom work through modelling, Solange spontaneously said "I can recognize that the pedagogical work stopped being that mechanical process that can take the learner just to learn an algorithm or a formula, but I developed, somehow, the attitude of maintaining a constant dialogue with my students, and among them, in order to motivate curiosity and problem posing, and... now I can face circunstancial questions from the part of

my students". Gilberto said: "I am finding better means of access to the didactical variables we need to study and the autonomous questioning from the students are not as poor as before.

During the coursework, I could note a great change in the teachers' ability to transform the problem between the real word and mathematics. This competence could be developed by means of suitable/successful processes, as discussed in "formative pro-argument", as quoted in Blum. According to him (and I could see this progress as well), the ability to translate from a practical/social context to the mathematical context, in which data would be presented by means of tables, graphs and equations, can only be advanced by means of experiences where the entire mathematical modelling process is covered.

It is also important to point out that the three teachers naturally noted/observed (what I was expecting!) that mathematical modelling, motivated by a problem that emerges from social reality, can guide the pedagogic work to a transdisciplinary cooperative teaching-learning process. They said something like: "the questions posed by the learners don't belong to a very defined area of studies and so, in order to find the means/ways for their solutions, we frequently transit into different areas".

The process of mathematical modelling with respect to intellectual/emotional/political students and teachers development, is a great challenge for both. That is, in order to teach the mathematics through modelling method, teacher and student should establish relations/connections with the world around them and the mathematical content, which demands a vast investigation out of the matter of mathematics. For instance, the *condoms* discussions made instruction *more open* and required classroom interaction unusual for the student-teachers and their students. Blum refers to this second aspect as one of the obstacles, from the teacher's point of view, to teach through modelling.

Based on these considerations, I intend to make some changes in the next experimental courses that I guide. First of all, I will attempt to make the register/practice diary more centralized, using much more time to examine the notes and to understand what set of variables could be the best for the teaching of mathematics through modelling. Second, the teachers should elaborate, as learners, alternative models from experimental data, before acting as a modelling teacher.

Finally, I would say that in spite of the process not being precise (a handicraft one) and the fact that this was the first experience teaching in this format, I found my own perspectives reinforced, which means that I reinforced patterns of beliefs about the use of social sources and personal experiences in making the learning/teaching of mathematics more effective and more meaningful.

Acknowledgment: The author would like to express her gratitude to Gilberto Chieus Jr., Maciel Gomes dos Santos and Solange Regina Pedroso for their helpful comments.

Note: The teacher Maciel was also involved in the course but he did a theoretical analysis of population growth phenomena and did not carried modelling classroom work)

Appendix I

Specialization Course: "Science, Art and Pedagogic Practice"

Task related to: the individual monograph / the classroom practice / pedagogic experience using a innovative method / teacher's development as a researcher / action research.

Dear student_____

Please, from now on, I would like you to observe and register your difficulties and facilities in reference to: a) the teaching through modelling process in general; b) the students' actions and questions that show their involvement or not with the process of modelling and, c) the understanding, from the part of the students, of a mathematical fact. I ask you to make the registration in twice: 1) soon after each class, and 2) from your past classes/situations (either very interesting or very difficult).

THE DEVELOPMENT OF ELEMENTARY SCHOOL CHILDREN'S IDEAS OF PRICES

Regina D. Möller
Institute of Mathematics
University of Koblenz/Landau, Germany

Abstract
The study reported in this paper investigates the competence of 6-10-year-old children with respect to putting prices on real-world goods. The methodological framework of the project is based on a qualitative and quantitative research approach and uses structured interviews with each student of the first four primary level classes. The results show competence for the "economic world" which could enhance the teaching and learning of applications in math classes.

Introduction

In his chapter "Towards a way of knowing" Bishop argues that a performance-orientated Curriculum with its emphasis on techniques, methods, skills, rules and algorithms is portraying mathematics as a "doing" subject and not as a reflective subject. In order for mathematics to educate the pupils he emphasises:

> *Surely what is needed now is more understanding and critical awareness of how, and when, to use these mathematical techniques, why they work, and how they are developed? This requires not only much greater thought, but also a different kind of thinking and therefore it requires a very different approach to the curriculum.*
>
> (Bishop 1995, 8)

Curriculum guidelines of many countries recognise the importance of applications of mathematics to everyday situations. Applications however are very often methodically used as a field of practice for previously introduced operations with different types of numbers and therefore occur at the end of a chapter unit. And although these applications of mathematics should manage to link the learning of mathematics with real world questions, children and elementary school teachers frequently seem to struggle with the applications.

This project was begun with the concern that little is known about elementary student's competence and strategies concerning real-world prices of goods. One of the first types of applied problems in elementary mathematics classrooms include price-value problems. Traditionally this type of problem (formerly called „regel de

BEST COPY AVAILABLE

tri") belong to practical arithmetic serving the purpose to prepare for real life situations:

> *The solving of these problems was understood as a training for applying mathematics to real life and also for logical thinking.*
>
> Vollrath (1992, 229)

The didactical analysis of Kirsch (1969) clarified that the underlying mathematical structure of this type of problem is a functional relationship between two kinds of domains of magnitude (in German called Größenbereiche; Griesel 1973, 1997). Domains of magnitude are ordered semi-groups and some of them are isomorphic to (Q , +, <) which makes them a useful basis for elementary school mathematics concerning applications (Kirsch 1970, Steiner 1969). Kirsch argues that neither proportionality nor antiproportionality is a property of a real life situation and therefore this type of problem could not be used as an instrument for teaching logical thinking in math classes. However in the centre of real-world applications is the study of relations between magnitudes.

Kirsch (1969) suggests tables as a methodical tool to work with functional relationships. Nowadays already second grade pupils at primary level have to fill out tables in order to solve these price-value problems. A typical example looks like this:
Find out the prices for cold meat:

Gewicht	50 g	100 g	200 g	400 g	500 g	600 g	1 kg	1,5 kg
Preis		0,88 DM						

In solving these problems pupils use either an additive or a multiplicative approach. Both of these solving strategies are valid because they are properties of the underlying proportional relationship. Nevertheless the knowledge about this relationship is a subject matter of seventh grade mathematics classes.

In order to understand and solve this kind of problem children need competence in three ranges: Knowledge of the

- number system including decimal numbers (as prices)
- "money world", that is the money system (coins, bills)
- "economic world" (e.g. prices of goods, tasks of a bank)

While we are reasonably aware of students' abilities of the number system and of stages of knowledge of students concerning the money system (e.g. Burris 1983, Burti/Bombi 1981) we know little about the understanding of the "economic world" children have in industrialised countries. Because in contrast to the students Nunez et al. (1993) described in their study school children normally do not experience the "economic world" on a basis of everyday personally experienced buy-and-sell-situations. They have to rely more on observing experiences (e.g.

when parents buy groceries taking goods from long shelves in a supermarket) and of negotiations with other children (e.g. when they barter favourite toys). Piaget (1932/1973) therefore stresses the necessity of social mediation for economic situations.
Basic factors of prices of goods are production costs and properties like freshness with fruits and vegetables. Supply and demand are also important factors of trends of prices which can well be observed on markets. This kind of knowledge depends on processes of enculturation and of socialisation (Bishop 1991, p.37). Traditionally math classes inform with and through price-value problems about all subject matter linked with physical quantities like length, weight and time.

Basic ideas of functional relationships are the

- idea of one-to-one correspondence,
- idea of systematic change
- idea of observing a function as a mathematical object (Vollrath, 1989, p.8ff.)

These ideas emphasise the conception of a dependency between two (sets of) values together with methodical variations and an overall view of properties of a function. On primary school level the second idea is stressed because of the use of tables.

On the basis of the functional approach to price-value problems there are various problems:
Problem of fore-knowledge:
To solve the price-value problems the underlying assumptions of proportionality are neither openly assumed nor touched upon in class. Therefore the students rely with the methodical help of the offered tables on their intuitive strategies.
Problem of schematic solving:
Since it is not the explicit goal (in the German curriculum) to teach the proportional idea in early math classes, students rely more on a schematic solving procedure with these problems.
Problem of fixed assumptions:
Price-value problems with their representations of tables to use in order to find the solution give students the impression that prices of goods follow proportional rules as it is the case with the other physical quantities (Keitel 1979, 264). However prices of goods are not properties of goods like the length or the weight but assigned economic values by humans which can change according to peoples' necessities or opinions.
Problem of the concept of values:
Students bring to math classes a variety of value conceptions which is normally not touch upon explicitly when price-value problems are discussed. Although the system of coins and bills is normally discussed, the idea of linking their values to real life goods is generally not stressed upon. It is assumed that the solving of price-value problems give the pupils the appropriate ideas of concept of values. The task of reflecting upon economical facts linked to price-value problems are normally not undertaken in class.

Necessary knowledge to solve price-value problems belong to functional thinking which involve abilities like stating dependencies of domains of magnitude and/or making assumptions about the kind of dependency and/or finding the influence of changing one magnitude on the dependent other (Vollrath, 1992). These abilities and possible deficiencies become apparent in economical situations in which the student is asked assign prices to real-world goods.
The research questions underlying this study involve two aspects of research focussing on elementary students.
What kind of individual strategies and competence do students of the first four classes apply with respect to prices for real-world related goods?
How do they assign the prices? What reasons do students give for their prices?

Theoretical framework
Additionally to the theory of learning about functional relationships (Vollrath 1989) two further theoretical assumptions form the basis of our study: they are concerned with social constructivism as the underlying theory of learning and with problem solving as a part of mathematics (education).

1.Constructivism emphasises the individual's unique knowledge schemata (von Glasersfeld 1991; Davis et al. 1990) and also the role of interaction in the learning process (1995, 191) The inclusion of a social dimension (i.e. linguistic and cultural factors (the way one talks about money), teachers' conceptions (their opinion and experience about and with money) and their role in classes) in a constructivist theory of learning is referred to as social constructivism. The learning about the money system and its functions in economical situations depends highly on human interactions and influences the individual's learning (Bishop 1995, Seiler 1978).

2. For a long time problem solving has been regarded as an important part of mathematics. However the specific economic contexts have not been sufficiently emphasised with respect to open real-world related tasks in either (elementary) classroom practice or classroom research (Pehkonen 1991). Price-value problems belong to „Sachrechnen" (that is „real-world-related mathematical problem solving). Particular emphasis lies nowadays on real world contexts so that children's knowledge about real-life situations can aid them in their learning of mathematics.

Research Method
The structured interview approach (Bortz, Döring 1995) was chosen as the methodological framework of the study. Hence, the data collection and interpretation follow a strict procedure: each student of the elementary math classes was individually interviewed and had to respond to a series of questions.
The data collection and interpretation also followed a strict procedure: Each student out of the four classes of one elementary school was set aside from the usual math lesson and introduced to the specific set-up. All answers were taped

and transcribed. To be able to compare and recognise a development of qualifications in the answers of all students the first and second graders were joined together and the third and fourth graders. A Chi-square test for each of the questions produced significant results. The comparisons of the pupils' respective explanations gave rise to distinguish certain types of understanding of prices.

The Problems used in the Study:

Each student of all four classes (99 altogether) was given the idea to be an owner of a toy-shop in which he sold different kinds of wooden playthings of different shapes and colours (red, green, blue and yellow): cubes, quadrilaterals of different volumes, each two or three-times as big as one of the cubes and a flat quadrilateral, which had the volume of a cube, but was twice as long. In order to sell them the students were asked to assign prices to each of the objects. To make the investigation comparable, the starting point in assigning prices was given by the investigator: the price for the red cube is 1DM.

In the sequence of questions that followed the prices were asked of

1. each of the yellow, green and blue cubes
2. each of the small, big and flat quadrilaterals
3. two, three and five of the dices, of the small quadrilaterals and of the big quadrilaterals.
4. In the last question the student was informed that another shop sold the die for 1,50DM. Do you stick to your price?

The first question aimed at the relevance of colour stressed in psychological literature (Burti/Bombi 1981). The next question aimed at the ability to think proportionally with a number of pieces. The proportional aspect was also offered by the next question: What price do you give the quadrilaterals (the one being two and three times bigger than the die and the „flat" one)? Bags with three or four different kinds of these wooden pieces had to be taxed by the children looking for their abilities to proportionally appraise and allocate prices. The last question was used to assess the students' abilities to think about other peoples' motivation within economic situations.

Findings

The findings relate to:

(1) childrens' mathematical problem solving abilities,

(2) their learning of social conventions,

(3) their ability to apply the social knowledge to math class problems.

Owing to space restrictions this paper can only focus on some of the answers of the students. Examples of student answers as well as specific responses to the questions will be compared during the presentation.

With respect to childrens' problem solving ability the study suggests that primary school children have far more social knowledge of price-value problems than are asked for in math classes. They use much more "common sense" in assigning

prices and explaining their assessment than is normally asked for in usual textbook problems.
The results obtained indicate the following:
First and second graders did not clearly understand that the prices depend on the volume of the wooden toys. However the third and fourth graders understand this relationship well.
The ability to perceive a proportional relationship between the prices and the volumes of the various quadrilaterals grows with regard to age. However 50% of the pupils at the end of fourth grade still have difficulties with it.
The ability to perceive that the price of half a volume is half the price still cause difficulties for about 30% of the children at the end of fourth grade.
The understanding of the number system becomes obvious with the assigning of prices. The use of only natural numbers for the prices of the wooden toys was predominant with first graders.
Colour also plays a role when prices are put on to the toys. There are first and second graders who price the objects by their colours. For example, first grader`s reasoning was: "because it is green and flat".
The power of perception increases with age: more pupils of second and third grade mention the specific form of the toys than the first graders.
The answer to the hypothetical question shows that some pupils have already a good understanding of prices. Some know that different shops offer the same goods for different prices. Others bear in mind the customer's motivation: "I keep to 1DM, then more people will come to my shop."

With respect to children`s problem solving abilities the study suggests that pupils use far more criteria to solve real-world problems when the given problems are open and when "common sense" is necessary to their understanding. However, the levels of sophistication indicated by the pupils' explanations can vary quite drastically within one class.
As to the problem of fore-knowledge:
Although proportional relationships belong to the curriculum of seven graders' mathematics classes the pupils show economic competence in their assigning prices. They know about proportional price assignments with respect to a number of wooden toys and with respect to their volume. When growing older they are more capable of making the correct mathematical operations.
The problem of fixed assumptions:
Keitel (1979, S.264) was assuming pupils might think of prices as naturally given rules as within physical contexts. With respect to the flexible price assigning capabilities of the students with their knowledge of reductions and motivational incentives this observation looses its importance.
The problem of schematic solutions:
The solving of price-value problems might lead to schematic solutions on the part of the students. As to real-world situations like the one investigated in this study pupils use strategies and explanations which derive from their own experiences.
Problem of conception of values:

The students in this study use various categories like size, number of wooden toys to price their goods, but also as criteria for intended use, usefulness, moral and appreciation.

The problem of functional thinking:

The ability of proportionally assigning prices to real-world objects lying in front of them is present in elementary students. However the answers show significantly different results between first and second graders versus the third and fourth graders. The ability of proportionally assigning prices rises significantly with the second group, which has already been observed by Piaget. On the other hand the ability is already present in the first group. This result emphasises the existence of domains of subjective experiences (Bauersfeld 1983).

The ability of proportional assignment to a number of toys is present in third and fourth graders without any difficulties. They assign prices quickly without hesitation. First and second graders assign prices, in almost all cases the time with an additive and not a multiplicative strategy.

Generally the abilities of the proportional assignment of prices to volumina is less apparent than to numbers. The proportional assignment to different volumina seem to be difficult for third and fourth graders. In this study the students use the cube as a "measure" for the quadrilaterals. Either they "see" the cube into the quadrilateral and count how many times they could place the cube into the quadrilateral or they cut the quadrilateral into pieces of the size of the cube.

The consequences of this study suggest that the abilities and the competence of elementary students reach well into the "consumer world". The students carry into the classroom a variety of experiences and perceptions of real-world economic situations so that price-value problems can be estimated variously according to the students observations.

RETEACHING FRACTIONS FOR UNDERSTANDING

Hanlie Murray, Alwyn Olivier and Therine de Beer
University of Stellenbosch, South Africa

This paper reports on the viability of a programme aimed at encouraging sixth grade students who have already been exposed to teaching practices leading to entrenched limiting constructions, to construct the concept of a fraction anew and to invent solution strategies for realistic problems involving fractions, in a school and classroom environment with serious practical and organisational problems.

Introduction

Much research has been done on the problems elementary school students experience with common fractions and on the design of teaching programmes for fractions at different grade levels (see Pitkethly and Hunting, 1996, for a review of the research).

An important issue is the effect that limiting constructions (D'Ambrosio & Mewborn, 1994) has on students' attempts to make sense of fractions. These include, for example, the influence of whole number schemes, which encourage the student to interpret the fraction symbol as two separate whole numbers, and limited part-whole contexts, where the student has had no or not sufficient experience of fractions as parts of collections of objects. Another issue is the possible adverse effect of rote procedures on students' attempts to construct meaningful algorithms for operations on fractions (Mack, 1990).

The above problems can be *prevented* by appropriate programmes for learning fractions in the lower elementary grades (e.g. Empson, 1995; Murray, Olivier & Human, 1996). However, when these limiting constructions are already firmly entrenched, it is to be expected that the task of encouraging students to develop strong and error-free conceptual and procedural knowledge about fractions will be much more difficult. Such attempts have already been made successfully (e.g. Bell, 1993; Kamii & Clark, 1995; Mack, 1990) in what we believe to be favourable learning environments.

In this paper we explore the possibility of implementing a programme for common fractions for Grade 6 students in less than favourable learning environments.

Theoretical framework

In line with our approach to the teaching and learning of whole number arithmetic (e.g. Murray, Olivier & Human, 1994, 1998), we believe that the teaching and learning of fractions should be based on eliciting and clarifying students' intuitions about fractions through posing realistic problems for which students have to invent their own solution strategies (cf. Empson, 1995; Kamii & Clark, 1995).

The following aspects are crucial in our approach to the teaching and learning of fractions:

1102

Choice of problems. Knowledge about fractions involves knowledge about the concept of fractions, of which two subconstructs are the part-whole relationship between the fractional part and the unit, and the idea that the fractional part is that quantity which can be iterated a certain number of times to produce the unit. The unit may be a single object or a collection of objects. Fractions are also used in different ways and have different meanings, for example the part-whole mentioned above, but also a ratio, a quotient, a measure, etc.

If the problems posed in a teaching programme do not include, and students do not experience, these different subconstructs and meanings within a reasonable time, limiting constructions are formed (e.g. Murray, Olivier & Human, 1998). For the same reason, the fractions addressed should also immediately include thirds, fifths, etc., and not only halves and quarters, as is common in many teaching programmes. For example, in a previous study we found that Grade 1 students freely constructed appropriate different sized fractional parts in response to realistic problems, whereas many of the Grade 3 students in the same school who had only been exposed to halves and quarters during their teaching programmes for fractions, could not conceptualise thirds and/or could not recognise the difference between halves and thirds when they were trying to solve the same problems (Murray, Olivier & Human, 1996).

Social interaction. Social interaction creates opportunities for students to *talk* about their thinking, and this talk encourages reflection. "From the constructivist point of view, there can be no doubt that reflective ability is a major source of knowledge on all levels of mathematics ... To verbalise what one is doing ensures that one is examining it. And it is precisely during such examination of mental operating that insufficiencies, contradictions, or irrelevancies are likely to be spotted." Also, "... leading students to discuss *their* view of a problem and their own tentative approaches, raises their self-confidence and provides opportunities for them to reflect and to devise new and perhaps more viable conceptual strategies" (Von Glasersfeld, 1991, pp. xviii, xix).

We therefore believe that we should not only provide opportunities for students to build on their informal knowledge, but that students should be encouraged to make explicit and *become aware of* the nature of their own personal constructions (Bell, 1993).

Students' own representations. Students are expected to create their own representations of fractions. This is achieved by confronting students with sharing situations where a remainder also has to be shared out, for example sharing four chocolate bars equally among three friends (Murray, Olivier & Human, 1996). Prepartitioned materials are not used until later and the introduction of written symbols for fractions is delayed until the need for fractions and some conceptions of fractions have been developed by the students themselves.

This study

This study forms part of the Mathematics Learning and Teaching Initiative (MALATI) project aimed at curriculum and teacher development. The project teachers received student worksheets and teachers' guides which were studied during workshops, and were supported by regular classroom visits of project workers during the 1998 academic year. The student worksheets consist of two packs of activities, an introductory pack and a further pack.

The introductory activity pack of 33 worksheets is aimed at

- developing the fraction concept through sharing situations
- introducing realistic problem situations for operations involving fractions (e.g. division by a fraction)
- comparison of fractions
- equivalence of fractions
- introducing the fraction notation

The further pack attempts to make explicit students' informal procedures for the operations developed in the introductory pack.

Teachers were requested to firstly spread out the work over the year, and secondly to use the worksheets in the suggested sequence, with all the students in the class working on the same worksheet during a particular lesson period. The reason for this is that students are encouraged to solve a problem at whatever level they feel comfortable, and that students share their conceptualisations with the class to the benefit of all. Since our materials repeatedly pose problems with the same structures, it provides students with repeated opportunities to make sense of particular structures.

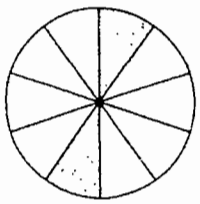
In this paper we limit ourselves to describing the effect of this intervention on a specific sixth grade class in one of the MALATI elementary project schools in a black township near Cape Town. The circumstances in the school and in the community do not support learning. Many students have transport problems to school and come from extremely unstable and impoverished homes. Absenteeism is not only high, but malnutrition and chronic health problems prevent some students from functioning optimally even when they are at school. The school organisation is poor; the lesson timetable is not followed and there are continual unscheduled interruptions in the form of staff meetings, celebrations and outings during school time. It is difficult to persuade teachers to attend workshops after school hours.

There were 42 students in the class. The teacher, Nolo, was eager to co-operate and although she started the year in a very traditional way (in spite of the initial workshop), she had after a few weeks established a culture of enquiry, argument and discussion among most of the students. However, even by the end of the year some students were unwilling to share their ideas through fear of being wrong.

By the end of the year, this class had only completed the introductory pack. This reflects their low level of knowledge at the beginning of the year as well as the above-mentioned practical and organisational problems during the year.

Results

We have available two sets of written tests and all the students' written work during the year as well as several videotaped classroom episodes.



Test Set A comprises a pre-test completed in November 1997 (the end of the previous academic year) by all the sixth graders of the school under discussion, and a post-test completed in November 1998 by the sixth graders of Nolo's class. These are therefore not the same students, but students in the same grade in successive years in the same school.

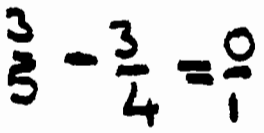
Test Set B comprises a pre-test completed at the beginning of the 1998 academic year by Nolo's class and a post-test (a different one from Set A) completed by Nolo's class at the end of the academic year.

Test Set A. The items testing students' part-whole conceptions showed a very substantial gain in 1998. For example, these are the percentages of students correctly stating the fraction shaded in the following figures:

1997: 40%
1998: 90%

1997: 33%
1998: 89%

The following item testing the comparison of fractions also showed a substantial gain from 18% in 1997 to 31% in 1998:



Anwar and Amina each received R30 pocket money. Anwar spent $\frac{5}{8}$ *of his pocket money and Amina spent* $\frac{7}{10}$ *of hers. Who spent more? Explain your answer.*

Test Set B. The pretest at the beginning of the year revealed that students had very little knowledge of fractions. The post-test showed definite gains. For example, the success rate for the item "*Which is bigger,* $\frac{3}{5}$ *of a cake or* $\frac{3}{4}$ *of the cake?*" had a success rate of 4% in the pre-test, and a similar item had a success rate of 45% in the post-test. The success rate of the item "$\frac{3}{5}$ *of 10*" increased from 4% to 31%.

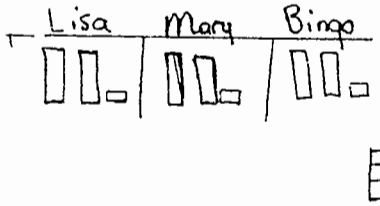
Both pre-tests identified the following main problem areas in students' understanding of fractions:

- a very weak understanding of the fraction concept
- strong interference from whole number schemes
- strong interference from rote algorithms

For example, this type of error occurred frequently as a response to *"Which is bigger, $\frac{3}{5}$ of a cake or $\frac{3}{4}$ of a cake?"*

Although both post-tests showed substantial gains, we felt the success rates to be low considering that students had solved similar and more difficult problems during their lesson periods.

Students' written work. At first, there were strong signs of previous teaching. Mangaliso offered this incorrectly partitioned *apple* as solution to a problem involving *chocolate bars* (apples are frequently used to demonstrate fractions in many teaching programmes).



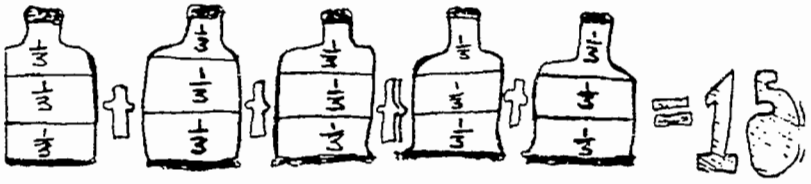
Because A Hole divided by three is a third

After a while, this type of response did not occur again in Nolo's class.

Most students produced their own representations of fractions in response to the initial sharing problems. For example, Thomboloxole solved the following problem as follows:

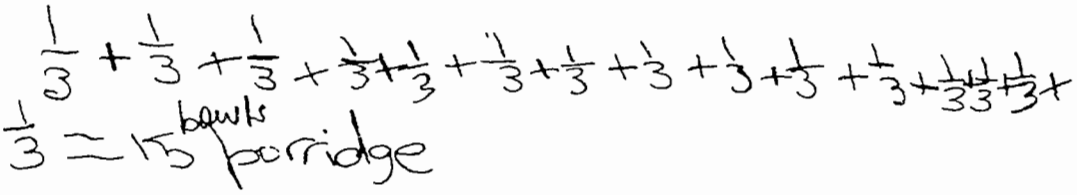
Lisa, Mary and Bingo have 7 bars of chocolate that they want to share equally among the three of them so that nothing is left. Help them to do it.

They also solved problems which prepared the way for operations with fractions successfully through their own representations of the physical situations. For example, Worksheet 9 poses an addition and a division-type problem. Zanele solved the two problems like this:



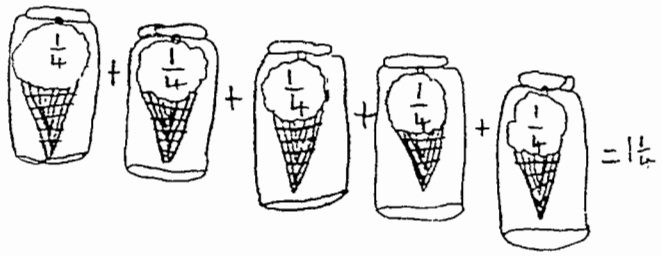
Peter and Anna prepare soft porridge for breakfast. For each bowl they use $\frac{1}{3}$ of a litre of milk.

- *If they make 6 bowls of porridge, how many litres of milk do they use?*

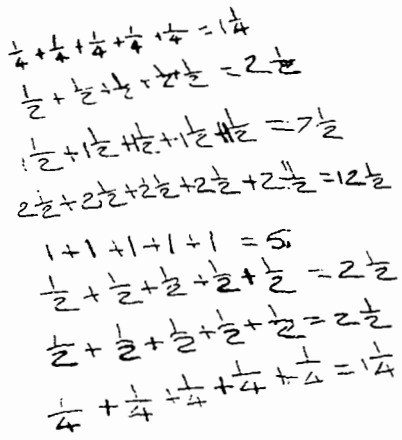


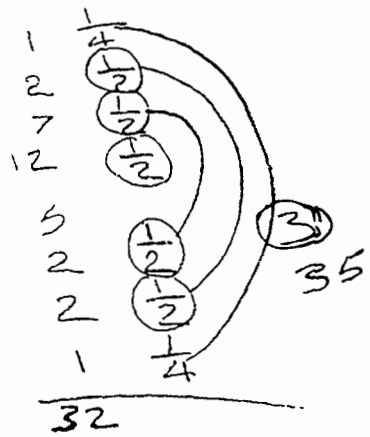
BEST COPY AVAILABLE

- *They have 5 litres of milk. How many bowls of porridge can they prepare?*



Although all the students worked on the same worksheet during a particular lesson, they functioned at different levels of abstraction. For example, Dumisani solved the previous problem like this:





Students frequently used drawings which seemed inappropriate to us. After the initial realisation that drawings were acceptable as solution methods and as means of communication, some students came to believe that they *had* to make a drawing. For example, this drawing by Bonziwe as a solution to the following problem seems to be more decorative than functional:

How much ice-cream in total does Lisa have if there are 5 containers of ice-cream, each $\frac{1}{4}$ full?

Other classrooms in the same school produced a peculiar marriage of sense-making and rote learning. For example, Worksheet 8 lists the ingredients and their amounts in cups and teaspoons for one cake, and requires students to calculate how much of each ingredient would be needed for five cakes. Some students successfully calculated the quantities of each ingredient needed for five cakes, and then (correctly, but inappropriately) added up all the quantities in order to produce a *single* numerical answer. When challenged whether this was the *sensible* thing to do, the response was "no, but in mathematics we have to give only one answer to a sum". A solution such as this never appeared in Nolo's class (these are the different ingredients):

Discussion

The results show that in this class the intervention achieved decided success in addressing students' conception of fractions. Students' written worksheets show that inappropriate whole number schemes had disappeared, and that students were able to invent procedures to solve realistic problems involving fractions. It is also quite clear that in an approach like this, the traditional idea that division by a fraction is the most difficult problem type does not hold. Zanele's and Dumisani's solutions for the second problem of Worksheet 9 ($5 \div \frac{1}{3}$) illustrate this. We suspect that division may be the easiest of the four operations for which to invent informal operations as long as the context is sensible to the student (Mack, 1990).

On the negative side, many students could not manage realistic problems in the test situations although they had solved similar problems successfully as collaborative groups without the help of the teacher. It is possible that because many students missed worksheets through absenteeism, their understanding of a particular problem structure could not become stable.

We tried to help the teacher to identify students who were behind so that they could be given additional learning opportunities, but this proved to be organisationally unmanageable. We still believe that students solving problems collaboratively, combined with whole class discussions, is a better approach than individualised learning (compare Bell, 1993).

It is also possible that language caused a problem during the tests. English is the second language of these students, and in class the groups spent a significant amount of time talking about the problem situation before they started to solve it. Although the teacher explained the wordings of problems during the tests, this was probably not sufficient. It is possible that one or two written tests *in the course of the year* might have improved their performance in the final test. (We originally strongly rejected the idea of regular written tests because the then-existing school culture depended heavily on written evaluations.)

BEST COPY AVAILABLE

The question we posed at the beginning of the paper was whether it was possible to develop anew a stable conception of fraction in students who had already formed limiting constructions, using an approach which expects students to make sense of realistic problems and invent their own procedures in an atmosphere of discussion and argument, and whether this could be done under difficult conditions. This has proved to be possible.

An intervention in extremely adverse learning environments also has positive effects: An approach only reveals its essential aspects in difficult teaching and learning environments, whereas a competent teacher in a supportive environment unconsciously anticipates and copes with possible problems. As an example, we cite the case of the students who did indeed solve the problem where they had to calculate the quantities of ingredients needed for five cakes competently and sensibly, but then offered solutions which they considered to be mathematically correct but which made no sense at all. It has therefore become clear that encouraging students to build on their informal knowledge, and solve problems through their own inventions, without also changing their beliefs about the *nature* of mathematics, is not sufficient.

Operations on "open phrases" and "open sentences" expressions- Is it the same?!

Musicant Bracha
Beit Berl Teacher Training College, Israel

Abstract

It has been assumed, based on the daily practice of teachers, that students tend to apply to open phrases the properties and rules for open sentences (equations). The present research carried out on 9th and 10th grades confirmed that hypothesis. It was found that most of the students performed the transformations required for solving an equation. mechanically, without having in mind the corresponding formal justifications. The basic concept of equivalence with its properties seems to be totally absent.

Researches dealing with how students are performing operations on open phrases and open sentences apply differently, to models, which characterize students' mistakes in open phrases and in open sentences. The source of these mistakes is in abiding the rules in the wrong way, in generalizing of rules and errors in operating (Mutz, 1982). For example: researches dealing with open phrase indicate some cognitive obstacles in simplifying open phrases which are related to "incomplete nature" of algebraic expression, Tirosh, Even, Robinson (1994). That is to say, there is a tendency, among students, to simplify every open phrase until receiving a pattern of **ax** or **a**.

This research focused in two main questions:

1. Can the student identify permitted operations in open phrases or open sentences and what is the mathematical justification that a student gives to the operations he performed on those expressions?
2. Do students apply the permitted operations on "open sentences" to the operations on "open phrases" as well?

Methodology

Subjects:

The subjects were students enrolled in 9^{th} and 10^{th} grade (52 students in grade 9 and 53 in grade 10). In each grade, two levels of mathematical competence were

considered: group A, the high level and group B, the lower level. In all, the research population was consequently divided into four groups: 30 subjects in group 9A and 22 subjects in group 9B; 30 subjects in group 10A and 23 subjects in group 10B.

The levels of competence were established by the school itself and were expressed by the quantity and subject-matter of the mathematics taught to the respective students. The schools in which the research was conducted were situated in a region with a population of average and high socio-economic status.

Instruments:

a) A questionnaire was administered in which equations and open phrases appeared. The subjects had to estimate whether the operations performed (and indicated in the questionnaire) were mathematically correct. The central concept was that of equivalence. The subjects had to estimate whether the transformation was valid ones, that are whether the successive steps of successive transformation were correct and led to equivalent expression. After each question, the subjects were asked to justify their answers.

b) A number of subjects, different from those to which the questionnaire was administered, were interviewed with regard to the same questions.

Results:

A. Operations on "open phrases" and "open sentences" expressions and the Justification of their performance.

In performing operations on "open phrase" and "open sentence" expressions, we shift from one expression to another, repeating the process of replacing one expression by another, until we obtain an "open sentence" expression which is easy to solve, or a simpler "open phrase" expression which is easy to use. To the extent that all the shifts are reversible, we will obtain equivalent balanced "open sentence" expressions, and correspondingly, compatible "open phrase" expression. Therefore it is important for the student to be acquainted with the permitted operations.

Operations in equation

The reasons given by the subjects to justify their judgments in operations upon the "open sentences" expressions can be classified to the following categories: (Table 1)

a)Reasons relating to the operations maintaining equivalence, for example:

"Multiply both sides with the same number" or "you need to multiply both sides". This reason led to a correct judgment.

b) Reasons relating to the link between given numbers in the "open sentence" expression and the operations, for example:

1. In the equation $3x = 9$ a multiplying operation was performed both sides in the number 1/3. 14% of the subjects reasoned their judgement, regarding the number which multiplied the equation, when the number 3 written in the equation, "to multiply with a 1/3 is the same as dividing in 3". Therefore they came to the correct judgement. 10% from the subjects saw 1/3 as a "strange" number for the equation ("Where did the 1/3 come from?") and that's why the operations that were performed with this number were, in their opinion, incorrect.
2. In equations with fractions, the subjects reasoned: "eliminate the common denominator".

c)"Calculation" reason: some of the subjects ignored the performed operations and set their judgement only after they solved the given equations.

It can be explained by these reasons:

* The students do not have a deep understanding of the meaning of equivalence.
* The students tend to use ways they know well and feel secured with them.
* It is possible that the principle of equivalence is known to the students, but they feel a need to check every case. (Fischbein, 1982).

The wrong way in calculating led some of the subjects to an incorrect judgement, here they performed operations only in one side (especially true in equations with fractional multipliers), while calculating wrong or when there was no possibility in reaching a solution from the shape x = number.

d) "Lack of information" reason, for example: "right way", "these is the way to solve". Such reasons (with no information) were given sometimes even when the judgement was correct.

Table 1: distribution of the judgements and reasons (in percentage) in the whole population (n=105)

examples of questions for multiple operation on equations	the judgments	The reasons				
		Referring to equivalent	link to numbers and operations	calculation	Lack of information	No explanation
$3x = 9$ $\Leftrightarrow$ $\frac{1}{3} \bullet 3x = \frac{1}{3} \bullet 9$ right or wrong, explain.....	correct 74 incorrect 16 no answer 10	19	24	21	16	20
$\frac{x}{2} + \frac{x}{3} = 10$ $\Leftrightarrow$ $3x + 2x = 60$ right or wrong, explain	correct 83 incorrect 13 no answer 4	18	44	9	2	27
$\frac{5}{3-x} + \frac{7}{3+x} = y$ $\Leftrightarrow$ $5(3+x) + 7(3-x) = y$ right or wrong, explain	correct 54 incorrect 34 no answer 12	35	33		4	28
$p(x) = \frac{2-x}{3} + \frac{2+x}{2} + 4$ $\Leftrightarrow$ $p(x) = 2(2-x) + 3(2+x) + 24$ right or wrong, explain	correct 39 incorrect 55 no answer 6	15	44	3	7	31

Additional findings were given in multiplying operations in equations with fractions:

a. The numbers of given addends with fractions in one side of the equation does not affect on the subjects' judgement and reasons. The explanation is in focusing the algorithm of eliminating the common denominator, performed by the subjects.

b. In "open sentence" expression that include fractions, the students tended to perform operations on one side only. As the given expression on one side became more "abstract", this "algorithmic behavior" grew stronger.

In the interviews where the subjects explained the incorrect judgement ("right") in the equation where the expression p(x) is written down: "it doesn't seem like an equation" or "it is a function therefore no operations are performed".

Operations in "open phrases" expressions

Table 2: distribution of the judgements and rationales (in percentage) in the whole population (n=105)

examples of questions for multiply operations on open phrases	the judgments	reasons					
		Referring to equivalence	Explanation regarding solving equations	links to numbers and operations	Lack of information	Turn to equation	No explanation
$3x + 9y = \frac{1}{3}(3x + 9y)$ right or wrong, explain.....	correct 40 incorrect 49 no answer 11	11	26	8	17	2	3
$\frac{x}{2} + \frac{x}{3} = 3x + 2x$ right or wrong, explain	correct 29 incorrect 67 no answer 4	11	46		9	8	26
$\frac{5x}{3} + 1 = 5x + 3$ right or wrong, explain	correct 27 incorrect 64 no answer 9	8	36	5	16	4	31

This research indicates that most of the subjects assume that it is possible to perform a multiplying operation on a "open phrase" expression. The main reasons that the subjects gave, to explain their judgements in the multiplying operations performed on different "open phrases" expressions, can be classified in the following categories:

a. Reasons related to compatible "open phrase" expression. For example, in a multiplication operation performed on an "open phrase" expression, the student reasoned, "the expression changed after the operation was performed".

b. The reasons taken from the repertoire of explanations related to the solution algorithm of "open sentence" expression. For example: "eliminated the denominator", "multiplied it all in the required number", "multiplied diagonally". Such reasons led to incorrect judgement.

In interviews, made with some subjects, the following explanations were given to the interviewer's question: "What do you rely on when transferring from a given expression to the one you wrote after the simplification?"

* *"As I was taught, the goal is to eliminate the fraction, I work according to the rules".*

  One student explained: "The rules are to eliminate the fraction".

* "*According to the formula, according to the examples given in class, in any exercise*

BEST COPY AVAILABLE

with fractions one multiply the common denominator".

* *"I relied on the common denominator, I wanted to eliminate it". A student added: "This is how I was taught all through the years so it will be easier, more esthetic and more simplified".*
* *"I eliminated the denominator because I have already used it and I don't need it any more".*

c. Reasons related to the link between the number employed in performing the operation, and the given number in the "open phrase" expression. For example: "It is impossible to multiply a number that isn't in the expression".

d. Reason with lack of information - for example: "That's the way you solve it".

e. Transferring the "open phrase" expression to an equation.

B. Comparison between the performed operations on "open sentences" and "open phrases" expressions

Observe the following question:

"open sentence" expression	"open phrase" expression
$\frac{x}{2}+\frac{x}{3}=10$	$\frac{x}{2}+\frac{x}{3}=3x+2x$
$\Leftrightarrow$	
$3x+2x=60$	
right or wrong, explain_____	right or wrong, explain_____

On this question 60% of the subjects gave an identical answer "right, right" to the operations they performed on the two expressions. 46% of the subjects gave identical reasons to their answers, the most noticeable one was "he eliminated the denominator". In order to understand the way of the subjects' thinking here are parts from some of the their interviews:

Interview a - a student from group 9A (T = teacher, S = student)

T : Given the expression: $\frac{x}{2}+\frac{x}{3}$ *can you simplify it?*

S: The student writes: $\frac{3x+2x}{6}=5x$

T: On what did you rely when you transferred from the first to the second expression?

S: One cannot simply add the two fractions. One has to find the common denominator.

T: On what did you rely when you eliminated the common denominator?

S: Because I have already used it and did not need it any more.

Interview b - a student from group 10A

T : Given the expression: $\frac{x}{2}+\frac{x}{3}=10$ *can you simplify it?*

S: The student writes: $\frac{x}{2}+\frac{x}{3}=10 \rightarrow 3x+2x=10$

T: On what did you rely when you operated the above transformation?

S: One has to find the common denominator.

T: Can you explain what you mean by common denominator?

S: Common denominator is something, which is common for a number of things.

T: On what did you rely when you looked for the common denominator?

S: One has to eliminate the common denominators.

T: Can you explain more?

S: No, it is the way to solve it and that is that.

From the comparison between the operations performed on "open phrases" and "open sentences", one can observe that most of the subjects perform identical operations in both types of expressions. The explanations, which follow the subjects' answers, are related to the algorithm's solution of the "open sentence". The identical elements in the "open phrases" and "open sentences" led to a hidden model of "a common solution" to both types of expressions.

Discussion

The "open phrase" and the "open sentence", as in many mathematical concepts have two aspects which complete one another: one is the formal-conceptual aspect which is represented by axioms, definitions, sentences and proofs, and the logarithm aspect which includes calculation knowledge and the understanding of the processes performed while calculating. The two aspects are combined in the mathematical operation. Skemp (1976) claims that learning the "rules not the reasons" enables the student to function in a very determined frame but without fully understanding the concepts, he wouldn't be able to deal with new assignments. This understanding enables the student to deal with any kind of information according to the changing variables.

The research indicates that only a small percentage of subjects use discretion that are related to operations which maintain equivalence. A great part of the subjects apply, in

their reasons, to specific numbers which were useful to them in order to perform the operation in the expression. Focusing on numerical hints causes them to perform some operations on "open phrase" permitted only in "open sentence" expressions.

As in "open phrase" (mainly with fractions) the subjects captured visual elements from the algorithm of solving "open sentence" expressions with fractions and implemented them in "open phrase" expressions. The justification to their operations came from the repertoire of explanations regarding the algorithm of solving open sentences.

Fischbein (1996) sees in the algorithm of equation solving a "Structural Scheme of Equation". In equations with fractions, students remember certain procedures of solving those equations. Open phrases with fractions are comprehended by the students as a structural scheme of equation that is why the student uses certain procedures of solving equations on "open phrase" expressions.

Summary

Teaching often focuses on the students' mastering procedures, and does not attempt to link formal knowledge with the procedures and situate these within a comprehensive framework. Such fragmented teaching may cause the student to perceive only the visual elements of the algorithm which will lead to faulty executions on "open sentence" and "open phrase" expressions. It is important to create links between formal knowledge and the algorithm process. in order to help the student understand the operations permitted on "open sentence" and "open phrase" expressions.

USING SEMI-STRUCTURED INTERVIEWING TO TRIGGER UNIVERSITY MATHEMATICS TUTORS' REFLECTIONS ON THEIR TEACHING PRACTICES

ELENA NARDI, UNIVERSITY OF EAST ANGLIA, UK

Integrating the findings from a qualitative study of 20 first-year undergraduates' learning difficulties in their encounter with the abstractions of advanced mathematics within a tutorial-based pedagogy at Oxford (Nardi, 1996), a study of the tutors' responses to and interpretations of these difficulties was conducted. The study was intended as a bridging project between (Nardi, 1996) and a related ESRC-funded research project which started in October 1998 regarding current conceptualisations of teaching at university level as reflected in practice and issues arising from their relations to mathematics as a discipline. For the above purposes, samples of the data and the analysis from the initial study were presented to the tutors and discussed in semi-structured interviews. Here I demonstrate the tutors' reflective statements regarding their teaching practices as triggered by the interviewing process.

The study[1], on which the findings discussed in this paper originate from, is a small-scale follow-up of the author's doctorate (Nardi, 1996) and a precursor to the Undergraduate Mathematics Teaching Project (*UMTP*) currently being conducted at Oxford. In the following I briefly outline the doctorate (Project 1). Then I describe the aims, methodology and some of the findings of the bridging study (Project 2). Finally I outline briefly *UMTP* (Project 3).

PROJECT 1: A STUDY ON THE LEARNING OF MATHEMATICS AT UNIVERSITY LEVEL

The study[2] was a psychological study of first-year undergraduates' learning difficulties. For this purpose twenty first-year mathematics undergraduates were observed in their weekly tutorials for two terms. Tutorials were tape-recorded and fieldnotes kept during observation. The students were also interviewed at the end of each term of observation. The recordings of the observed tutorials and the interviews were transcribed and submitted to an analytical process of filtering out episodes that illuminated the novices' cognition. An analytical framework consisting of cognitive and sociocultural theories on learning was applied on sets of episodes within the mathematical areas of Foundational Analysis, Calculus, Topology, Linear Algebra and Group Theory. This topical analysis was followed by a cross-topical synthesis of themes that were found to characterise the novices' cognition. The findings were arranged in themes relating to the novices' difficulties regarding their image construction of new concepts as well as their adoption of formal mathematical practices.

[2] Research supported by the Economic and Social Research Council (ESRC) in the UK

PROJECT 2: A STUDY ON UNIVERSITY MATHEMATICS TEACHERS' PERCEPTIONS OF THEIR FIRST-YEAR STUDENTS' LEARNING DIFFICULTIES

Project 2 is a follow-up study to the doctorate in which the tutors were invited to reflect and comment upon samples of data and analysis from the doctorate. In the following I describe this study as a bridge between the strictly psychological concerns of Project 1 and the directly pedagogical concerns of Project 3.

Aims. The primary aims were: to provide feedback to the tutors who participated in the doctorate and enrich its findings by including the participant tutors' point of view; to introduce a pedagogical dimension in the psychological discourse developed in the doctorate; and to inaugurate the collaboration between mathematicians and mathematics educators involved in *UMTP* in the development of discourse and methodology.

Methodology of Data Collection. For the above purposes, three tutors who participated in the doctorate were invited to participate in a series of semi-structured interviews. This choice resides theoretically in the methodological considerations, in particular regarding the interviewing of the students, in (Nardi, 1996) and in the literature regarding the teachers' reflections on their own pedagogical practices (see section on Project 3). Prior to the interviews the tutors were presented with samples of the data, transcribed extracts from the tutorials, and the analysis, presented in the doctorate. The samples were deliberately chosen to trigger tutors' reflection upon the students' learning processes, their own teaching actions as well as their response to the analysis in (Nardi 1996). The interviewees were informed of this agenda (see Fig.1) in a note covering the samples of data and analysis that were to be discussed.

An agenda for the Interview:

A Introduction: clarifications regarding the sample.
B Issues regarding learning:
- B1. a critical perspective on the sample of analysis
- B2. the interviewee's perspective on the sample of data

C Issues regarding teaching:
- C1. a critical perspective on the sample of analysis
- C2. the interviewee's perspective on the sample of data

Please read keeping in mind the interview agenda. The discussion can zoom in and out of the particular pieces of data and can address issues generally regarding your perception of your role as a tutor.

Fig. 1

BEST COPY AVAILABLE

Methodology of Data Analysis. The analysis of the interviews (Nardi, 1998 and Nardi, in preparation[3]) aimed at juxtaposing the analysis in the doctorate and the tutors' interpretations, as expressed in the interviews; and, moreover, at inaugurating reflection upon the tutors' teaching practices which is a fundamental aspect of the partnership currently being set-up in Project 3. The recordings of the interviews were transcribed and the contents of the transcripts were catalogued.

Subsequently the analytical perspectives on the data varied considerably. Some chronological considerations proved significant: when analysis was due to start, the provision of funding for Project 3 was confirmed by the ESRC. This altered the nature of Project 2 from being a self-contained follow-up to Project 1 to, additionally, being a prelude to Project 3. Three analytical perspectives were applied on the data. I will elaborate on the third one[4] by providing samples of the data and relevant analysis.

Analytical Perspective 3: a strong incorporation of methodological considerations. Did the interviews trigger the participants' reflection on their students' mathematical thinking and on their own teaching practices? If yes, how? If not, why? The answer to this question is affirmative[5]. A small set of categories emerged from the scrutiny of the transcripts:

R – S: The tutor describes standard practices, or standard difficulties observed in the students, or standard difficulties in the teaching.

R – D – CEP: The tutor defends their practice in the episode by challenging the critique in the sample on epistemological or pedagogical grounds.

R – D – U: The tutor defends their practice in the episode against the critique in the sample by undermining the representation of the events in the sample.

R – R: The tutor re-evaluates, or even regrets, their practice in the sample either by simply agreeing with the critique in the sample or by engaging in reflection on the students' learning processes.

In the following I present samples relating to the R-R category for each one of the three interviewees. In view of Project 3, in which the tutors are interviewed on a weekly basis, this category is particularly significant as the tutors' explicit self-evaluative reflections may have an immediate impact on their imminent teaching.

---

[3] By the time this research report is presented at the conference and if the paper has been accepted, the full reference will be available.

[4] Analytical Perspective 1: this emerged from the need for a transition from looking at episodes from the tutorials from a learning to a teaching point of view, and to immerse in the relevant literature. So I used the data as an empirical basis in which to embed my reading of standard texts on teachers' thinking - for instance, on the Teaching Triad (Jaworski, 1994). Analytical Perspective 2: a domain oriented perspective. For this, I have isolated all domain-specific extracts and cited them along with findings in the literature and the thesis - for instance, on the difficulties of the students' enculturation into the necessity of proof as well as into specific proving techniques (a relevant presentation at the MAA conference in San Antonio, Texas was done by the third author).

[5] A number of methodological considerations were compiled and have influenced heavily the methodology on Project 3. These will be discussed elsewhere.

TUTOR 1: SELF-EVALUATIVE REFLECTIONS

Tutor 1's stronger self-evaluative statements were far lengthier and more elaborate about epistemological (regarding the logical coherence of his mathematical discourse to the students) than psychological (regarding his individual students' state of learning) or pedagogical (regarding his teaching decisions and actions) matters. For example he is spending a substantial amount of time during the interview on re-considering his appproach to proving what the derivative of x^n, for $n>0$ is[6]. In his concluding remarks however there is also a 'didactical reason' for his re-newed preference:

> Tutor 1: ... well, now my belief is that I would have preferred it for a didactical reason and justify my evaluation that it was a better proof on historical grounds partly. That it gets us... it is evident from the fact that we get closer back to the simple reasoning that it's the original proof, em ...So obviously I have got the wrong ... I have not presented things terribly well there.

Consistency is highly valued by Tutor 1, and, as he has always expressed a strong preference for 'more direct, simpler and for that reason more satisfactory' arguments, he possibly felt that in this case his consistency was partly let down. When confronted with a series of instances where his recommendations to the students about the use of pictures in order to acquire an intuitive understanding of an argument or a concept but not substitute for a rigorous proof, are rather lacking in consistency, he replies 'I try to be reasonably consistent about that. I may get it wrong from time to time...' and provides a lengthy and precise manifesto of what he believes the use of visualisation in the construction of mathematical meanings ought to be.

In the same vein of adhering to firmly established principles that guide his behaviour in the tutorial, the tutor is 'slightly embarrassed' that he has commented on a Calculus question that the students had great difficulty with, as an exceptionally hard one[7]:

> Tutor 1: [...] I believe that to be true but usually I try not to publish to the students evaluations of that kind, that this was a hard question or that wasn't. [...] I normally try not to do that.

Despite the fact that Tutor 1 was offered a set of concrete learning episodes to be discussed in the interview, he mostly preferred to use the episodes as a basis for exposition on the general principles that guide his tutorial teaching (his approach is in contrast with the approaches of Tutors 2 and 3). Among the three interviewees he is the one for whom stronger prompting was employed in order to explore his views on subtler psychological issues regarding his students' learning. Even so, when pressed to focus on specific learning incidents, he demonstrated a belief in the individuality of his students and in the need to adjust his teaching to this individuality:

---

[6] In the tutorial he had expressed a preference for a proof based on the Binomial Theorem as a 'historically original' one. In the interview he says he should have based his preference on that it is a proof on First Principles.

[7] He grounded his comment on that 'it is harder to prove that something does not have a limit, than to prove that it does have a limit'.

Tutor 1: [...] Well, it's the picture that I've got in my mind and the picture I use for teaching but of course it's no damn good if you've got a student with a different type of psychology from mine. One has to be aware of that. [...] this particular em, metaphor, this particular picture, adaptation of the notion of a Venn diagram[8], em, needs to be abandoned or rethought through with this particular student, doesn't it? Quite probably abandoned.

In the following sections Tutors 2 and 3 engage in psychological and pedagogical discourse immediately and on their own initiative totally.

TUTOR 2: SELF-EVALUATIVE REFLECTIONS

In contrast to Tutor 1, Tutor 2 preferred immersing into the specific learning episodes she was provided with for reading before the interview — even though she would often conclude with a reference to her standard practices. Therefore a large part of the conversation was devoted to her reaching a new understanding of her students' utterances which at the time of the tutorial might have seemed to her as bizarre reactions. For instance, when reminded of the Linear Algebra episode[9] where all eight of her students reply Tp(1)=2, her initial assessment was that the students lacked knowledge of the relevant definitions. When I pointed out to her that in two of the tutorials the students had just demonstrated knowledge of these definitions, she responds that 'they still could not apply [them]'. She elaborates her reassessment:

Tutor 2: Well, polynomials ought to be easy but functions they have problems with, thinking about a function as being an entity in its own right. Whether that came into it...

Interviewer: You mean they cannot see a function as an object, to use it as an element of a set as opposed to a process.

Tutor 2: Yes, that's right, it's always been a process: you apply it to an element and another element comes out.

Apart from an insightful observation into her students' thinking, the above are also in resonance with findings on the learning of functions — the process/object duality of their nature is a well-trodden area of research in Advanced Mathematical Thinking (e.g. Dubinsky and Harel, 1992).The significance of the statements lies in that they come from a practitioner who is unaware of this literature and who, in the event of the interview, gains this awareness. This exchange highlights a convergence of perspectives and interests between mathematicians and mathematics educators on which the emphasis is largely missing in the field. Numerous similar exchanges took place in these interviews and will be reported elsewhere (Nardi, in preparation).

[8] He refers to a misunderstanding regarding the use of an illustration of cosets in Group Theory as equal-sized parts of a square.
[9] T is the linear mapping Tp(x)=p(x+1), for p a polynomial of degree 3. Therefore 1 is the constant polynomial mapped via T on itself, not 2. A similar incident occurred with the zero element.

Towards the end of the interview Tutor 2 offered an unprompted evaluation of the interviewing process. In this she seems to have valued mostly the discussion of alternative interpretations of her students' utterances:

> Tutor 2: So therefore I think there is other possibilities I hadn't had in mind because on the whole I don't actually know how much tutors think about their role as a tutor and what actually one is doing as opposed to, you know, what end result you would like to get out of it all. A lot of it I suppose is really done by what has worked in the past with our students. [A similar statement was offered by Tutor 3].

TUTOR 3: SELF-EVALUATIVE REFLECTIONS

As with Tutor 1, Tutor 3's initial persistent focus seemed to be on how epistemologically comprehensive was his introduction to the notion of spans and spanning sets in Linear Algebra. In the course of the interview however it transpires that his persistence was on trying to understand what initiated the discussion of the concept on the part of the student. When he hears that the definition of span used in the lectures was different to the one he used in the tutorials and that nobody had hinted at the equivalence of the two definitions, he responds that 'it seems in retrospect to be a great mistake' and that 'It's quite likely that I never discovered that of course which is a mistake'. Tutor 3 seemed to perceive the interview as an occasion for directly evaluating his teaching. In fact he had prepared a list of cases – based on the samples of data he was provided for reading before the interview – where he 'could have handled things differently'. He distinguished between 'errors that I am making here and I think I know why I am making them' and 'other ones that are pretty bad mistakes and it's not quite clear why I was making them'.

Given the limitations of space, I offer in the following his first mentioning in the interview of what he perceived as an example of each of the above mentioned types of 'mistake'[10]. Both 'mistakes' were discussed to great detail, in fact large parts of the interview were devoted to a line-by-line scrutiny of the transcripts:

> Tutor 3: Well, for example, [...] it seems to me to be a major error to go on talking about the theory of cosets without going immediately or fairly immediately to some concrete example. And I am amazed I am making a mistake like that. The other general mistake that I noted throughout both episodes is that I am rather keen on pushing for what I regard as the right understanding of concepts, or the right way of proving something, instead of pursuing what the undergraduate is thinking about. And I think I know why I make that mistake. It's quite a lot to do with the rather fast pace of the Oxford course, that there is a lot of pressure to try and get the student keeping up with the pace and then of course in the long run it's far better if they have a thorough understanding of the concepts and then we can accelerate the pace and catch up later. But I think that's a general mistake that I perceive in retrospect.

In the detailed scrutiny of the transcripts mentioned above, in which again a mathematician's and a mathematics educator's perspectives were actively co-ordinated, Tutor 3 seems to maintain a balance between strong self-evaluative comments and challenges to the analysis in (Nardi, 1996). In most cases his challenges regard a 'slightly more positive' assessment of the student's state of learning at the time. Nevertheless he

[10] The first refers to an episode from Group Theory and the second to one from Linear Algebra

always concludes with re-evaluations such as 'in retrospect maybe I should have taken time to explain the difference', 'maybe I should have spent more time trying to find out what she really meant there' or 'one should be more patient and follow up what the student is thinking'.

SYNTHESIS AND IMPLICATIONS FOR PRACTICE

Whether the tutors in these interviews engaged in an explication or re-evaluation of their standard tutoring practices, in reflection on their students' thinking or in challenging the analysis in (Nardi, 1996), the aims of the interview, as outlined earlier here, were certainly fulfilled. This fulfilment can be partly seen in the extracts of the interviews exemplified in the previous three sections. In sum – and I offer these also as an evaluation of the methods used in Project 2:

- The tutors engaged in an articulation, justification and often reassessment of their teaching actions in the discussed episodes, or even more generally. Occasional inconsistencies in their practices were also highlighted.
- The tutors engaged in a scrutiny of the evidence on their students' thinking, a task for which any time is rarely allowed. This often amounted to their gaining an awareness of existing research literature , for instance, in specific areas of learning difficulties in undergraduate mathematics.
- Certain analytical themes from (Nardi, 1996) were enriched by the tutor/practitioner's point of view, e.g., in the extracts illustrated here, regarding the debatable value of using certain concrete graphical representations to introduce abstract mathematical concepts or the need to enhance a co-ordination of intuitive and formal practices for the novice advanced mathematics learner.

Implications for practice. During the interviews the tutors expressed their concern for a potential limitation of the study which related to their difficulty with recalling the specific learning episodes they were invited to discuss. All of them claimed that had the interviews taken place closer to the incidents, their recollections would be fresher, hence more reliable. It was agreed however that what was actually discussed in the interviews were the transcripts of the recorded events and the analysis in (Nardi, 1996). It was also agreed that had they been interviewed immediately after the event, there would have been no analysis to discuss. This would alter the nature of the data – actually this immediacy is exactly what Project 3 aims to achieve. These more immediate interviews would also benefit from a more balanced input from both the practitioner's and the researcher's point of view. As the tutors themselves acknowledged the impact of this exchange, in particular when taking place on a regular basis, on the tutors' perception and enactment of their role can be significant. These considerations have been built into the formation of the aims and the methodology of Project 3. In the concluding section I outline Project 3 which is currently in progress.

PROJECT 3: THE UNDERGRADUATE MATHEMATICS TEACHING PROJECT

UMTP is a one-year study which commenced in October, 1998. Its broad aim is to explore, in a clinical partnership (Wagner, 1997) with university mathematics teachers, current thinking and practices in mathematics teaching at first-year undergraduate level and to begin to provide a knowledge base on which to make decisions affecting teaching. *UMTP* develops theoretically from educational research at pre-university levels: in particular, the growing literature into teachers' thinking processes and personal theories and their links to pedagogy (e.g. Brown and McIntyre, 1993) and research on the correlation between teachers' perceptions of mathematical epistemology and cognitive development and their classroom practices (e.g. Jaworski, 1994). *UMTP* extends this literature to address pedagogical issues in university mathematics teaching, drawing on studies of advanced mathematics in epistemological and cognitive domains (e.g. Tall, 1991; Sierpinska, 1994). Another root of the study resides in a close collaboration between mathematicians and mathematics educators: *UMTP* addresses and seeks reconciliation between the differing emphases of these practitioners. The set of qualitative data developed in the study consists of tutorial observations, semi-structured interviews with the tutors and participant group discussions. The UMTP project team have submitted a Research Report to PME23 in which they discuss findings from the project (Jaworski, Nardi and Hegedus, submitted[11]).

ADDRESSING STUDENTS' CONCEPTIONS OF COMMON FRACTIONS

Karen Newstead and Alwyn Olivier
Mathematics Learning and Teaching Initiative, South Africa

Grade 6 and 7 South African upper elementary school students' conceptions of and operations with common fractions were investigated before and after a year of exposure to materials which had been designed to challenge common limiting constructions identified in a previous study, and to a teaching approach of which reflection and interaction are essential components. There was a significant improvement in several of the items in the written tests, in line with the aims and extent of the materials used.

Introduction

This paper reports on the impact of an approach for the teaching of common fractions on Grade 6 and 7 students' conceptions of fractions. The approach was intended to challenge common limiting constructions (D'Ambrosio and Mewborn, 1994) and included materials that were designed to specifically address students' problems with fractions which had been identified in a previous study (Newstead and Murray, 1998) in a larger sample of which the current sample is a subset.

The approach and materials were used during the first year of implementation of the Mathematics Learning and Teaching Initiative (Malati) teacher and curriculum development project in schools, as a vehicle for introducing elementary school teachers to our approach. This approach requires a classroom culture as described below which originates from our theoretical orientation as reported in previous PME papers (e.g. Murray, Olivier & Human, 1996). Such an approach is based on the view that students construct their own mathematical knowledge irrespective of how they are taught. Cobb, Yackel and Wood (1992) state: "... we contend that students must necessarily construct their mathematical ways of knowing in any instructional setting whatsoever, including that of direct instruction," and "The central issue is not whether students are constructing, but the *quality and nature* of these constructions" (p. 28, our italics).

Based on the previous study (Newstead and Murray, 1998) and on the existing literature, and in line with the Malati philosophy, the fractions materials were designed according to the following basic principles:

- Students are introduced to fractions using sharing situations in which the number of objects to be shared exceeds the number of 'friends' and leaves a remainder which can also be further shared (e.g. Empson, 1995; Murray, Human & Olivier, 1996).
- Students are exposed to a wide variety of fractions at an early stage (not only halves and quarters) and to a variety of meanings of fractions, not only the fraction as part-of-a-whole where the whole is single discrete object, but also for example the fraction as part of a collection of objects, the fraction as a ratio, and the fraction as an operator.

1126

- Students are encouraged to create their own representations of fractions; pre-partitioned manipulatives and geometric shapes do not facilitate the development of the necessary reasoning skills and may lead to limiting constructions (Kamii and Clark, 1995).
- The introduction of fraction names and written symbols is delayed until students have a stable conception of fractions. Written, higher order symbolization is not the result of natural learning, and students struggle to construct meaning for such representations of fractions in the absence of instruction which builds on their own informal knowledge (Mack, 1995).
- Similarly, students can and should make sense of operations with fractions in a problem context before being expected to make sense of them out of context (Piel and Green, 1994).
- The materials repeatedly pose problems with similar structures to provide students repeated opportunities to make sense of particular structures. Fractions are taught continuously throughout the year, once or twice a week rather than in a concentrated 'block' of time.
- A supporting classroom culture is required in which learning takes place via problem solving, discussion and challenge and in which errors and misconceptions are identified and resolved through interaction and reflection. Teachers do not demonstrate solution strategies, but expect students to construct and share their own strategies and thus to gradually develop more powerful strategies.

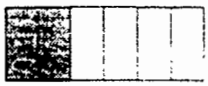
The Malati elementary school material and approach was implemented in 4 traditionally disadvantaged schools near Cape Town in 1998. In addition to student worksheets and comprehensive teacher notes, the teachers attended workshops and reflection sessions and were visited regularly in their classrooms by Malati project workers.

Methodology

To study the impact of the Malati materials and approach, research was conducted on both teacher and student change in two of the four elementary schools. The impact on Grade 6 and 7 students' learning was investigated using both written individual tests and observation of students interacting in groups to solve challenging problems. This paper reports on changes in students' responses to the common fractions items in the written tests only.

The written tests were designed by Malati researchers to 'cover' both the curriculum traditionally taught in the schools, and the intended Malati curriculum. Thus items in the Grade 6 and 7 tests differed in some cases according to the existing curriculum aims. All the Grade 6 and 7 students completed the three tests on the same day towards the end of the academic year in November 1997. For one of these tests, calculators were not allowed. The tests were administered by Malati project workers who encouraged the students to try their best, but assured the students that the results were not for school 'marks'. Exactly the same procedure was followed with the Grade 6 and 7 students in the same two schools in November 1998. The tests were coded by Malati project workers according to a coding schedule devised after an initial analysis of the first dataset. Out of every class of approximately 30 to 50 students, the first five complete tests were coded by two Malati

project workers who then compared and discussed any discrepancies before continuing to code individually. The data was input and the analysis carried out using SPSS for Windows.



Results

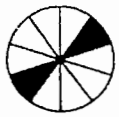
The response categories for the fractions items were collapsed for the purpose of a chi-squared analysis. In some cases, certain responses were coded as showing some understanding of the problem, in which case a third 'semi-correct' category is indicated. In these cases, the chi-squared analysis was conducted using the categories 'no correct response', 'semi-correct response' and 'correct response'.

The following tables show the success rate on the common fractions items. The items are numbered for convenience and not according to test item numbers. All the values in the cells are percentages of the total number of students who were tested. The number of students in each grade differ in 1997 and 1998 owing to the non-longitudinal research design, e.g. Grade 6 students in 1998 (who have been exposed to the intervention for a year) are compared to Grade 6 students in 1997 (who had not been exposed to the intervention).

Item 1 tested students' part-of-a-whole conception of fractions:

1. What fraction of the following figures is shaded? If it is not possible to say, explain why not.

(a)  (b)  (c) 



(d)  (e)  (f) 

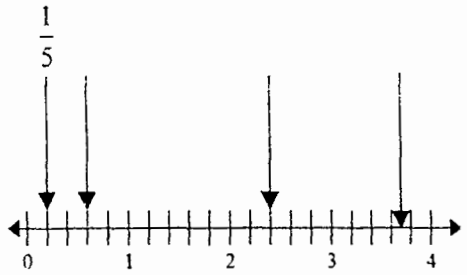


Table 1 shows the success rate on these items and significance of change in responses:

Item	Grade 6 1997 (N=208)	Grade 6 1998 (N=174)	Significance	Grade 7 1997 (N=191)	Grade 7 1998 (N=193)	Significance
1a	58	85	$p < 0,001$	71	78	$p > 0,05$
1b	52	83	$p < 0,001$	69	79	$p < 0,05$
1c	69	89	$p < 0,001$	87	90	$p > 0,05$
1d	53	79	$p < 0,001$	73	78	$p > 0,05$
1e	2	5	$p > 0,05$	4	12	$p < 0,01$
1f	48	77	$p < 0,001$	67	72	$p > 0,05$

Table 1: Success in identifying fractions using pre-partitioned shapes

Although rational number lines were not taught in the Malati curriculum, the following number line items were included to test students' conception of fractions as rational numbers:

2. *What numbers are shown by the arrows? The first one has been done for you*

3. *Show the following numbers on the number line below. The number* $\frac{3}{4}$ *has been done for you.*

(a) $1\frac{1}{3}$ (b) $\frac{12}{6}$ (c) $\frac{2}{3}$

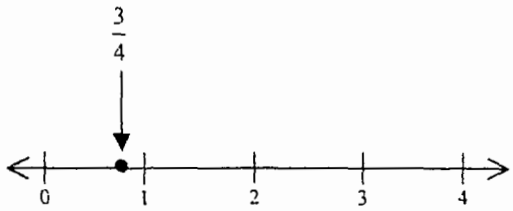

Table 2 below shows the success rate on these items and significance of change in responses. Blank cells in the table indicate that these particular items were not included in (in this case) the Grade 7 tests.

	Grade 6			Grade 7		
Item	1997	1998	Significance	1997	1998	Significance
2a	35	46	$p < 0,05$	33	47	$p < 0,01$
2b	16	32	$p < 0,001$	19	27	$p < 0,05$
2c	4	14	$p < 0,01$	14	17	$p > 0,05$
3a	17	35	$p < 0,001$			
3b	6	18	$p < 0,001$			
3c	9	17	$p < 0,05$			

Table 2: Success on items using rational number lines

Additional items that were included in the Grade 6 and 7 tests are shown in Table 3 and 4 respectively. For Item 5, a 'semi-correct' response indicates that students correctly chose Amina as having spent more, but did not supply a reason. For Item 6, a 'semi-correct' response indicates that students gave a response of 6 or 7 rather than the precise correct answer of $6\frac{1}{3}$. 'SC' indicates the frequency of semi-correct responses (where such a category was coded), while 'C' indicates the frequency of correct responses.

Item (Grade 6 test only)	1997 SC	1997 C	1998 SC	1998 C	Significance
4. Jackie spends $\frac{3}{4}$ of her pocket money and Piet spends $\frac{1}{2}$ of his pocket money. Could Piet have spent more money than Jackie? How?		3		2	$p > 0,05$
5. Anwar and Amina each received R30 pocket money. Anwar spent $\frac{5}{8}$ of his pocket money and Amina spent $\frac{7}{10}$ of hers. Who spent more? Explain your answer.	11	17	19	17	$p > 0,05$
6. Mrs Brown wants to cook porridge for 10 people. She normally uses 5 cups of oats for 8 people. How many cups of oats does she need for 10 people? Show your calculations.	16	<1	33	4	$p < 0,001$

Table 3: Success on comparison of fractions items and the use of fractions as a ratio

Item (Grade 7 test only)	1997	1998	Significance
7a. If the diagram below represents a whole, show by means of a suitable drawing how you would represent $\frac{2}{5}$. 	9	6	$p > 0,05$
7b. If the diagram below represents a whole, show by means of a suitable drawing how you would represent $\frac{1}{2}$. 	47	59	$p < 0,01$
8a. Four pizzas were bought: $\frac{1}{3}$ of the pizzas was eaten. Show this fraction by shading: 	13	24	$p < 0,01$
8b. How many pizzas were left?	7	17	$p < 0,01$
9. $\frac{1}{3}$ of a man's salary is R3200. What is his salary?	39	37	$p > 0,05$
10. After a party $\frac{1}{5}$ of a cake is left. The next day John eats $\frac{3}{4}$ of the leftover cake. What fraction of the cake is left then?	6	4	$p > 0,05$

Table 4: Success on items in context testing concepts of and operations with fractions

The following items tested operations with fractions out of context. Students were not permitted to use calculators for these items. For Items 11 and 12, a 'semi-correct' (SC) category was included for responses in which a suitable common denominator was used but the correct answer was not obtained. In the case of Item 17, a SC category was also included for responses of '30 min + 15 min' and '$\frac{1}{2}+\frac{1}{4}$'. Table 5 shows the frequencies in the various categories and significance of change in responses. In some cases, a chi-squared analysis could not be conducted as some of the cell frequencies were too low.

Item	Grade 6					Grade 7				
	1997		1998			1997		1998		
	SC	C	SC	C	Significance	SC	C	SC	C	Significance
11. $\frac{5}{8}+\frac{4}{5}$	1	<1	5	2	-	10	11	9	8	$p > 0,05$
12. $3\frac{1}{4}+1\frac{4}{5}$	1	<1	6	2	-	8	11	2	8	$p > 0,05$
13. $\frac{1}{6}\times 26$							5		9	$p > 0,05$
14. $\frac{7}{8}\div\frac{1}{4}$		1		1	-		6		6	$p > 0,05$
15. $\frac{3}{4}$ of $\frac{1}{5}$							19		9	$p < 0,05$
16. $\frac{3}{4}$ of R120		11		16	$p > 0,05$					
17. half of $1\frac{1}{2}$ hours	1	17	6	34	$p < 0,001$					

Table 5: Success on context-free items testing operations with fractions

Discussion

Fraction as part-of-a-whole The results show a significant and substantial improvement in many of the items that reflect the students' conception of the fraction as part-of-a-whole, which is considered to be an essential foundation to the understanding of fractions. This improvement was most evident at the Grade 6 level in all Item 1 questions, except 1e (see Table 1). There was not a similar significant improvement in the Grade 7 responses, which could probably be ascribed to the relatively high success rate in 1997.

In Grade 7 there was a significant improvement in Item 1e which may indicate that some Grade 7 students are reflecting more successfully on the necessity of *equal* parts - In 1998, 78% of the Grade 7 students gave the answer as $\frac{1}{5}$, as opposed to only 44% in 1997. In Grade 6, the percentage of students who gave the answer as $\frac{1}{5}$ changed from 69% to 66%. However, the poor success rate in both grades on this item indicates that more emphasis needs to be given to the necessity of equal parts.

Fraction as rational number It is interesting to note the significant and substantial improvement on most of the questions of Items 2 and 3 that require students to make use of the rational number line. The Malati material does not make use of any such number lines, so this may be ascribed to an improvement in the ability to make sense of fractions as rational numbers. The exception to the significant improvement on these items is the Grade 7 response to Item 2c, although 'semi-correct' responses like $\frac{18\frac{1}{2}}{5}$ and $3\frac{3\frac{1}{2}}{5}$ were included as

correct responses. It is expected that students will respond to this item with greater success once they have been exposed to decimal fractions, which were not taught in 1998.

However, the lack of success on Items 4 and 5 indicates that the Grade 6 students were not able to use fractions as rational numbers within the problem solving context. According to Watson, Collis & Campbell's (1995) classification, this particular use of fractions within the problem solving context represents the most complex level of fraction items. Indeed, our data indicates that students need more experience with fractions as abstract rational numbers in a problem solving context.

Other meanings: Fraction as part of a collection, as operator and as ratio We had expected that the materials had addressed fractions as part of a collection of objects sufficiently. Indeed, there was a significant improvement in the responses to Item 8a. The disappointing success rate on Item 9 could be ascribed to the fact that the materials neglected to address fractions as operators sufficiently. The significant change in the responses to Item 6 (the fraction-as-a-ratio) was, on the other hand, unexpected as we had felt that this meaning of fractions was not sufficiently addressed in the materials. However, the significant change is in fact in the semi-correct responses and not in the correct responses, and could thus be ascribed to better reasoning and/or estimation, or simply to an increased willingness to attempt the problem (see below).

The role of the whole The lack of success on Item 4 may be attributed to the fact that comparing fractions of which the whole is not necessarily the same was not addressed at all in the existing material. The conception of the relationship between the fraction and the whole will need to be further addressed in 1999, as indicated by the lack of success on Item 7a. There was however increased success on Item 7b.

Operations with fractions The students did not show a significant improvement on the non-calculator items (Items 11 to 17) which involved context-free operations with fractions. This can be explained by the fact that thus far in the materials they have only been required to make sense of operations in the context of problems. Context-free operations with fractions are expected to be revisited and consolidated in further fraction materials. The Grade 6 students' significant improvement in Item 17 could be ascribed to the fact that this item is not really context-free although it was included in the non-calculator test.

It is of concern that the students did not achieve more success on Item 10 which concerns multiplication of fractions in context. However, there was a significant improvement in subtraction of fractions in context (Item 8b), which can be expected as students had much experience with such problems.

Willingness to try Significantly more Grade 6 students (at least $p<0,05$) attempted Items 1a, 1b, 1c, 1d, 4, 5, 6, 16 and 17 in 1998 than in 1997. Significantly more Grade 7 students (at least $p<0,05$) attempted Items 1b, 2b and 2c in 1998 than in 1997. The only item in which fewer Grade 6 students attempted a response in 1998 than in 1997 was Item 11, and

significantly fewer Grade 7 students attempted a response to Items 11 and 15 in 1998 than in 1997. Items 11 and 15 involved context-free operations with fractions, of which the learners had little experience.

Conclusion The items on which the students performed poorly in 1997, and on which there was no significant improvement during 1998, may indicate insufficiencies in our curriculum design principles and implementation. For example the role of the whole needs to be more thoroughly addressed. In spite of our attempts to address various meanings of fractions, more attention needs to be paid to some of these such as the fraction as operator. As intended according to our design principles, operations with fractions need to be covered out of context now. Another aspect of fractions which may not have been sufficiently addressed in our materials was the transition from unit fractions to related non-unitary fractions. This transition is not one which occurs naturally (Davis, Hunting & Pearn, 1993). This may account for the lack of success on several of the items.

However, in this study design principles to facilitate improved learning of fractions were developed based on research on students' understandings and limiting constructions. The resulting materials and classroom culture of reflection and discussion helped to facilitate a better basic understanding of the conception of fractions, and a greater willingness on the part of the student to try.

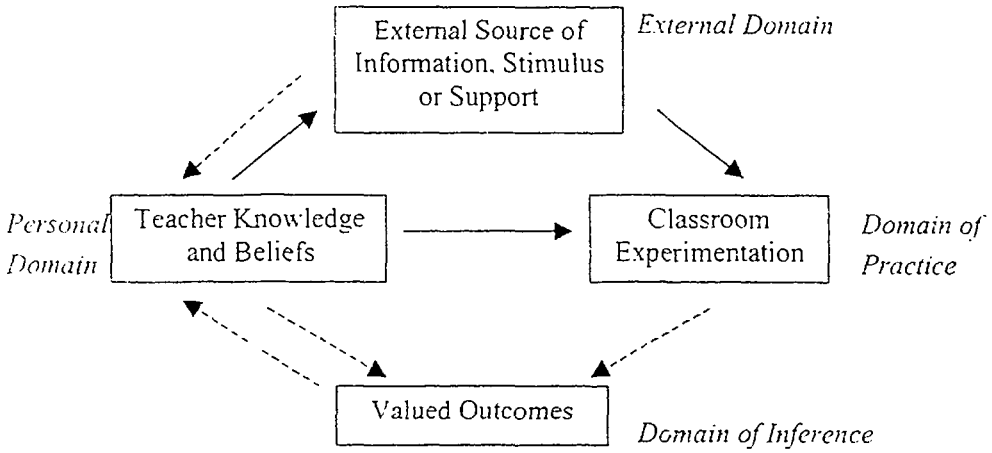
THE EFFECTS OF A DIAGNOSTIC ASSESSMENT SYSTEM ON THE TEACHING OF MATHEMATICS IN THE PRIMARY SCHOOL

Steven Nisbet (Griffith University, Australia)
& Elizabeth Warren (Australian Catholic University)

Abstract

This paper reports that the introduction of a diagnostic assessment system in Year 2 has had a significant and positive impact on mathematics teaching and assessment in the primary school. Teachers reported using a wider variety of assessment techniques (notably individual interviews & observations), using assessment data for planning instruction, having a greater sense of accountability, and including more problem solving and hands-on activities in their teaching.

Introduction



School teachers are continually faced with the challenge of implementing innovative ideas, some which are mandated by the school or the school system, and others which are promoted but not enforced. The literature on teacher change and professional development includes a sequence of models which, in turn, purport to describe the process and explain the success or otherwise of curriculum innovation.

The traditional model of implementing curriculum innovation assumes that teacher change is a simple linear process along the following lines. Staff development activities lead to changes in teachers' knowledge beliefs and attitudes, which, in turn, lead to changes in classroom teaching practices, the outcome of which is improved student learning outcomes (Clarke & Peter, 1993). Later models recognise that teacher change is a long term process (Fullan, 1982) and that the most significant changes in teacher attitudes and beliefs occur *after* teachers begin implementing a new practice successfully and see changes in student learning (Guskey, 1985). The professional development model of Clarke (1988) has refined the Guskey model by recognising the on-going and cyclical nature of professional development and teacher change. Later Clarke and Peter (1993) adapted the Guskey model further by broadening the original conceptual elements within the model. *Staff Development Activity* was broadened to include any external source of Information, Stimulus or Support, and was labelled as the *External Domain*. *Classroom Practice* became the *Domain of Practice* to include any Classroom Experimentation. *Student Learning* became the *Domain of* Inference to include any Valued Outcomes. Finally, *Teacher Beliefs* became the *Personal Domain* to include Teacher Knowledge and Beliefs (see Figure 1).

Reference to the above model of professional growth has the potential to illuminate the reasons why some innovations in mathematics education have succeeded and others have not. For instance, the importance of teachers' knowledge and beliefs in the cycle of professional growth was confirmed by Leonidas (1996) who found that the failure of a mathematics curriculum change in a centralized system was due to the

fact that teachers' perceptions of mathematics were inadequately considered at the adoption and implementation stages. Similarly, Philippou and Christou (1996) noted that if bright new ideas are to find their way into mathematics classrooms, it is imperative that change agents have a deeper understanding of classroom teachers' views, beliefs, conceptions and practices. Their study found that although teachers may be aware of and accept contemporary ideas (in this case about assessment), there can be a distance between their knowledge and intentions on the one hand, and their actual practice (in assessment) on the other.

Figure 1: The Clarke-Peter model of professional growth

Note on Figure 1: solid line = *enactive* mediating process; broken line = *reflective* mediating process. The mediating processes translate growth in one domain into another. The term *enactive* distinguishes the translation of a belief or a pedagogical model "into action" from simply "acting". Acting occurs in the Domain of Practice and each action represents the enactment of something a teacher knows, believes or has experienced (Clarke & Peter, 1993).

One particular example of an innovation which was not only successful at changing assessment practice at the target years but also produced a *ripple effect* through other school years was the system-wide adoption of the Victorian Certificate of Education (VCE) and its multi-component assessment scheme (Clarke, Stephens, & Wallbridge, 1993). It demonstrated that changed assessment practices in Years 11 and 12 mathematics had a strong impact on how mathematics was taught and assessed *throughout* the secondary school. The new assessment methods contained in the VCE included the use of multiple-choice skills test, an extended-answer analytic test, a ten-hour challenging problem, and a 20-hour investigative project. Such a wide range of assessment methods reflected the contemporary mathematics education literature, and would have been endorsed by the informed mathematics education community. In terms of the professional growth model (Clarke & Peter, 1993), the changes in the domain of practice must have produced valued outcomes for students as perceived by their teachers, and modified the beliefs and attitudes of practising teachers enough to continue the practice and to extend it to other grades in the school (the *ripple effect).*

This paper is concerned with the effect of a new state-wide system of assessment in lower primary mathematics on the teaching of mathematics throughout the primary school. In terms of the professional growth model (Clarke & Peter, 1993), the paper explores the nature of the enactive mediating process indicated by the arrow between the *External Domain* and the *Domain of Practice,* and the reflective mediating process indicated by the arrow between the *Domain of Practice* and the *Domain of Inference.* The process started in the *External Domain* with an imposed diagnostic assessment system, which lead to the teacher making changes in the mathematics classroom *(Domain of Practice)* and noting improvements in the *Domain of Inference* (valued outcomes).

The background to the adoption of the new system of diagnostic assessment in lower primary classes in the state of Queensland and a brief description of it now follows.

As a result of concerns about the levels of literacy and numeracy of children leaving school (Wiltshire, McMenniman, & Tolhurst, 1994), two state-wide initiatives have been undertaken recently. One is the *Year 2 Diagnostic Net* (the other being a *Year 6 Test*). Briefly, the Year 2 Diagnostic Net is a mandated process of monitoring and reporting on children's literacy and numeracy development in the early years of schooling. It identifies those children who are experiencing difficulties in literacy and numeracy and provides a framework for developing appropriate intervention programs for those children. The *Net* is a process in which teachers (i) observe and map all children's progress individually using *developmental continua* for aspects of literacy and numeracy, (ii) validate observations of children requiring additional assistance through specifically designed assessment tasks, (iii) provide appropriate learning support for children, and (iv) report to parents about these aspects of children's literacy and numeracy learning and development (Handbook for schools, 1996, p1). The numeracy section of the Net deals with patterns of simple objects, counting skills, and representing numbers from 0 to 10. This paper examines the effect of the introduction of the Year 2 Diagnostic Net on teaching and assessing mathematics in the primary school.

Methodology

In part of a survey, primary teachers were asked to indicate whether or not the introduction of the Year 2 Net had influenced their (1) teaching and (2) assessment of mathematics (by circling *yes* or *no* for each item). A blank space (20cm x 3.5cm) was provided below for respondents to explain how the Net had been influential. Fifteen hundred survey forms were sent to a random selection of primary schools representing different school systems (government & catholic), socio-economic areas (high & low) and geographic locations (metropolitan, provincial & rural). The return rate was 26% (n=387) and the resulting sample was representative of the different systems, socio-economic areas and geographic locations. The sample was also representative of school year levels.

Results

More teachers reported that the Year 2 Net had an influence on their assessment (42.2%) compared to an influence on teaching (28.3%) (see Table 1). However the majority of teachers influenced by the Net taught Years 1, 2 and 3: 70% of these teachers indicated that it influenced their assessment, and 43% said that it influenced their teaching. Teachers in other grades reported levels of influence lower than those for lower-primary teachers, reducing to 31.3% (assessment) and 20.8% (teaching) for Year 4 teachers and 15.2% (assessment) and 13.6% (teaching) for Year 7 teachers.

Table 1: Distribution of percentage of responses across grades on the question of *whether* the Year 2 Net influenced the teachers' assessment and teaching.

Year Level	Influenced assessment %			Influenced Teaching %		
	Yes	No	No response	Yes	No	No response
Preschool	25	58.3	16.7	25	66.7	8.3
Year 1	75.5	18.9	5.7	39.6	52.8	7.5
Year 2	80.7	15.8	3.5	50.9	45.6	3.5
Year 3	63.9	26.2	9.8	45.9	40.1	13.1
Year 4	31.3	54.2	14.6	20.8	64.6	14.6
Year 5	12.8	76.6	10.6	12.8	76.6	10.6
Year 6	11.9	61.9	26.2	9.5	64.3	28.6
Year 7	15.2	62.1	22.7	13.6	63.6	22.7
Averages	42.2%	44.5%	13.4%	28.3%	57.8%	13.9%

Only 175 (45%) of the respondents wrote an explanation in the space provided of *how* the Year 2 Net had influenced their teaching and assessment of mathematics. The explanations that were provided fell into four categories, with significantly more explanations given about *assessment practices* (n=73, 42%) than about *content taught* (n=37, 21%), *methods used for teaching* (n=38, 22%), and *comments about students* (n=27, 15%), $F(3, 18) = 4.15$, $p < .05$. More explanations were given by teachers of years 1 to 3 (n=138, 79%) than years 4 and 5 (n=31, 18%) and years 6 and 7 (n=6, 3%), $F(6, 18) = 9.24$, $p < .0001$.

(i) *Comments on assessment*: The comments on assessment were about different types of assessment tools the teachers now used or about different ways of implementing assessment procedures in the classroom setting (see Table 2).

Table 2: Distribution of comments on *changed assessment practices* (n = 73)

Category	Yr. 1	Yr. 2	Yr. 3	Yr. 4	Yr. 5	Yr. 6	Yr. 7	Total
Type of assessment								
Observation	4	5	3	1	2		1	16
Journal	1		3					4
Individual interview	5	6	1	2				14
Focussed assessment	3	1					1	5
Review sheets	1							1

Implementing assess.								
More systematic	1	5	4		1			11
More individually based	1		1		1			3
Greater array		1	2	4	2		1	10
Influenced recording	1	3	2		1			7
Influenced reporting		1	1					2

The majority of teachers who reported an increased use of observation and individual interviews taught in the lower primary grades. This increase should be seen as a positive effect of the introduction of the Year 2 Net. Many teachers reported that they assessed more systematically and used a greater array of assessment methods.

(ii) *Comments on content*: Many comments show that many teachers have embraced the Year 2 Net not only as an assessment device but also as indicator of what to teach (see Table 3), for instance more problem solving and activities with number patterns.

Table 3: Distribution of comments on *changes in content* (Total = 37)

Content	Yr. 1	Yr. 2	Yr. 3	Yr. 4	Yr. 5	Yr. 6	Yr. 7	Total
Number emphasis (patterns)		1	2	1				4
Problem solving		2	2	1				5
Investigations		1						1
Continuum (Net) is syllabus	1	11	6	2	2			22
Emphasis on money			1					1
Emphasis on different aspects		4						4

(iii) *Comments on teaching*: Many comments indicate a greater sense of accountability and the use of assessment data to inform planning (see Table 4). Others included the greater use of hands-on activities, and self-reflections of teaching and mathematics.

Table 4: Distribution of comments on *changes in teaching* (total = 38)

Teaching (method)	Yr1	Yr. 2	Yr. 3	Yr. 4	Yr. 5	Yr. 6	Yr. 7	Total
More hands on	4				2		1	5
Real world contexts	1						1	2
Teaching (approach)								
Integrated approach	1							1
More accountable		2	1	1	1		1	6
Informs planning	2	2	2	1	2			9
Ensure all children have knowledge of all areas	3	5						8
Teaching (Prof Dev)								
Changed my perceptions of mathematics	1	1						2
Identified my weaknesses	1	2						3
Network meetings inservice	2							2

BEST COPY AVAILABLE

(iv) *Comments about students*: These comments show that many teachers interact more with students on a one-to-one or small-group basis, and identify more children at risk (see Table 5). Such responses are consistent with those shown in Table 2 and should be seen also as a positive effect of the introduction of the Net.

Table 5: Distribution of comments on changes relating to *students* (total = 27)

Categories for *students*	Yr. 1	Yr. 2	Yr. 3	Yr. 4	Yr. 5	Yr. 6	Yr 7	Total
More one to one	2	5	2	2				11
More small group interaction	1	2						3
Identify chn needing extension		1			1			2
Identify children at risk		4	1	1	2			8
Adapt to developmental levels	1	1						2
Plotting children's progress			1					1

Discussion

These results should be interpreted in the context of the methodology of self-reporting by teachers and the return rate of just over a quarter. Although the state-wide figures may not be as high as the sample figures, it can be argued that the introduction of the Year 2 Net nevertheless has had an impact on the teaching and assessment of mathematics in Queensland primary schools especially in the lower grades (Years 1, 2 & 3). The fact that 80.7% of the Year 2 teachers in the sample reported that it influenced their assessment methods and 50.9% reported that it influenced their teaching, indicates that the impact has been substantial. Even a worst-case scenario of a quarter of these percentages implies that the impact was not insignificant, with many teachers across the state improving their assessment and teaching skills.

In terms of the Clark-Peter model (1993) of professional growth, the External-Domain stimulus of a mandated assessment process has lead to changes within the Domain of Practice, namely, better assessment and teaching methods. The Year 2 Net has offered many lower-primary teachers a pedagogical model which they report being able to translate into action through the *enactive mediating process*. Hence the success of the Net may be explained in terms of teachers noting the outcomes of the assessment tools of the Net as being positive and *valued*.

The effect on the teaching and assessment of mathematics reported by teachers in grades other than Year 2 is another example of the *ripple effect* described by Clarke, Stephens and Wallbridge, (1993), this time in the primary school, with the effect in this case waning in year levels more distant from Year 2.

The impact of the introduction of the Year 2 Net has been positive in terms of *valued outcomes*. Why positive? The responses by teachers have largely referred to outcomes that have been *endorsed by the informed community* (Stephens, Clarke, & Pavlou, 1994). The mathematics education literature is replete with calls for broadening the range of assessment techniques used in mathematics classes (Clarke, Clarke & Lovitt, 1990; Beyer, 1993; Swan, 1993; Webb, 1993). Hence, it is

1139

gratifying to note lower-primary teachers in this study reportedly using a greater array of assessment techniques, including observation and individual interviews. Similarly it is gratifying to note a reported increased emphasis on identifying children at risk and conducting more one-to-one and small group activities, in the light of public concern about standards of numeracy and the thrusts in the literature on intervention in early mathematics (Pearn, 1994; Steffe & Cobb, 1988; Wright, 1994). Given the sustained endorsement of problem solving and hands-on activities over the last twenty years (NCTM , 1979; Cockcroft, 1982; AMEP, 1985; NCTM, 1989, AEC, 1990), it is also satisfying to note more teachers reporting an increase in their use of such activities in the mathematics classroom.

The fact that many teachers have embraced the Year 2 Net not only as an assessment device but also as indicator of what to teach may imply a perceived inadequacy of the current syllabus statement (Department of Education, Queensland, 1987) and/or insufficient promotion of the syllabus and its accompanying resources. Nevertheless, it is a concern to educators when the assessment *tail wags* the curriculum *dog*.

However, other comments in the category of teaching indicate that there have been other positive outcomes of the introduction of the Year 2 Net. Firstly, some teachers report using the assessment data to inform planning - a positive outcome, given that a major purpose of assessment is planning instruction (Cole & Chan, 1994). Secondly, some teachers believe that they are more accountable, and that they ensure that their children "have knowledge of maths in all areas" – another positive result in the light of calls for achieving learning outcomes (Australian Education Council, 1994). Thirdly, it is gratifying to note some teachers being more self-reflective in relation to their own strengths and weaknesses and their perceptions of mathematics. This supports another facet of the Clarke-Peter (1993) model of professional development i.e. the personal domain, and is a cue for the next stage of this investigation.

STUDY OF JUSTIFICATIONS MADE BY STUDENTS AT THE "PREPARATION STAGE" OF BADLY DEFINED PROBLEMS

Noda, A.; Hernández, J. and Socas, M.M.
University of La Laguna

SUMMARY

In this work we describe and analyze the behaviour of three final year Infant Education teacher training students when at the "preparation stage" (Bourne, et al., 1979) they have to solve six badly defined find problems in arithmetic, algebraic and geometric contexts. More specifically, we analyze the ways in which the students identify problems as either well defined or badly defined, the relationships they establish between the data and the aims of the problems, and the type of arguments they use in order to justify their actions in terms of validation and refutation.

INTRODUCTION

Attempts have been made to characterize the notion of problems from the viewpoint of Mathematics (Polya; 1957), Psychology (Newell and Simon, 1972; Chi and Glaser, 1986), as well as from that of Mathematical Education (Schoenfeld, 1985). Also, there have been many attempts to classify and group them (Simon, 1973; Butts, 1980; Charles and Lester, 1982; Frederiksen, 1984; Borasi, 1986; Pehkonen, 1991, 95).

As Greeno (1978) and Kilpatrick (1987) point out, it is very difficult to make precise classifications of problems because many problems possess common features in different categories.

We use the classification adopted by Polya (1945) who distinguishes find problems from prove problems, and adapt some elements found in the definition of problem space put forward by Newell and Simon (1972). In our work we have had to make a "local" characterization of well and badly defined find problems in order to identify the problems to be included in our research. One term we have had to introduce is that of the "Semiotic State" of a well or badly defined find problem; this term stands for the set of semiotic representations of the problem that the ideal solver would produce from the initial state E_0 up to the final state R. The notions of initial state, desired final state, operators, etc., are set out by Newell and Simon (1972, p.810).

It should be pointed out that while in their definition these authors refer to the various cognitive representations of the problem the solver makes on the basis of the task environment, we refer to a "formal competence model" and to the possible semiotic representations of the problem solution made by an ideal solver.

So, a find problem is determined by the tern <E,O,R> where **E** is the set of semiotic states, **O** the set of operators, and **R** the set of solutions; so, $\mathbf{E}=\{E_0, E_1, \ldots, E_n\}$, with $E_n \in R$, and E_0, the initial state, formed by the set of data given.

We characterize a find problem as well defined when in the previous tern $E_0 \neq \varnothing \wedge \exists (E_i)_{i\in\{0,1\ldots n\}} \wedge E_0 \subset E_i,\ \forall i \in \{1, \ldots, n\}$. { $(E_i)_{i\in\{0,1\ldots n\}}$ represents a succession of states included in E }

That is, when we go through a solution process in which we can relate all the data to the solution by means of some type of analysis or synthesis, be it numerical, algebraic, or some other type

So, if in this definition we again take the tern <E,O,R> and deny the conditions that characterize the well defined find problem, a badly defined find problem would be

characterized as $E_0=\varnothing \vee \nexists (E_i)_{i\in\{1,\ldots,n\}} \vee E_0 \not\subset Ei,\ \forall i \in \{1,2,\ldots,n\}$. That is, when there is no possible relationship between the data and the solution.

We can now classify badly defined find problems as: Type I (too few data) when $E_0 = \varnothing$, Type II (too few data) when $E_0 \neq \varnothing \wedge \nexists (E_i)_{i\in\{1,\ldots,n\}}$, Type III (too many data) when $E_0 \neq \varnothing \wedge \exists (E_i)_{i\in\{1,\ldots,n\}} \wedge E_0 \not\subset Ei,\ \forall i \in \{1,2,\ldots,n\}$. (Noda, A.; Hernández, J. and Socas, M.M., 1997,1998).

EXPERIMENT DESCRIPTION

In this experiment we consider the models proposed by Dewey (1933) and Bourne et al. (1979) for problem solving and we basically analyze the "preparation stage", focusing especially on students' actions at this stage. In Dewey's terms, these actions can be specified as: identification of the problem situation, characterization of the problem, and analysis of means-ends, in other words, how solvers analyze and interpret the data initially available, the restrictions and how they identify the solution criteria.

Research questions.

Our aim is to study solvers' behaviour when they are faced with badly defined find problem in arithmetical, algebraic and geometrical contexts. To carry this out we ask ourselves the following questions: How do solvers identify the problem situations in terms of well or badly defined? How do they establish relationships between the data and the aims in these types of situations? And finally, how do the solvers justify their actions? Bearing these research questions in mind, we designed an analysis scheme to observe the real solvers at the preparation stage when working with well and badly defined find problems.

Methodology

Adopting the model established by Schoenfeld (1985), the scheme was designed as follows:

Reading: reading, silence, re-reading

L1. Have all conditions of the problem been noted?

L2. Has the aim of the problem been correctly noted?

L3. Does the environment (context) of the task affect the reading of the problem?

Analysis-Exploration: Understanding, reasoned actions

E1. Does the solver look for some relationship, either true or false, between the conditions and aim of the problem?

E2. Are the actions governed by the conditions of the problem (the data)?

E3. Are the actions governed by the aims of the problem (the question)?

Actions: Reformulation, introduction of elements, simplification of elements

A1. Does the solver explicitly or implicitly recognize that the problem is well or badly defined? Does s/he justify this?

A2. Does s/he reformulate the problem? Does s/he transform the problem into a well or badly defined problem? Explicitly? Implicitly? How? Does s/he justify the transformation?

A3 If s/he does not transform the problem either explicitly or implicitly, does s/he set about it as if it were a well defined problem? Does s/he justify this?

Checking-Transition.

V1. Does the solver revise his or her actions? As a result of the process or of the result obtained? Does s/he justify this?

V2. Does s/he change his or her action plan? Does s/he justify this?

V3. Is the plan adopted suitable for the change made?

The justifications made by the solvers for their actions must be considered in terms of validation or refutation To this end, we establish, as in the case of well defined problems, three general types of resource (Calderón and León, 1996):

Internal cognitive resources (related to mathematics) For justifications made with regard to the mathematical relationships established by the solver or mathematical behaviour decided upon by the solver in the procedures followed.

External cognitive resources. For justifications made by using culturally established concepts to justify mathematics. The level of systematization in such justifications refers to beliefs and attitudes held about mathematics rather than to authentic processes of mathematical inference

Discursive resources. For interpretations made in a verbal or written form that exteriorize and show concepts and processes to do with well or badly defined problems or problem situations.

Subjects

In order to gather oral data, the experiment was carried out on three-year teacher training students specializing in Infant Education at the Centro Superior de Educación at La Laguna University (Tenerife, Spain). The three subjects were split into two groups: Group 1, made up of two students of average ability, and Group 2, made up of one student of high ability.

Instruments

Both groups were given a set of six badly defined problems (see Table 1): three badly defined Type-II problems with a lack of data (A1, B2 and B3), and three badly defined Type-III problems with too many data (A2, A3 and B 1). The problems were worked on in two one-hour sessions carried out on different days.

Context / Sessions	Arithmetic	Algebraic	Geometric
Session 1	(A1) M.D. Type II	(A2) M.D. Type III	(A3) M.D. Type III
Session 2	(B1) M.D. Type III	(B2) M.D. Type II	(B3) M.D. Type II

Table 1

The sessions were videotaped. Group 1 carried on their session by means of discussions between the two students in such a way that they alternately played the roles of interviewer and solver regarding the various problems, while in Group 2 a clinical interview was carried out.

RESULTS

Let us now look at the results obtained in the experiment in accordance with the analysis scheme we have designed.

By way of example, we shall describe the behaviour of the solvers when solving one of the six problems they worked on (A1), and include the transcription of the video recording of both groups of students. The parts underlined highlight the justifications made by the students.

A1: The menu in a bar reads as follows: Hot-dogs 100 pesetas: coffee 75 pesetas: fried potatoes 85 pesetas, Coca Cola 125 pesetas, toast 100 pesetas, and hamburgers 175 pesetas. If Luis does not like hot-dogs, how much did he pay for his breakfast?

Group 1: Student 1 (S1) plays the role of interviewer while Student 2 (S2) that of the solver

S1 Reads out the problem

BEST COPY AVAILABLE

S2: As S1 reads out the problem, S2 notes down the problem data (both the text as well as the numerical data in the form of a table with two columns: the left one for the text and the right one for the numerical data). When S1 finishes reading the problem, he asks: "What does the problem ask?"

S1: "How much he paid for breakfast."

S2: Does not note down the question but immediately says: "Well, if he ate fried potatoes, toast, coffee ... (she pauses a little and then goes on) ... he can't have Coca Cola, he isn't going to mix Coca Cola and coffee. Look, if he had a hamburger and Coca Cola (writing on the board Hamburger and Coca Cola, and beneath this text the numerical data 125 + 175 = 300 pesetas, and doing the calculation in a slightly lower voice) he paid three hundred pesetas for breakfast.

S1: "Eh! And how do you know he had a hamburger and Coca Cola and not fried potatoes, toast, coffee, Coca Cola and hamburger, but not the hot dogs because he doesn't like them? If the problem doesn't tell you what he ate, how can you know?"

S2: "That's stupid! Anyway, if he mixes coffee and Coca Cola, he'd be sick."

S1: "Well, you might think that, but you don't know about Luis."

S2: "Well, let's say he had toast, coffee and fried potatoes."

S1: "And why not everything except what he doesn't like, that's the hot dogs? The problem doesn't tell us anything else."

S2. "Well, in that case then, we'll say that for breakfast he spent (she begins to put all the numerical data on the board and does the calculation aloud 85+100+75+125+175=560 pesetas) five hundred and sixty pesetas.

S1: "Alright?"

S2: Yes, though he could have had (she begins to say all the possible cases, including in each case two of the items on the menu) fried potatoes and coffee, or toast and coffee, or ..- anyway, whatever he pays depends on what he eats. Any solution is right."

S1: (Nods, but at the same time shows he doesn't agree with the various solutions suggested by his classmate.)

Description of actions referred to the solver student.

The student looks for a relationship between the conditions and the aim of the problem, her actions being governed by the aim. She implicitly recognizes that the problem is badly defined and reformulates it, justifying this by means of refutation and by applying external cognitive resources based on common sense ("social logic"). Then, following a period of checking-transition, she modifies her actions, and identifies the problem as well defined with many possible solutions, justifying this action through validation and using discursive resources, such as description[1].

Group 2: Student (D), Interviewer (I).

D: Reads out the problem but does not write any notes on the board, and says: "it depends on what he eats, because if he chooses toast and coffee from the menu he'll pay a hundred pesetas plus seventy-five pesetas which would be one hundred and seventy-five pesetas, but if you take into account that he probably likes other things for breakfast, those amounts would be added up."

I: In that case, what would in fact the solution to the problem be?"

D. "Well, I'd answer that it'd depend on what he ate."

I: "O.K. Do you think, then, that there is something missing in the problem or that there's too much information, or do you think the problem's well expressed?"

D: "Something's missing in the text, for example, 'The cafe menu reads: Hot dogs 100 pesetas, coffee 75 pesetas, fried potatoes 85 pesetas, Coca Cola 125 pesetas, toast 100 pesetas, and

[1] Verbal explanation, by means of identifying, explaining or projecting the features of the situation.

hamburger 175 pesetas. If Luis had so much money, what could he eat?' Alternatively, 'The cafe menu reads: Hot dogs 100 pesetas, coffee 75 pesetas, fried potatoes 85 pesetas, Coca Cola 125 pesetas, toast 100 pesetas, and hamburger 175 pesetas. If Luis likes to have this and that, how much will he pay for his breakfast? But, the way it's formulated, we can't answer, because you don't know what he's had nor what he likes to have for breakfast."

Description of actions

The student looks for a relationship between the conditions and the aim of the problem, her actions being governed by the aim. She explicitly recognizes that the problem is badly defined and transforms it. She justifies her actions through refutation and uses internal cognitive resources based on counter-examples[2].

Here we briefly summarize the solvers' behaviour when working with the rest of the problems.

4.2: Some farmers stored hay for 4 days, but as the hay was of better quality than they had thought, they saved 100 kg per day, so that they had hay for 6 days. They spent a total of 1,200 pesetas. How many kilograms of hay did they store?

Description of actions of the solver student of the Group 1 (G1).

The student does not look for a relationship between the conditions and the aim of the problem. His actions are governed by the conditions. At first, he sets about the problem as if it were well defined. This action is validated though the use of external cognitive resources of a ritual kind[3]. Later, following a period of checking-transition, he changes actions and transforms the problem, justifying his actions by an authoritative (belief) refutation[4].

Description of Group 2 (G2) actions

At first, she sets about the problem as if it were well defined, justifying her actions through validation and using external cognitive resources based on authority. Later, after a checking-transition period, she looks for a relationship between the conditions and the aim of the problem, her actions being governed by the aim. She recognizes that the problem is badly defined and transforms it. Her actions are justified through refutation, using internal cognitive resources such as contradiction.

A3: How far is the school from the park if to get from one place to another the 60-cm diameter wheel of a bicycle travels 62 metres and it takes 6 hours.

Description of actions of the solver student of the Group 1 (G1).

The student does not look for a relationship between the conditions and the aim of the problem. Her actions are governed by the conditions (the data). At first, she sets about the problem as if it were well defined. The action is validated through the use of external cognitive resources of a ritual kind. Later, following a period of checking-transition, she transforms the problem, justifying her actions by refutation and using external cognitive resources based on authority (belief).

Description of Group 2 (G2) actions

[2] She gives an example, taken from the same situation or from an analogous one, in order to justify the fact that the situation is badly defined or takes the same situation as an example.

[3] The subject tries to establish validity because of the way in which the situation is presented. The appearance rather than the coherence of the contents is more influential.

[4] The justification comes from a source that enjoys complete credibility: teacher, task (book), competent classmate, etc

At first, she sets about the problem as if it were well defined and she puts forward her validation arguments by using empirical internal cognitive resources[5]. Later, after a checking-transition period, she looks for a relationship between the conditions and the aim of the problem, her actions being governed by the aim. She recognizes that the problem is badly defined and transforms it. Her actions are justified through refutation and she uses internal cognitive resources, in this case a counter-example.

B1: A woman raises a goat and 3 rabbits for 52 weeks. She buys 760 grams of fodder for one week. If the animals eat all the fodder except for 128 grams, how much fodder was left over at the end of the week?

Description of actions of the solver student of the Group 1 (G1).

The student does not look for a relationship between the conditions and the aim of the problem. His actions are governed by the conditions. At first, he sets about the problem as if it were well defined, validating this through the use of cognitive resources of an authoritative kind. Later, following a period of checking-transition, he looks for a relationship between the conditions and the aim of the problem. He identifies the problem as a badly defined one, justifying his actions through refutation and using internal cognitive resources such as a counter-example.

Description of Group 2 (G2) actions

At first, she sets about the problem as if it were well defined. The action is validated through the use of external cognitive resources of an authoritative kind. Later, following a period of checking-transition, she looks for a relationship between the conditions and the aim of the problem, her actions being governed by the aim of the problem. Then, she recognizes that the problem is badly defined and transforms it. Her actions are justified by refutation and she uses internal cognitive resources, in this case a counter-example.

B2: In a farmyard there are hens and rabbits. If there is a total of 116 legs, how many hens and rabbits are there in the farmyard?

Description of actions of the solver student of the Group 1 (G1).

The student does not look for a relationship between the conditions and the aim of the problem. Her actions are governed by the conditions, and so she sets about the problem as if it were well defined. This action is justified by means of validation through the use of analytical internal cognitive resources[6].

Description of Group 2 (G2) actions

The student does not look for a relationship between the conditions and the aim of the problem, her actions being governed by the conditions (the data). At first, she sets about the problem as if it were well defined. These actions are validated by using empirical internal cognitive resources

B3: If the square in front of your house is rectangular and measures 90 in by 60 m, how far is it from your school to your house?

Description of actions of the solver student of the Group 1 (G1).

The student looks for a relationship between the conditions and the aim of the problem, her actions being governed by the aim of the problem. She recognizes that the problem is badly defined, justifying her actions through refutation and uses discursive resources such as

irony[7]. Later, following a period of checking-transition, she transforms the problem. These actions are justified through refutation, using internal cognitive resources such as the counter-example.

Description of Group 2 (G2) actions

The student looks for a relationship between the conditions and the aim of the problem, her actions being governed by the aim of the problem. She recognizes that the problem is badly defined and transforms it. These actions are justified through refutation, using discursive resources such as irony.

FINAL CONSIDERATIONS

- Regarding the solvers' behaviour, generally speaking, and except in the case of Group G2 when doing Problems A1 and B3, we can see two clearly differentiated semiotic states which we call initial and final, and in which the students use clearly differentiated validation or refutation justifications. These types of behaviour regarding the "Identification of the badly defined problem in terms of well or badly defined" and "how they justify their actions" in terms of validation or refutation, can be represented in the following scheme, which also enables us to see the paths the students follow:

- Certain difficulties arise when identifying problems in terms of badly defined, where the influence of the context is notable. So, when we analyze the final semiotic state, identification as well defined (option C in our Scheme) only occurs in the algebraic context (both groups of students identify Problem B2 as a well defined problem). In the initial semiotic state these problems are considered to be well defined by both groups in the three contexts studied (Problems A2, A3 and B 1), all of these being Type III problems.
- With respect to the paths followed by the students when working on the problems through the various semiotic spaces, we can see that it is in Type III problems where they go from one vertex to another in the Scheme; in other words, they modify their action plans following a checking-transition period (in the three Type III problems).
- With regard to whether the actions are governed by the aim or the conditions, we can see that:
  - When the actions are governed by the aim and not the conditions, the students recognize that the problem is badly defined as such (option A or B in Scheme); on the other hand, when the actions are governed by the conditions, the students identify badly defined problems as well defined (option C in the scheme).
  - With regard to context, differences can be seen. Actions governed by the conditions of the problem are always undertaken in the algebraic context. However, regarding the

7 She refutes the validity of the situation by implying the opposite of what she literally says. This is a type of indirect justification.

BEST COPY AVAILABLE

types of problems, there is a large degree of balance between Type II problems (lacking data) and Type III problems (too many data).

- When we analyze justifications by means of either validation or refutation, we note different types of argumentation which, initially, can be categorized and classified as in the following table

Resources / Justifications	Internal Cognitive	External Cognitive	Discursive
Validation	Empirical Analytical	Authority (beliefs) Ritual (attitude)	Description Comparison
Refutation	Counter-example Contradiction	Authority (beliefs) Social Logic	Irony Ridicule

Table 2

In both validation and refutation types justification we note a certain degree of balance between external and internal cognitive resources. There are fewer justifications in discursive terms.

Finally, we should point out that of resources used in our analysis becomes a theoretical instrument that relates and typifies the students' justifications when they work on badly defined problems at this "preparation stage".

or
HOW CAN THE STUDY OF MATHEMATICS IN WORK ADVANCE OUR UNDERSTANDING OF MATHEMATICAL MEANING-MAKING IN GENERAL?

Richard Noss, Celia Hoyles and Stefano Pozzi
Institute of Education, University of London

Our data involves a detailed study of the ways in which a group of paediatric nurses think about the notion of average and variation. We describe some continuities and discontinuities between mathematical and nursing epistemologies, and draw some general conclusions about the ways in which more general mathematical meanings are constructed.

Over the past few years, we have been studying the ways in which mathematical meanings are constructed and mobilised in a variety of workplace settings[1]. Our overarching objective is to try to understand in the most general terms, how individuals make mathematical sense: that is, to try to exploit the richness and complexity of mathematical activity *in situ* in order to analyse mathematical activity *per se*. Our method has been to focus attention on the kinds of problems professionals actually solve, in order to try to make visible a range of activities that can usefully be described as mathematical, in terms of their participation — at least at some level — in the manipulation and interpretation of quantitative and spatial data and relationships (see Noss et al., 1998; Pozzi et al., 1998).

As our research progressed, we became aware that it was possible to make a provisional epistemological classification of some of the activities we were observing, and that it made sense to analyse them in terms of what they represented from our mathematical point of view. This analysis could then be synthesised and compared with the practitioner viewpoint. In this paper, we report the outcome of one such mathematical classification, consisting of the interpretation of statistical data on the part of a group of paediatric nurses.

There are numerous findings which appear to illustrate how people's intuitions often seem to stand in the way of developing statistical notions. Shaughnessy (1992) provides a comprehensive overview of this research. With regard to the mean and other measures of central tendency, there appears to be an incompleteness in what people believe, a perceived lack of balance between computational and conceptual

[1] The workplaces studied involved investment bankers, airline pilots and (the subject of this paper) paediatric nurses. We acknowledge the support of the Economic and Social Research Council, UK, Grant No. RO22250004. The final report of the project *Towards a Mathematical Orientation* can be found at www.ioe.ac.uk/moss/tmo/.

understanding, and little understanding of why a mean should be calculated. As far as the understanding of variation is concerned, Shaughnessy notes that: 'people inappropriately believe there is no random variability in the "real world"' (p. 478). This is not only a problem for novices: for example, Batanero *et al* (1994) reported that a widespread misconception amongst university students was a deterministic conception of association; students do not admit exceptions to the existence of a relationship between variables and if they find any reject the idea that there is a relationship.

While providing a wealth of information, these studies can provide only a limited number of starting points for our research, as they fail to acknowledge the range of sense-making devices and strategies which people actually use in practice to describe, for example, randomness and variation. Neither do they identify important continuities with a view to understanding better how functional knowledge may be extended 'beyond its productive range of applications' (Smith, diSessa and Roschelle, 1993 p. 152).

It might be, of course, that there is a simple discontinuity between taught/school and intuitive/practical knowledge. Mokros and Russell (1995), in a study of fourth and eighth graders, concluded that some students 'were concerned with procedures, not with meaning. For them, average means a series of steps involving addition and division' (*ibid* p.35). The authors ascribe this procedural strategy to a failure of reification — and it is here that they locate the students' difficulties.

There is much in this argument that merits discussion, and we cannot do it justice here[2]. It does, at least, propose some rationale for students' misunderstandings. But if the reification hypothesis makes sense, we ought observe process-oriented strategies characterising everyday thinking about data, not just school students. In working situations, people mobilise all kinds of meanings for manipulating and making sense of data, and this ought to throw light on the construction of specifically mathematical meanings.

The Nursing Studies

The practice of nursing involves making sense of a wide range of quantitative information through the measurement, recording and interpretation of patient data.This clinical experience would suggest that nurses will have well-formed intuitions about a wide range of statistical ideas, although what these intuitions are and how they can be developed has not been researched in any depth. Moreover, analysis of texts and interviews with nurses suggest that only measurement and recording are regarded as obviously mathematical, while interpretation is mostly seen in terms of clinical knowledge alone. The question for research was this: what meanings do nurses construct as they interpret data within their day-to-day practice?

[2] A full version of this paper is in press by Pozzi, Hoyles and Noss

We gathered data on this issue in three ways: ethnographic observation on the ward, clinical interviews and questionnaires, and a short teaching experiment. We will outline our findings in an abbreviated and non-chronological form, in order to highlight the central issues, reserving detailed data for our presentation. We begin with an interesting insight from our teaching experiment.

The teaching experiment: We recruited for our teaching experiment 28 paediatric nurses who were enrolled on a research awareness course as part of their professional development. We aimed to explore the relationship between nurses' and 'mathematical' views of average and variation, in the context of teaching a range of statistical modelling ideas using data analysis software (we used *Tabletop*™)[3]. The teaching experiment involved a combination of computer-based hands-on work and whole-class presentations, during which different ways of analysing data were introduced, alongside discussion of the substantive nursing issues involved.

We asked the nurses to consider explicitly the relationship between age and blood pressure, and to write down or illustrate their hypotheses. Suppressing all details, a fascinating phenomenon occurred. While most quickly opted to present the data as a scattergram of blood pressure against age their reaction to this graph was as surprising as it was puzzling. Given their practical and theoretical knowledge regarding the relationship between BP and age, we believed that the group would be prone to a high degree of confirmation bias, i.e. finding a relationship of some description regardless of how it was represented on the computer. Instead, many found it difficult to see any relationship at all in the scattergram — and here was the surprise — decided there could be none after all.

It seemed clear that the nurses' judgements were influenced by three main factors. Firstly, the high variation in the blood pressure data was a hindrance to seeing any relationship and obscured the identification of any trend; i.e. variation and relationship were somehow antithetical. Secondly, the rise in the data, in as much as one could be seen, struck many as involving a slope too gentle to possibly indicate a relationship that was so important that it stood as an a priori assumption of nursing knowledge, i.e. important relationships should have impressive-looking gradients. Thirdly, the nurses *could* explain the variation on the basis of their practical knowledge. — i.e. they were able to reiterate substantive reasons for differences in blood pressure for particular age-groups (lifestyle, health and other physiological factors). Some of the extreme data points were of particular interest, not from the point of view of variation from a trend but because they indicated to the nurses that the data were unreliable. As one nurse put it, 'this patient should be dead!'.

These three factors together — in part predictable from the literature, in part more specific to nursing — meant that the nurses tended to focus on variation at the

[3] *The Tabletop*™ (TERC Inc.) is a database with an appealing graphical interface, which allows students to overcome unfamiliarity with the software quickly.

expense of the relationship. At this point, most of the nurses had reached an impasse, so we prompted them to model the data using the other tools available. Many split the data into age groups, finding the mean blood pressure for each group — a familiar number to all the nurses. This introduction of central tendency allowed many nurses, to our surprise, to reaffirm what they believed but had previously rejected: i.e. that BP did indeed increase with age! The use of the average enabled them to push the variation in the data into the background, as they took on board the increments in the means from the youngest age group to the oldest.

What was it that changed in the nurses' thinking which allowed them to reach this reconciliation? Of course the tools mediated the ways in which the data were conceived — to divide the data into quartiles, to calculate the means — clearly played significant roles. This tool-mediation served as an essential aid in clarifying how the nurses' views developed, and just how their practical knowledge of the average BP of an age group could be effectively mobilised. But to illuminate the puzzle further, we needed to look more closely at the ways in which statistical concepts were actually employed in practice by the nurses on the ward. Accordingly, we now turn to the ethnographic study and the insights we derived from analysing statistically-based ideas as they arose *in situ*.

The interviews and the ethnography: We reconstructed our ethnographic data into a set of episodes each describing a nursing-mathematics activity. While the episodes painted a broad picture of routine practice, we also identified and analysed a number of *breakdown* episodes, which involved a rupture in the normal routines. On these occasions, activities which were normally characterised by unproblematic, routine action were replaced by conflict, disagreement and doubt, which resulted in spontaneous explanations and considerably more articulated (and therefore explicit) reasoning and problem-solving strategies. Although these breakdowns were rare, they provided a rich source of information about participants' views and the knowledge they mobilised in order to substantiate them. Apart from providing insights as they occurred, we reconstructed these episodes and used them as a basis for clinical interviews with a subset of nurses.

One such episode involved the interpretation of blood pressure data plotted on a standard nursing chart. We asked the nurses to find the (deliberately vaguely stated) 'average' of a set of blood pressure data plotted on a BP chart. Only one nurse used the mean[4]. One mentioned it while adopting another strategy, while reference to either the median or mode was never explicit — although both were used implicitly. The nurses used a variety of strategies, almost all of which would be judged 'wrong' on the straightforward criteria of general mathematical correctness, e.g. *'I looked at the chart and judged which was the middle range'* or *'At a glance, all the systolic pressures are on or around 110 mm Hg'*. But they made perfect sense and were

[4] To use any standard calculational technique would have been quite difficult, given the way the data were displayed.

correct as estimates of the child's blood pressure — a kind of everyday average. The graph presented the nurses with a familiar situation in which the *sense* of average was unambiguous, and for which the idea of *representativeness* posed no difficulty because of the naturally symmetrical distribution of hourly BP readings.

In order to make sense of the nurses' strategies, we need to give a more detailed account of the practice underlying them, derived from our ethnographic observations on the wards. When a nurse takes charge of a patient, she immediately establishes his or her *individual baseline*. For example, nurses will attempt to answer questions such as 'what is this patient's normal, stable blood pressure?' This means that nurses have a tendency to take less account of the *whole* body of data when looking at average, and instead focus on clusters of data around the same value — especially if they think the patient was stable or settled around the time of these readings. As all patients have their own individual physiology, their profile of vital signs when they are stable is in some sense unique to them. Establishing a patient's normal profile of vital signs thus enables a nurse to judge when data deviate from the normal. A further feature of this process is that nurses develop an awareness of non-critical factors that lead to unusual readings (e.g. instrument error, patient over-activity) in order to distinguish them from significant changes in the patient's condition.

The notion of an individual baseline is not the only organising idea in nurses' judgements of average, since they must also take account of population norms. As we have reported, nurses 'know' that blood pressure is related to age, and can usually spontaneously quote a number for the average BP for a given age. But we found that nurses will only use it when it makes sense in terms of clinical practice. For example, the nurses were sceptical of the meaning of an overall population average for a young child and some refused to acknowledge that it existed! Thus the variability of the measures meant there was no average — something which makes no sense mathematically but which makes sense for the nurses.

On one level, these are completely understandable responses. The average blood pressure *for an individual child* obviously depends on whether the child was premature, its size and so on. Yet these kinds of considerations are, of course, included in the notion of average — indeed, it is the variability in population data which makes the statistic necessary. Nurses have difficulties because of their work of considering an average *independently* of the individual as it is the *individual* who is the focus of her care. The fact that 'average' necessarily masks individuality — like any statistic — is therefore seen as problematic. For a nurse, it is the variation that is crucial, and she is prepared to accept the notion of average provided it is individually mediated.

Discussion

We begin with a straightforward assertion: no description of the nurses' view of average and variation is adequately characterised in terms of misconceptions of the official, mathematical definitions. The nurses' meanings were different from the

mathematician's, interwoven with meanings from their practice, and efficient and effective at work.

Nor does it make sense to describe the nurses' strategies as, for example, failing to have reified the notion of average. On the contrary, if reification means anything, it means that an individual has made sufficiently strong links between elements of a concept to ensure its functionality: and as we have seen, this certainly applied to the nurses' notion of average.

What, then, is the status of the nurses' knowledge? The notion of nursing average was, as we have seen, on the one hand a description of the normal state of a patient over time, and on the other, a data point for a population — a measure of location unrelated to variability. In relation to the first aspect, the average provides a baseline — for example, an individual's blood pressure when it is stable. Here the nursing average works like a mathematical average so it can be seen as another example of what we have termed a situated abstraction (Noss and Hoyles, 1996). It is well articulated and abstract, but abstracted within rather than away from the nursing setting. It retains crucial elements of the setting in the way it is conceptualised which define the limits of its general applicability. But as with a mathematical average, the nursing average is indeed representative of the data as a whole and is recognised as such by nurses, because of the small variability in the data and the approximately symmetrical distribution. Additionally, in this context, outliers really must be explained — as physical 'extraneous variables' or functions of a medical condition.

The population view of an average differs considerably. Contrasting data on an individual with the population from which the individual is drawn is a complex issue from a mathematical perspective. Yet our research showed that the readings taken by nurses, or data which are interpreted by them, take account of population norms in ways which are finely tuned to nursing practice.

When nurses are acting in their familiar situations of monitoring blood pressure over time, they coordinate these different meanings of average to produce functionality. They use the notion of average to reason about their patients' condition, to relate the state of their patient to others in a virtual and deliberately ill-defined population (e.g. an overweight nearly 7 year-old), to communicate information to each other and to doctors, and to make rounded judgements concerning what action to take. Thus, significant background factors in blood pressure readings (e.g. age, sex, obesity, smoking) have to be taken into account by nurses when they interpret daily BP readings, and consider the condition and treatment of patients. Variation *has* to be explained. Not surprisingly, this practice spilled over into the nurses' answers in the questionnaire for the average blood pressure of a particular age group.

How do these insights of 'statistics on the ward' help us understand the nurses' responses in the teaching experiment? Recall that they wanted to explain away variation and found variation and relationship antithetical, while we wanted to introduce them to a fundamental principle of statistical modelling: that data is made

up of an explanatory model and random or unexplained variation around this model. On first reading of the nurses' responses, it seemed that their 'intuitions' were falling foul of this important statistical principle, and were based on a deterministic conception of association. Like the university students in the study by Batanero *et al* (1994), it appeared that they were using the many exceptions (or variations) to the blood pressure-age relationship to reject the idea that there was a relationship at all. Or, to restate the problem in the terms used by Rubin and Rosebery (1990), there seemed to be a confusion between the variables in the model and extraneous variables, which meant that presence of the latter made conclusions about any relationships in the model less possible.

Yet our study indicates that the roots of the responses might be rather different: the 'transfer' of the successful strategies of dealing with data over time on the ward to the consideration of population datasets — which then had to be debugged. We use the word 'transfer' with due caution, as we are well aware of the pitfalls. Yet it seems that something like transfer is involved here. If the nurses' appreciation of average is situated — i.e. ward practice dictates that explanation is required for significant variation, while smooth plateaux in data suggest normality and stability and require no explanation — then we may well ask how this can connect with other 'situations', and in particular, mathematics, where the situation is more or less reversed.

In Noss and Hoyles (1996), we outline the idea of webbing, as a notion with which to make sense of the ways in which people connect together pieces of their conceptual and physical world to create understandings. The crucial idea is that individuals' sense of situation and the tools they have to hand, provides support for making meaning, and also the means for reconstructing these pieces in new ways (or developing new knowledge pieces).

We do not want to rehearse our earlier arguments, but rather propose that our current findings throw some light on the cul-de-sac in which the situated cognition perspective seems to leave mathematics. The point is that the nurses *had* made the idea of average an object, defined in relation to their connection with other objects, and their functionality within the cultural domain in which they are used. What we see in the teaching experiment is how the mathematical domain could be brought into contact with the nursing domain, and how different tools (in our case, including the technological tools of a particular database program) could catalyse this contact, by exploiting the fact that the nurses could make sense of the new (mathematical) world by using the one tool which they used in their day-to-day practice — the mean blood pressure for an age group. It was this notion that helped them to see the trend in the variability and recapture what they knew of a relationship between age and blood pressure.

Mathematical objects are defined in relation to other objects, typically other mathematical objects. For the learner or practitioner, there is not necessarily any privileged status for these objects — and as we have seen, in nursing epistemology,

the privileged elements of mathematical epistemology simply do not make sense compared with the notion of nursing average.

THE RESEARCH OF IDEAS OF PROBABILITY IN THE ELEMENTARY LEVEL OF EDUCATION

Ana-María Ojeda S.
Cinvestav del IPN, México; University of Nottingham, U.K.

Abstract. *Ideas of probability have been investigated in Mexican elementary education. Two examples are given to illustrate the way in which epistemological aspects are considered in this research. Teaching experiments with 6-7 year old children suggest that pupils' interpretations of the tasks they were asked about may result in answers which do not inform on their idea of chance, since they tend not to focus on it. Additionally, by using questionnaires and clinical interviews with 10-15 year old children, it was found that correct performance in arithmetic does not assure that they can cope with questions about probability for which a quantification is required.*

Introduction

A research project interested in students' understanding of fundamental ideas of probability in the Mexican system of education has been carried out for five years. The project, which ranges over all the educational levels, considers epistemological, psychological and social aspects of the ideas of stochastics, in order to give an account of problems arising either from the teaching or learning of these ideas, as well as of their possible answers. The work we present here concerns only with the epistemological aspect, from the ontogenetical point of view, for the elementary mathematical education (primary and secondary school).

In this respect, one of the issues we have been investigating is the suitability of ways in which the ideas of probability have been introduced, nowadays apparently everywhere, in the educational elementary level. More specifically, we claim that the lack of consideration of factors influencing children's interpretation of the tasks proposed to them when ideas of probability are involved may mislead proposals for the curriculum of probability. We exemplify this with two of the studies which our project has undertaken; one concerns with the absence of the idea of chance in the Mexican syllabuses for the 6-7 year old pupils (Gurrola, 1998). The second study considers the role of arithmetic concepts in 10-15 year old pupils' understanding of probability (Perrusquía, 1998).

The problem and theoretical considerations

The delay of educational research in stochastics with respect to that research in other ideas of mathematics has led to call on results from this latter and from research on developmental psychology about the idea of chance (Piaget & Inhelder, 1975), for probability to be included in the mathematics curriculum. However, these views leave aside some aspects about children's interpretations of random situations, which seem to be important for the process of teaching.

Among the consequences of this, there is that probability is not considered in Mexico for kindergarten (5 year old children) nor for the first two grades of primary school, because after Piaget's model for the development of intelligence, children are uncapable to understand chance at stages previous to the stage of concrete operations (from 7 or 8 years of age). However, research in education with younger children (Falk *et al.*, 1980) suggests that the idea of probability can be introduced even for kindergarten pupils. On the other hand, children's performances when using other mathematical concepts to answer questions about probability, such as rational number, may not reflect their understanding of random situations, as probability demands a way of thinking that differs from the one used to face deterministic situations (Fischbein, 1975). Hence, Garfield and Ahlgren's allusion to the deficiencies in handling fractions as one of the difficulties for children to understand probability (1988) may result in delays for the introduction of probability or in waste of ways to profit on children's potential to approach this idea.

We are concerned here with the problem of characterizing children's understanding of the ideas of chance and probability specifically for educational purposes. More precisely, we are interested in having information from children's idea of chance and with what their quantifying of probability may reveal for considering their teaching in elementary education.

The problem has been investigated by referring to models of thinking proposed by other researchers. In particular, we refer to the origin of the idea of chance in children after Piaget & Inhelder's work for the study with young children without

instruction in probability. The study on the quantification of probability with older children was framed in Kieren's proposition of constructs for rational number (1988), in particular the constructs in the basic stage.

The studies and the methods used

The methods used in our research appeal to the aim pursued for education. Consequently, after having general data from the children who participated in our studies, interviews in depth with selected pupils took place.

The idea of chance in young children. Gurrola (1998) sought information about the convenience of introducing the idea of chance for 6-7 year old primary children. Accordingly, six children of this school age were asked about ideas of probability within a teaching experiment protocol (Glasersfeld, 1983). When using this method, a clinical interview is prolonged until evidence is obtained from the interviewed child making clear his/her understanding of the situation he/she is asked about.

A device was used to question children about random mixture similar to the one Piaget and Inhelder used (1975). It consisted of a rectangular tray which can be made to swing up and down by means of a fulcrum fixed at its base. Twelve equally sized marbles, six white and six green, can be arranged on both sides of a divider that the tray has at the middle of one of its sides, before letting them free by balancing the tray (see Figure 1), what we did with no intention for the marbles to mix to the least extent from each seesaw movement, as Piaget and Inhelder did. According to these authors, children of the age considered here do not anticipate the irreversibility involved in random mixture; instead, they try to find any kind of order on the grounds of common properties of the elements or of their original arrangement. As a result, they are not able to start understanding what chance is.

Nevertheless, among the six children we interviewed, four foresaw the mixture of the marbles when balancing the tray, that is, a different position from the one they had originally; the other two children proposed the marbles arriving at the same position they had at the start, but finished the teaching experiment stating that

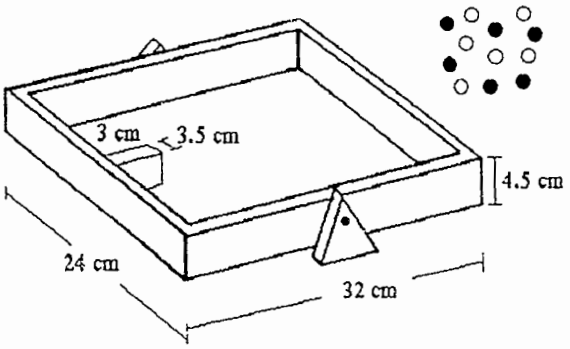

Figure 1

different positions should be expected. They realised that, as a consequence of the balancing of the tray, collisions between the marbles may well take place. Additionally, during the questioning, it arose that when interpreting the whole activity, some children may not focus on chance, but rather on trying to overcome it. That is, they may interpret the situation as a task to control the movement of the tray so to obtain, after each swinging, the marbles arranged as originally. This was the case of Almendra (7 years, 9 months).

In the first arrangement, the twelve marbles were shown to the girl separated by colour at both sides of the divider (in the following transcripts, *E* stands for interviewer, *A* for Almendra):

E *What do you think is going to happen if we balance the tray like this?*
A *One* [marble] *can go here, another here and another here* [she describes lines towards the opposite side of the tray but in the same direction]. *But without crossing here* [as she points to the middle of the tray extending an imaginary line stemming from the divider]: *these are green and these are white.*

After one movement of the tray, the girl sees that some marbles have changed their position. Before each of the subsequent trials, she arranged the marbles as they were presented to her at first. Apparently, she does not conceive the irreversibility of the mixture, but she states she does not know how to prevent the changing of the places between the marbles, and continues referring to the role of the divider:

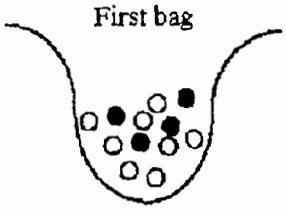
A *This is meant to keep them* [the marbles] *at their place.*

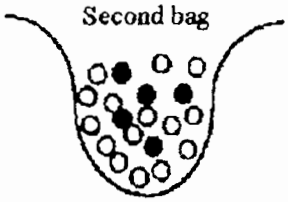
Therefore, the divider was removed from the tray and the device was presented to her again showing the marbles mixed, i.e. not obviously arranged by colour (p. 99):

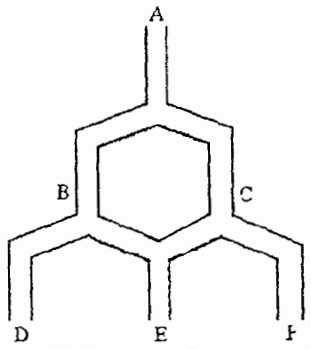
E *Do you think the greens will go back to their place and the whites to theirs?*
A *No.*
E *No? Why?*
A *Because the movement makes them change their places.*

She even realises that the collisions between the marbles contribute to the mixture.

The teaching experiment cases examined in Gurrola's research suggest that, in fact, young children could be faced with the idea of chance by posing to them appropriate situations and questions, so they could focus on features of that idea, such as variation in the occurrence of results and the possibility of different arrangements.







Arithmetical and probabilistic thinking. In order to analyse what children's use of numbers may reveal about their understanding of probability, Perrusquía (1998) aimed at obtaining information from 10-15 year old pupils (5^{th} and 6^{th} grades of primary school, 1^{st} and 2^{nd} grades of secondary school) when they assign fractional numbers to the likelihood of an event. After Kieren's work (1988), understanding rational numbers is shown when these numbers are used according to the different interpretations for which they are meant.

This qualitative oriented study had two phases. The first one consisted of a general inquiry involving 145 pupils who answered a questionnaire. The second phase was carried out with eight children chosen from the sample in the first phase.

The questionnaire used in the first phase was designed in an arithmetic version and in a probabilistic version, each of which included ten problems, two for each of the five basic interpretations of rational number (part-whole, measure, quotient, operator and ratio (Kieren, 1988)). The questions posed in the probabilistic version referred to the same situations posed in the arithmetic version but now involving chance and to number assignation to the outcome given in the answer. These questions required the child to identify events, to express the probability of events from a partition of the sample space, independent events, and to decide which of two random situations offered higher probability for a given event. Examples of the questions posed are shown in Table 1.

Pupils answered the arithmetic version of the questionnaire a week before they dealt with the probabilistic version.

Table I. Examples of questions posed in the two versions of the questionnaire.

Arithmetic version		Probability version
9. Some marbles are contained in two bags: in the first, there are twelve, eight are white and four are black. In the second bag, there are twenty marbles, fifteen are white and five are black. *What fraction of marbles in each bag are black?* _____ *Which bag has the biggest fraction of black marbles?* _____	(Ratio construct) First bag  Second bag 	*9. Some marbles are contained in two bags: in the first, there are twelve, eight are white and four are black. In the second bag, there are twenty marbles, fifteen are white and five are black.* *Without seeing, I want to draw a black marble. What bag should be chosen?* _____ *According to the bag you chose, what is the fraction of black marbles for that bag?*
10. Balls are let free in this maze. If one hundred and twenty are introduced at A, what fraction of the whole lot would come out through each of the exits D, E and F? *D* _____ *E* _____ *F* _____	(Operator construct) 	10. *Balls are let free in this maze. If one hundred and twenty are introduced at A, what exit, D, E or F do you think more balls will come out?* _____ *What fraction of the whole lot of balls do you think will come out through the exit you chose?* _____

The youngest pupils (27 children in the 5th grade of primary school) obtained the lowest rate of incorrect answers in the probability version (85%) of the ratio construct questions (the most abstract of the constructs we considered). For each of the school grades considered here, there was at least one pupil showing poor performance in fractions and a good performance in probability questions (e.g. Alberto, aged 10, 6.2% and 70.5%, respectively).

For the second phase of this research, the highest rates of correct answers were taken as the reference to choose two pupils from each school grade: one having the highest score in the arithmetic version of the questionnaire (four in all), the other in the probabilistic version (four in all). These eight subjects were interviewed using a protocol of semi-structured questions based on their answers given to the

probabilistic version.

According to the results, the children from the arithmetic group gave answers in the interview without referring to chance. Although their handling of fractions was correct, they showed a deterministic or linear approach to the questions posed. On the other hand, the pupils of the probability group accepted or even proposed the variation in the occurrence of possible events; they did not refer to a pattern to explain the probability they assigned to events. Only the oldest of these pupils (2^{nd} secondary grade) considered equiprobability. As an instance, we present some transcripts for question 10 (in Table 1):

Question 10. Probability group (pp. 127-128)

E *If we get 60 balls in A, which exit is more likely to have more balls come out?*
G *Twenty or thirty?*
E *60.*
G *Then there would be 30* [pointing at D], *saying twenty* [pointing at F] *and 10* [pointing at E]; *or thirty here* [D], *twenty this side* [F] *and ten here* [E]. *It could vary a lot.*

Question 10. Arithmetic group (p. 198)

E *If we get 60 balls in A, what exit is more likely to have more balls coming out?*
An *E*
E *What part of the sixty* [will go out through E]*?*
An *Thirty over sixty* [she writes "E 30/60"].
E *What part of the sixty will be out through the less likely exits?*
An [She writes "D 15/60" and "F 15/60"].

The pupils of the probability group did not show a consistent performance in the arithmetic version. However, in the probability version, three of these four children answered correctly the questions requiring the ratio construct (for instance, question 9 in Table 1):

Question 9. Probability group (pp. 172-173)

E *From what bag is it less likely to draw a black marble?*
D *Black .. from the second ... Cause .. in the first there are four and in the second five; then it increases but also there are fifteen whites in the second, and in the first there are eight; that difference of seven whites reduces chance.*

Question 9. Arithmetic group (pp. 200-201)

E *Let's consider two bags, the first having 6 whites and 12 blacks, and the second one white and 5 blacks. From what bag is it more likely to draw a black marble from?*
An *The first .. Because there are more blacks.*

E *.....If the first has 5 whites and 3 blacks , and the second three whites and 1 black?*
An *The first one ... Because there are more whites.*

The 'probability' pupils interpreted the random situations from a frequential approach more often than the children from the arithmetic group, or quantified by means of percentages.

Remarks

The results obtained suggest the convenience of introducing didactical activities for teaching probability at elementary education by giving priority to a frequential focus as a natural approach pupils have to chance. Preferences and interpretations young children make of the tasks proposed when these involve chance should not be neglected as the aim pursued may not be attained. However, an inquiry in depth is required to know about the results of children's understanding of random situations when the idea of chance is introduced into the classroom environment by means of a didactical activity. Finally, the fact that different basic interpretations of fractions can be required when facing questions about probability, offer an opportunity for the child to give sense to the use of these numbers by focusing on the study of chance.

An Analysis of Individual Students' Views of Mathematics and its Uses: the Influence of Academic Teaching and Other Social Contexts

Tasos Patronis (Department of Mathematics, University of Patras, Greece)

This paper presents, analyses, interprets three long interviews with Greek students of mathematics and physics, as case studies of individual students' views of mathematics and its uses in various social contexts, with an attempt to investigate the influence of these contexts and in particular the influence of academic teaching on students thought and perspectives. As a framework of analysis of students' views, the interrelation is considered between the notions of a context representation and of a scenario, which leads to a classification of the views presented into the following scenarios: i) a scenario of «passiveness», in which the individual does not essentially act of all; ii) a scenario of «self-objectivization» in which the involvement of the self as a subject of reflection is ignored; and iii) a scenario of social construction of mathematical meaning.

Questions about the nature and applicability of mathematics are rarely discussed in school or in university courses. Students' perceptions of such questions may be considered as an important component of their beliefs about mathematics and science in general, and it is well known that such beliefs affect students' decisions and their mathematical performance as well (see e.g. Garofalo and Lester, 1985; Borasi, 1990).

In accordance with Paul Cobb's remarks on the close relationship between *contexts, goals and beliefs* in learning mathematics (Cobb, 1986), the question here arises, to what extent the students' epistemic views of mathematics and its uses depend: a) on the context of teaching in academic institutions and related ideology; and b) on broader contexts related to various social problems and to the overall goals and intentions of the individuals themselves.

The research of Ruthven and Coe (1994) had more or less similar aims to the present one In that research a structured questionnaire was used, which made it possible (with the help of factorial analysis) to derive a classification of students' beliefs between certain central factors. However, as the authors themselves say, (their findings suggest that) «there is no simple systematic relationship between beliefs about the nature of mathematical knowledge and activity and about the teaching and learning of mathematics». This suggests that qualitative methods are necessary (in addition to quantitative ones), for investigations in the sociology and/or social psychology of mathematics education, in order that individual students' views are explored and analyzed in some more depth

LOCATION, METHOD AND OBJECTIVE OF THE RESEARCH

A research with long and minimally structured, but taped interviews has been carried out, in Patras University, of which three individual cases will be presented here.

The compulsory core of content in the Mathematics Department of Patras University consists of 16 courses, 10 of which are traditional courses in Pure Mathematics (Algebra, Analysis and Geometry). These courses, as well as some «advanced» optional courses such as e.g Topology, Measure Theory and Functional Analysis, begin by a set of axioms and abstract definitions The so-called «axiomatic foundation» of real numbers gives students a

good taste of formalism from the very beginning of their studies. The situation in the Physics Department is similar in what concerns the teaching of mathematics and mathematical physics.

There are two interviews with students of mathematics and one with a student of physics. These subjects need not be considered as representative of any students' population, but simply as interesting cases of students with particular views and perspectives. It had been decided from the beginning that the research would be restricted to female subjects of about the same age (22-24 years) in order to have some uniformity and facilitate comparative analysis of the responses.

The main objective of these interviews was to perceive in what extent formal teaching in academic institutions as the above departments has an influence on the formation of students' views. Another related objective was to investigate the influence of other (non-institutional) social contexts. Thus, although discussion varied in each individual case, there was a focus in all interviews on two main questions:

- *Do you think that mathematical relations and operations express anything about the real world?*
- *Do you believe that mathematics should be used in building models for social needs?*

In addition, each student was asked about her total experience with mathematics during the school and university period, and about her future plans. In this way supplementary data was collected, which was necessary for putting the subjects' views in a broader perspective in connection to their overall interests.

THE SUBJECTS' STORIES

The method of presentation followed here is similar to that of Byrd (1982), who investigated some deep reasons for students' difficulty with mathematics. In order to understand better the views and representations of the subjects on such «charged» and subjective matters we need first to write in short a «story» for each individual case

The subjects' names used below are not the real ones.

1. *Hypatia*, graduate of mathematics

Hypatia had graduated just before the interview. Hypatia's story is typical of many young people in Greece who come to study mathematics. Her father had not finished the primary school, and yet he was able to solve practical arithmetical problems that were difficult for her when she was a primary school pupil. Later she used equations in order to solve such problems, while it was always difficult for her to follow her father's way of thinking When Hypatia entered the secondary school, she asked for a private tutor in mathematics, as she was not feeling «safe», because her parents were not able to help her With her tutor's help she found school mathematics very easy.

Mathematics taught at the University has «enlarged» Hypatia's views and improved her «inner life». She believes that «freedom in thinking» is possible only in mathematics, which permits the scientist to «create new entities» and find new solutions to problems. But her possibilities for a job are now reduced to private tutoring, since most graduates of

mathematics remain unemployed in Greece. Hypatia is afraid that she could «humiliate» mathematics by connecting it with earning money.

Concerning mathematical relations and operations Hypatia thinks that these may not have a *direct* connection with reality:

> There are many mathematical operations, relations and formulas that directly express reality - and this can be perceived at a first glance. But there are other notions, as for example the negative numbers, which we cannot immediately say «express» something real, although we can think of sense (orientation) as a kind of physical reality expressed by those numbers.

Concerning model building for social needs, Hypatia wonders whether mathematics could help people eliminate classes and bring equality and justice in human society, but the idea of *using* mathematics seems to bother her. Mathematics is not an instrument for a rational organization of society; «rationalism exists within mathematics itself». When she was asked if mathematics would necessarily be useful just because of its rational character, Hypatia reflected a little. «It depends», she said, «on the way it is used; it may be good for society or it may not». In human society there is, according to Hypatia, a coexisting of the *rational* and the *irrational*, which makes doubtful the successful application of mathematical models. Perhaps, the «harmony» existing in mathematics should make possible a «harmonic solution» of social problems without conflict. But it is *in the philosophy of mathematics, not in its logistic or technical part*, that one must search for this spirit; thus «the vulgar, uncultivated men of power», who use mathematical techniques and calculations in their business, have nothing to do with true mathematics, since calculations and techniques «do not represent the nature of mathematics».

But how is it possible that a mathematical model, which is a rational and «harmonic» construction, lead sometimes to absurd conclusions when applied to human beings? Hypatia reflected on this question and after a while replied that

> ...there are unpredictable factors which are very serious, because when we try to comprise many things in large categories, some special cases escape, so that we lose them in generality - especially when we refer to mean values. For example, by using the normal distribution we miss all special interesting cases which are hidden at the extreme parts of the curve. This happens in particular in intelligence tests and in the evaluation of students' performance.

2. *Sophia*, final year student of mathematics

Sophia is the daughter of a shop keeper. Her experiences with mathematics in the primary school were «rather superficial, as is the case with a lot of children». However, the knowledge and abilities she developed in this «mechanistic way», as she said, were useful in her subsequent career and gave her a feeling of confidence. During the Gymnasium (lower secondary school from 13 to 15 years) she decided to be a «good pupil», and her mathematics teachers gave her a kind of psychological support

At the moment of the interview Sophia considers mathematics in a totally different way. She tries «to get deeper» into everything she reads, and «to grasp the meaning, the applications and connections with reality»

> I try to analyze everything But sometimes I am not satisfied with my explanations For example, when I make the correspondence of real

numbers to concrete things, I wonder if this correspondence could be avoided. It is necessary to speak of all these things?

She explains the meaning of numbers and their operations on the basis of human communication.

When we say to someone «yesterday I saw five men...», this expression gives him an image of what we have in our mind.

She says that in the case of number we have an immediate connection with the real world, while in other cases we have an «internal» act of generalization, which seeks to integrate many things to one in our mind. She mentions as an example of this kind of mathematical abstraction the *addition of equivalence classes*, but she does not seem able to produce a relevant example of such an algebraic construction (as for instance is the case of addition of vectors in the plane). Sophia concludes that the purpose of mathematical science is...

to enlarge our view, to reduce the situation to a more general level, at which all things can be examined in a unique way and under a general point of view.

Concerning mathematical models in social contexts Sophia says:

First, we could construct classes... not because I see it like a purely mathematical abstraction, but because one of the functions of human mind is to classify objects in certain categories; for instance the term «man» comprises certain beings with some known properties. When we have to deal with different things, e.g. a man, an animal, a chair etc., then we use another word to express all these things together; we may say «I have these things» or «I have these living organisms» (speaking of men and animals). What I mean by this is that we always have to do with classes of things Thus mathematics interprets and analyses the way in which our mind functions.

Moreover,

Generally speaking, the whole world can be considered as a set of classes Even if primarily we have distinction and differentiation, we always can find similarities between different objects

3. *Vangelio*, final year student of physics

Vangelio's parents were farmers, who had emigrated for some years to Germany She went to a rural school but she chose her field of study very early. Possibly the main reason for this was her teacher of physics, from whom she says that she also learned mathematics

She did not like practical arithmetic in primary school and she never memorized rules for solving problems; she always wanted to understand the task by herself. She never had a private tutor and disliked tricky and senseless exercises. When she entered the secondary school she had difficulties with equations and functions in mathematics courses, because she could not grasp the meaning of these notions from the irrelevant examples of the textbook and she refused to memorize rules and algorithms that she could not understand. Later, at the age of 15-16 years, she learned to solve equations of the first degree in the context of problems of physics

> I learned from my teacher of physics how to solve equations very simply. I met these things in practical problems about velocity, time etc. Given two quantities how to find a third. I learned to solve first degree equations at the first class of the Lyceum (tenth grade).

Vangelio said that she liked much to read literature, especially novels «with a social perspective». In general she liked to learn, she was curious about scientific questions (especially in physics).

All this changed when Vangelio entered the university. The physics courses seemed senseless to her.

> I come to the first lesson of mechanics and I see only formulas. Derivatives here and there - while we hadn't comprehended the notion of a derivative in the Calculus. I couldn't understand the physical meaning of all these formulas. I left the classroom and I didn't come again.

Vangelio earns her living by private tutoring (like many graduates and final year students of physics and mathematics in Greece). Mathematics is not so interesting for her any more. Here is, also, her impression of mathematical research:

> (In mathematics) one finds some hole and digs in depth. I am not interested in this, I like to have a global image of things.

Vangelio thinks that the relation of mathematics to the real world is not immediate, but is made apparent by the study of natural sciences.

> When we look at the real world we don't immediately think of mathematical formulas with *x.y.* etc. But.. by studying mathematics, physics and other sciences like that, for a long time, one sees that the real world is indeed expressed in mathematical quantities... Sometimes I think of a mathematical relation in connection with real things, as e.g. in the case of the relation $s = v.t$ between velocity, time and distance in uniform motion; this happens in all such cases when simple notions are connected together by definitions.

A concept such as that of *limit* (which is needed for a rigorous definition of velocity)...

> is a human abstraction which corresponds to a real situation. I don't know whether this concept is «physics» by itself, but surely it *corresponds* to that situation. It is like two sets of which is mapped into the other.

Vangelio finds that it is not truly possible to predict human reactions by using a mathematical model, because there are too many parameters that may affect the result in a «chaotic» way. The same stimuli do not produce the same responses, she says, this depends on many other factors. But even if it was possible to predict human behavior by some special mathematical model, Vangelio should not accept such a perspective.

> It is terrible, it is fascism, to predict systematically human behavior by a mathematical model. It is disgusting. I don't agree at any point with such a trend of mathematization. Because, first, this trend is not at all accidental; (these models) are finally used for some people's benefit. If these models could be really applied, then a man of power would be able, by using them, to build the worst dictatorship, the worst totalitarian state against other people

ANALYSIS AND INTERPRETATION

Context Representations and Scenarios

In this section a theoretical framework is introduced for the analysis and interpretation of the subjects' responses. This framework relates the idea of *context representation* to that of a *scenario*, which was introduced by Peacocke (1989) for the case of representation of a subject's perceptions and primary experiences.

As Evans (1994) says, «a full conception of the *context* needs to take account of the relations of power exercised (...) and the material and institutional resources» However, it is not possible, in our case, to analyze these relations and institutional resources without taking account of the individuals' own goals and perspectives, as these are influenced, regulated or prevented by the context. Thus we are led to introduce the idea of a «scenario» as dual, in some sense, to that of a «context representation». A *scenario* is a potential sequence of mental actions, which in general are viewed as permissible within a given context, according to a particular representation of this context. Conversely, a new *representation* of a given context may emerge through the mental actions of a scenario within this context. It should be emphasized that a scenario is a *potential* sequence of actions, so that two (or more) scenarios are possible of the same person acting within the same context.

A Scenario of «Passiveness»

Hypatia's view can be analyzed and interpreted in terms of the interrelation between scenarios and context representations. The individual stays in a continuous conflict under the influences of two contexts, which here are the context of teaching of pure mathematics in academic institutions, on the one hand, and the context of everyday life and practical needs, on the other. From the moment that Hypatia graduates and must earn her living, she is forced to solve the conflict in favour of the practical part. The only permissible scenario then is to leave the things as they are in both contexts and let everything be done without involving oneself at all. Such a decision can be justified by considering one of the contexts as «sacred» and the other as «evil» and refusing to «humiliate» the «sacred» one by «using» it for the purposes of the «evil».

In what concerns mathematical abstraction and generalization as a process *within* the context of academic institutions, *Sophia* also develops a «passive» scenario Her representation of this context is similar to that of Hypatia, although her approach seems to be a little more «formal». But when Sophia says that the purpose of mathematics is «... to reduce the situation to a more general level, at which all things can be examined in a unique way and under a general point of view», she does not seem to understand the inner mathematical needs for such a generalization.

A Scenario of «Self-Objectivization»

I borrow the notion of «self-objectivization» from Habermas (1976) The community of researchers and students of a reductionist science cannot perceive itself as the subject of communicative action

Sophia's view differs from that the *Hypatia* in two main aspects: First, although Sophia partly enters into a «passive» scenario, she does not identify mathematics with «freedom in thinking», as Hypatia does, but she reduces it to the act of generalization. Second, Sophia is much more specific than Hypatia is discussing the current meaning of numbers in everyday life, when she explains this meaning on the basis of «human communication».

By reducing the world to a set of classes and by identifying mathematical activity as generalization and classification of objects, which is «one of the functions of human mind», Sophia cannot perceive herself and other persons as acting within a social context.

Sophia does not separate mathematics from human and social reality. Mathematics can shape reality, but its function is like that of a «black box». She thinks of applying mathematics in this context by using *classes* for the description of similar things, and she considers the acts of classification, categorization and identification as natural functions of the human mind, thus objectivizing these acts in a similar way to that of early materialist (reductionist) philosophy.

A Scenario of Social Construction of Mathematical Meaning

In the last scenario which will be discussed in this paper, *Vangelio* operates in a reflective and constructive way on mathematics taught at school (and partly at the university). She consciously rejects formalism as a style of presentation and searches for the physical meaning of mathematics taught. The general education and social experience of Vangelio are part of her scenario.

Mathematical concepts are considered as «rooted» in a kind of physical «ground». For example, the meaning of the concept of *limit* in calculus is constructed by the human mind on the ground of the physics of motion and corresponds to *velocity*. While every mathematical concept is understood in this way (i.e. by a projection into a physical or social context or domain), the converse is not true, since not all of physical and social reality can or should be interpreted mathematically.

Compared with the previous scenarios, Vangelio's scenario is a non-passive and a non-reductionist one. Contrary to idealism, for which mathematics is exploring a reality limited into the mental sphere, this scenario develops an understanding of mathematical concepts outside the sphere of ideal mathematical abstractions. Furthermore there is a rupture with some prevailing context representations such as objectivization of mathematical activity and rationalization of human society according to science and mathematics.

CONCLUDING REMARKS

The present study shows that some students are exposed to a strong influence of the context of academic teaching of (pure) mathematics, while at the same time there is a lack of deeper understanding. *Sophia*'s scenario, in particular, illustrates the fact that

> *any de-personalisation of the mathematical process and reification of the product pushes mathematics back into the absolutist position by objectivising the 'truths'.*
>
> (Burton, 1995, p 284)

Moreover, it shows that such a de-personalisation and de-contextualisation restricts the opportunities of the learners for critical reflection upon the present situation of *teaching* mathematics in university institutions.

There is a deep assumption about mathematical knowledge, which more or less penetrates the three scenarios presented in this paper, namely that mathematics has always to do with stable and predictable facts or events, while human society and human life belong to the realm of unstable and unpredictable. The teaching of mathematics - at least in Greece - has done nothing to challenge this assumption, and new mathematical areas such as non-linear dynamics, complexity theory and fuzzy sets and systems remain out of the university syllabus, with very few exceptions.

Even focusing on «real» problems and applications to physics and other sciences does not seem to be a radical alternative to de-contextualised teaching of mathematics, since the picture of the main stream of mathematical thought still remains distant and uninteresting to the individual (in Vangelio's words previously quoted in this study, mathematical research seems like «digging a hole in depth»). Accordingly, new links need to be established, *within the process of education*, between mathematical knowledge and other contexts of social and political activity, which will enable the learners to integrate mathematics among their own perspectives and interests.

TO CHECK OR NOT TO CHECK?
(DOES TEACHING A CHECKING METHOD REDUCE THE INCIDENCE OF THE MULTIPLICATIVE REVERSAL ERROR?)

Duncan Pawley, University of NSW, Australia

Abstract

This study investigated the hypothesis that including a method of checking the answer in worked examples teaching translation from sentence to equation imposes excessive cognitive load, and thus interferes with learning. A measure of cognitive load (subjective) was used, finding that the level of difficulty of learning the materials was perceived as significantly higher by the "checking" groups than by the "no checking" groups. A third teaching method was then tested, introducing the checking method in the third week of the study, having used the "no checking" worked examples for the first two weeks. Groups using this "separate introduction of checking" method had significantly higher mean scores than both "checking" groups and "no-checking" groups.

Introduction

Bloedy-Vinner (1994, 1995 and 1996) identified defective knowledge of algebraic language as a cause of reversal errors. Following her work, results have been presented (Pawley and Cooper, 1997) showing that the use of worked examples emphasizing understanding of algebraic language had been effective in teaching translation from sentences to equations. This effectiveness was seen in the significant reduction in reversal errors made by students studying worked examples as compared with a control group using the "conventional" method.

This research had involved three experimental groups, all using worked examples, as well as the control group. In one of the experimental groups no checking method was included in the worked examples ("no-checking" group), in one the worked examples included a method of checking by comparison of quantities (Wollman, 1983), and in the third the worked examples included a method of checking by substitution of numbers for the variables.

The checking methods had been incorporated on the basis of previous research showing the importance of conscious checking in this kind of question. Davis (1980, p 192) suggested that an instructional program should make sure that the students "are aware of the likelihood of an incorrect choice, and form the habit of checking to see if they have in fact chosen correctly". Wollman (1983) notes that "experienced individuals consciously check their results" (p.170), and concludes that the inclusion of a check that the equation produced is correct is the "crucial step from a pedagogical point of view". These findings led to the expectation that in the test the groups studying worked examples which included checking methods would have higher mean scores than those studying worked examples which did not include

checking methods. This expectation was not supported. The conclusion of the study was "Taken singly, only the 'no-checking' method produced a significantly better result than the 'conventional' method" (Pawley and Cooper, 1997, p. 326). When the results were analyzed separately for grade 8 and grade 9, further divided into higher ability and lower ability levels, the only significant difference between any of the "checking" groups and the corresponding "no-checking" group was in favour of the "no-checking" group. The mean of the "no-checking" group was in most cases higher than that of either the "comparison" or the "substitution" group. (13 of 16 contrasts). (Pawley and Cooper, 1997, p 324, table 2)

The suggested reason for the lower mean scores of the "checking" groups was the imposition of a higher cognitive load by the inclusion of the checking method.

The concept of cognitive load is based on the fact that we humans have a limited working memory, though a very large long-term memory. We can only hold in working memory approximately seven elements. (Miller, 1956). These elements may be numbers, rules, mathematical operators, logical connections between other elements, etc. Cognitive load refers to the demands made on this limited working memory by the cognitive processing in progress.(Sweller, 1988). Cognitive capacity is required for learning, i.e., tasks such as recognizing a rule or pattern, formulating information into a schema, and storing it in long term memory. Overloading the cognitive capacity by requiring attention to too many elements at one time will prevent this learning taking place.

Thus the suggestion was that inclusion of the steps of the checking method in the worked examples increased the number of elements required to be attended to beyond the level at which the students were able to process the information. This seemed to be the only explanation of why teaching one group of students to check would actually make them do worse than another group of students of matched ability who were given identical instruction with the exception that they were not taught to check. If this explanation is correct, then teaching the checking method after the schema for translation had been acquired could not detract from students' performance. It would either make no difference to students' scores (if checking was unnecessary with the greater level of understanding obtained through the use of worked examples) or improve students' scores (if checking was still of importance).

Research Questions

The present study investigated two questions. The first was whether including the checking method in the worked examples imposed excessive cognitive load, hindering acquisition of the schema for translation. The second was whether the introduction of the checking method after the schema for translation had been better acquired would result improved performance.

Thus the two hypotheses were:

1. The perceived cognitive load for the "no-checking" group will be significantly less than for the "checking" group.
2. The mean score of the group taught the checking method subsequent to the translation schema (the "separate-checking" group) will be significantly higher than those of the "no-checking" and the "checking" groups.

Method

The subjects were all the students in grade 8 and grade 9 at a secondary school in Sydney. Each grade was divided into three matched ability groups, based on mathematics tests in the previous year. Each group was further divided into "higher" and "lower" ability levels.

All the groups had three acquisition sessions. The introductory material for all groups was identical. The worked examples studied by all groups in each acquisition session were identical except for the inclusion of the checking method in those studied by the appropriate groups

The first of the matched ability groups was the "no-checking" group. This group used worked examples with no checking method for all three acquisition sessions.

The second of the matched ability groups was the "checking" group. This group used worked examples incorporating the "comparison" checking method for all three acquisition sessions.

The third of the matched ability groups was the "separate-checking" group, which for two sessions used materials the same as those used by the "no-checking" group, and in the third session materials the same as those used by the "checking" group in its third session. This allowed two sessions for acquiring the translation schema without a checking method.

To measure the cognitive load imposed in learning this material by studying the worked examples, a subjective measure of mental effort was used. This approach was taken following use of the method in experiments by Paas, (1992) and Paas and Van Merrienboer, (1994). They argued for the reliability of subjective measures of cognitive load (Paas, 1992, p. 429) on the basis of the high correlation between such subjective measures and other (objective) measures of cognitive load obtained by previous researchers. For example, Bratfisch, Borg and Dornic (1972) obtained a Spearman rank order correlation of 0.9 between objective and subjective measures of task difficulty. The method used in this study was that at the conclusion of the first acquisition session the students were asked to indicate, on a seven point scale, "how hard or easy this material was to learn", by putting a cross in the appropriate box. The scale ranged from "extremely easy" to "extremely hard". The responses were scored by giving a value of 1 to "extremely easy" and so on, up to a value of 7 for "extremely hard". One group of students had thus spent one session studying worked examples incorporating the checking method, and the two other groups had spent one

session studying worked examples with no checking method. The means of the responses for the "no-checking" group and the "checking" group were compared, separately for each grade and ability level, using ANOVA contrasts.

An immediate test was administered to all groups at the end of the third acquisition session. After two weeks, a delayed test was administered. These tests each consisted of two questions on equation formation. For both the immediate test and the delayed test, for each of grade 8 and grade 9 separately, the mean score of the "separate-checking" group was compared with the mean score of the "no-checking" group and also with the mean score of the "checking" group, using the Student's t-test. In addition, comparisons were made using ANOVA contrast tests between the mean score of the "separate-checking" group and the combined mean of the "no-checking" group and the "checking" group. This was done for both the immediate test and the delayed test, for each of the whole of grade 8, the whole of grade 9, and both the higher and lower ability levels of grade 8 and grade 9 separately.

One-tailed tests were used in all comparisons, since both hypotheses were directional.

Results

Table 1 shows the means of the responses for the "checking" and "no-checking" groups to the questions on difficulty of the materials, separately by grade and ability level. Table 2 shows the results of contrasts between the means of the different group/ability level combinations for grade 8 and for grade 9.

Grade	Group	Level	N	Mean	SD
8	No-checking	High	31	2.68	1.38
		Low	33	3.48	1.70
	Checking	High	16	3.50	1.10
		Low	16	3.63	1.45
9	No-checking	High	28	2.71	1.01
		Low	29	3.38	1.18
	Checking	High	15	3.27	1.10
		Low	14	3.50	1.16

Table 1: Mean scores for Perceived Difficulty (on 7 point scale).

For grade 8 at the higher ability level the "no-checking" group found the task significantly less difficult than did the "checking" group, ($p = 0.016$ on a one-tailed test). For grade 9 at the higher ability level this difference is not significant, but it is approaching significance ($p = 0.062$ on a one-tailed test) (Table 2). There is no significant difference between the "no-checking" group and the "checking" group at the lower ability level for either grade 8 or grade 9.

For both grade 8 and grade 9 the higher ability level "no-checking" group found the task significantly less difficult than did the lower ability level. (Grade 8, $p = 0.020$, Grade 9, $p = 0.013$ on a one-tailed test) (Table 2). However, in the case of the "checking" group there is no significant difference between the higher and lower ability levels in either grade.

Grade	Contrast	Value of Contrast	Value of t	p value (1 tailed)
8	High Ability, No-check vs. Check	-0.82	-2.230	0.016
	Low Ability, No-check vs. Check	-0.14	-0.299	0.383
	No-check, High vs. Low ability	-0.81	-2.096	0.020
	Check, High vs. Low ability	-0.13	-0.275	0.393
9	High Ability, No-check vs. Check	-0.55	-1.556	0 062
	Low Ability, No-check vs. Check	-0.12	-0.334	0.370
	No-check, High vs. Low ability	-0.67	-2.262	0.013
	Check, High vs. Low ability	-0.23	-0.566	0.287

Table 2: Results of ANOVA contrast tests, Comparing Scores for Perceived Difficulty.

Table 3 shows the mean scores of the different treatment groups in both immediate test and delayed test for grade 8 and grade 9, both ability levels combined and higher and lower ability levels separately. Table 4 shows the results of t-tests for comparisons between these means. (**Note:** In this paper the results of contrasts are reported separately for the higher and lower ability levels only where one of these contrasts is significant and the other is not. Otherwise the contrasts are reported for the grade as a whole, meaning both higher and lower levels are significant or both not significant).

For grade 9, the mean of the "separate checking" group was significantly greater than the mean of the "no-checking" group and that of the "checking" group, in both the immediate test and the delayed test. The mean score of the "separate-checking" group was therefore significantly higher than the mean of the "no-checking" and "checking" groups combined ($p = 0.000$ for immediate test, $p = 0.000$ for delayed test). (See Table 5 for results of ANOVA contrasts between these means).

However, for grade 8 none of these differences was significant. Rather than the "separate-checking" group performing better than the other groups, it was the worst (note the signs of all contrasts for grade 8 are opposite to those for grade 9). For the higher ability level, the "no-checking" group performed the best, though not significantly. The contrast for grade 8 higher ability level between the "no-checking" group and the mean of the "checking" and "separate-checking" groups had $p = 0.089$ on a 2-tailed test.

Grade	Treatment	Level	Immediate Test			Delayed Test		
			N	Mean	SD	N	Mean	SD
8	No-checking	All	30	1.63	0.76	31	1.65	0.66
		High	16	1.94	0.25	17	1.71	0.69
		Low	14	1.29	0.99	14	1.57	0.65
	Checking	All	31	1.61	0.72	34	1.47	0.83
		High	16	1.63	0.81	17	1.71	0.59
		Low	15	1.60	0.63	17	1.24	0.97
	Separate-checking	All	32	1.41	0.87	31	1.42	0.85
		High	14	1.71	0.73	14	1.64	0.63
		Low	18	1.17	0.92	17	1.24	0.97
	Total		93	1.55	0.79	96	1.51	0.78
9	No-checking	All	30	1.23	0.90	28	1.11	0.96
		High	16	1.56	0.81	15	1.47	0.92
		Low	14	0.86	0.86	13	0.69	0.85
	Checking	All	30	1.37	0.81	27	1.41	0.84
		High	16	1.25	0.86	15	1.67	0.72
		Low	14	1.50	0.76	12	1.08	0.90
	Separate-checking	All	30	1.87	0.35	27	1.74	0.45
		High	14	1.86	0.36	13	1.92	0.28
		Low	16	1.88	0.34	14	1.57	0.51
	Total		90	1.49	0.77	82	1.41	0.82

Table 3: Mean scores for Immediate Test and Delayed Test, for Grade 8 and Grade 9, different treatments and levels.

Grade	Contrast	Immediate Test			Delayed Test		
		Mean diff.	Value of t	p value (1 tailed)	Mean diff.	Value of t	p value (1 tailed)

Table 4: Results of t-tests, comparing mean scores for different treatments, for Grade 8 and Grade 9.

Grade	Test	Value of Contrast	Value of t	p-value (1-tailed)
8	Immediate	-0.17	-1.026	0.154
	Delayed	-0.12	-0.675	0.251
9	Immediate	0.57	4.602	0.000
	Delayed	0.52	3.714	0.000

Table 5: ANOVA Contrasts- Mean score of Separate-checking Group vs. Average of Means of No-checking and Checking Groups, for Grades 8 & 9.

Conclusions

Hypothesis 1 was supported for grade 8 higher ability level; the perceived cognitive load for the "no-checking" group was significantly less than for the "checking" group. For grade 9 higher ability level there was a strong trend in the expected direction, the difference falling just short of significance. This smaller difference for grade 9 than for grade 8 is due to the fact that the mean result for perceived level of difficulty for grade 9 was slightly lower than that for grade 8. That is, grade 9 found it slightly easier to learn from the "checking" worked examples than did grade 8, which is what we would expect.

The fact that there is no significant difference between the "no-checking" group and the "checking" group at the lower ability level for either grade 8 or grade 9 means that the lower ability students found the "no-checking" materials almost as hard as the "checking" materials. These students are having enough trouble still in trying to acquire the schema for translation; the extra steps of the checking method don't make it much harder for them than it is already. Note that this test for cognitive load was after one acquisition session. Previous studies have shown that three sessions are required for lower ability students to acquire the schema for translation, (Pawley, 1997), which is why three sessions were used for all groups in this study.

The fact that there is no significant difference between the higher and lower ability levels of the "checking" group means that the higher ability students found the material just as difficult as did the lower ability students.

Hypothesis 2 was supported for grade 9, the mean of the "separate checking" group being significantly greater than the mean of the "no-checking" group and that of the "checking" group, in both the immediate test and the delayed test.

That this was not the case for grade 8 may again be due to insufficient time (only 2 sessions) for the "separate checking" group to acquire the schema for translation before introduction of the checking method. The "no-checking" group had certainly acquired the schema by the end of the third session, with a mean of 1.94 out of 2 for the grade 8 higher ability level "no-checking" group. It appears that grade 8 required

the three sessions on the translation schema before introduction of the checking method.

In summary, there was support for both hypotheses, the first at the grade 8 level and the second at the grade 9 level. In both cases the results suggest explanations in terms of acquisition time required as to why the expected results were obtained by one grade but not the other.

AN EXPLORATION OF THE INTERFACE BETWEEN VAN HIELE'S LEVELS 1 AND 2: INITIAL FINDINGS

John Pegg and Penelope Baker

Centre for Cognition Research in Learning and Teaching

University of New England

This paper is concerned with identifying a structure in the responses of students as they move from thinking at van Hiele's Level 1 to Level 2. This period in the development process is one in which students move from using global or overall features of a figure to having properties describe a figure. This development is important for students and marks the beginning of formal geometrical thinking. Three significant categories have been identified in this transition. First, specific features are identified. Second, attempts are made to qualify or quantify these features and, finally, the features take on an individual significance although they are not seen as determining the figure. To explicate the findings, a number of samples of student interviews are provided.

Introduction

The van Hiele theory (1986) continues to act as a catalyst for research into students' geometrical thinking. This is evident in the continuing numbers of papers, theses and book chapters which draw upon various aspects of the theory. Nevertheless, despite considerable empirical support (Clements & Battista, 1992) for various aspects of the theory there have been a number of sustained criticisms (Pegg & Davey, 1998). It appears that this conflict has resulted in some researchers rejecting the theory out of hand while others have attempted to move forward by taking specific issues and extending the theory in ways that maintain the original formulations. Four examples illustrate this latter approach. These are: the consideration of van Hiele's ideas within the SOLO model (Biggs & Collis, 1991; Pegg & Davey, 1998); the widening of the level descriptors to incorporate the original ideas but to allow for inclusion of coding of questions more typical of those currently asked in secondary schools (Pegg & Currie, 1998); deeper explorations of the nature of the levels and the properties associated with the level framework (Fuys, Geddes, & Tischler, 1985; Burger & Shaughnessy, 1986); and dividing van Hiele's Level 2 into two levels referred to as Level 2A and 2B (Pegg, 1997). It is the last of these issues which is relevant to this paper and provides the impetus for the research reported.

The splitting of van Hiele's Level 2 (in which figures are identified in terms of properties which are seen to be independent of one another) into two levels, Level 2A (in which students work with one property) and Level 2B (in which students work with a number of properties independently) is more than semantics. It represents an important psychological shift which is supported by empirical data which sees many younger students unable to move beyond applying a single property or 'concept' at a time, due to working memory constraints. It is only after some (considerable) time that students are able to simultaneously apply in sequence several properties.

The identification of Level 2A to student thinking is important. Its strategic position between intuitive/visual thinking at Level 1, where invariant features of a figure take no overt part in problem-solving activities, and Level 2 thinking, in which properties determine a figure, provides a

context for several research questions. Significantly for this paper is the question: Is there some identifiable cognitive structure to students' development of individual properties as students move from Level 1 to Level 2A? It is this question that is at the heart of this study.

Design

The study aimed to explore young students' responses to a series of questions concerning properties of figures on two occasions approximately 12 months apart. The sample comprised of twenty students. At the time of the first intervention 12 were nine years old, and 8 were twelve years old. The students were selected from two schools across each age group with equal numbers of males and females. The selection represents the bottom, middle and top 20% of the age cohort based upon their general mathematics performances on class tests. The nature of the intervention was such as to provide the students with a number of problem-solving contexts about which they could undertake an activity and then talk about the reasons for their actions. This technique seemed to be enjoyed by the students and the interviewer was free to probe for further information as was deemed important. However, care was exercised in asking additional questions so as not to prejudice further activities asked of the students. As was expected the twelve-month delay in re-testing was sufficient for the students to have no recall of the items or their earlier approaches. Due to space restrictions this paper reports on only one question and takes the interview data from the first intervention. A report on the second intervention and its relationship to the first for each child is currently under preparation. Significantly, the results of the second stage provide confirmatory support for the pattern suggested in this paper.

The task reported below was similar to that given to an older cohort of students and reported previously (Currie & Pegg, 1998). It was to have the students group and justify their groupings among seven different triangles, namely, equilateral, acute isosceles, obtuse isosceles, right isosceles, acute scalene, obtuse scalene, and right scalene. In this case, because of the young age and lack of geometrical experience of the students they were provided with a diagram of the seven triangles, each on a separate card, and were asked to sort the triangles into smaller groups. They were not given the names of the triangles and there was no attempt to have them provide names.

While the diagrams were designed to depict each type of triangle, they included no markings or labelling to indicate equality of sides or angle size. Individual cards for each type of triangle enabled the student to alter the orientation of the triangle when and where necessary. The student triangle groupings were used as a catalyst for discussion, involving prompts and probes, concerning the justification of the groupings. The investigation required the analysis of responses concerning the particular triangle groups formed, and the reasons for the identified groups.

Results

Of the twenty students interviewed four responded at Level 1 and three responded at Level 2A. For completeness, selected excerpts of their interviews are provided to indicate the boundaries of the groups of responses. No student in the sample tested was able to respond at Level 2B.

Level 1 responses

There were four students (all aged 9 years) whose responses were identified in this category. While the focus of attention was different in each case there was a clear attempt by each student to use aspects of the global appearance when grouping the triangles. These ideas ranged from using: fat and skinny by Emily; the position of the apex and how this position distorts triangles from some ideal template held by the student as in the cases of Patrick and David: and, to picking some important visual indicator of the triangle such as sharpness indicated in Joanna's response.

Int: Tell me about this group. (acute isosceles, right scalene and acute scalene)
Emily: Well they are sort of the long skinny type of triangle.
Int: And this group? (obtuse isosceles, obtuse scalene, right isosceles and equilateral)
Emily: They are the fatter triangles.

Int: Right so we have got the seven triangles. Why is that one on its own? (right scalene)
Patrick: Because it is not sort of like a triangle shape it is sort of like it is bent.
Int: And this group? (obtuse scalene, obtuse isosceles and acute scalene)
Patrick: This is the normal triangle except it is sort of like the point is not in the middle. This should be there like that.
Patrick: These ones here are normal triangles. (acute isosceles and equilateral)
Int: Can you tell me about the normal triangles?
Patrick: They're middle of the um, the point is facing the middle of the line.

Int: Tell me about this first group. (acute isosceles, obtuse isosceles and equilateral)
David: Oh, they are just straight triangles.
Int: What does that mean?
David: It just means that they um (pause) are just plain triangles without any changes to it.
David: Um these are triangles (scalene and right isosceles) that are pointing to the right hand side or the left.

Int: What is this group? (acute isosceles and equilateral)
Joanna: Those triangles are both going up in the same direction so I put them together.
Int: This group? (obtuse isosceles, right isosceles and acute scalene)
Joanna: These two are both pointing up and this one is kind of doing the same.
Int: And your last group? (right scalene and obtuse scalene)
Joanna: These are kind of the same?
Int: What is the same?
Joanna: They go sharp on the corner just here.

Overall, the responses in this category are consistent with findings of other research and the strong visual/intuitive nature of the students' thinking was evident.

Level 2A responses

Three students responded at Level 2A. Each had established three distinct classes of triangles, namely, equilateral, isosceles, and scalene. The decisions for these groupings were based primarily on the number of equal sides of the triangles. Interestingly, neither Sacha (age 12 years) nor Jessica (age 9 years) were able to name specific triangles. Cole (age 12 years), on the other hand had no trouble in using the more general names such as equilateral and scalene, although the word isosceles was not used. His response goes a little further than the other two students in that he mentions, under probing, equality of angles and, more importantly, he is willing to begin to consider links between isosceles and equilateral triangles based on them having similar properties.

Sacha: That group (equilateral) is a triangle and it has got three sides all the same length.
Int: What is it called?

Sacha: A triangle.
Sacha: This group (acute, obtuse, and right isosceles) all has a length at the bottom and its two sides coming to the point are the same.
Int: Your next group? (acute, obtuse, and right scalene)
Sacha: This group has um they are all different lengths. The sides are all different lengths.
Int: Do you think any of these different groups here can link together?
Sacha: No.

Jessica: This is the triangle (equilateral) that has roughly the same length sides.
Int: And this group. (acute, obtuse, and right isosceles)
Jessica: They are the triangles with the same length. The top two on each are the same length.
Int: And this group. (acute, obtuse, and right scalene)
Jessica: All the sides are different lengths.
Int: Do you think any of these groups belong together?
Jessica: These are sort of together because most of their sides are the same length.

Cole: Well they are equilateral ones and they have all three sides the same.
Int: Anything else they all have?
Cole: They have all the angles the same.
Cole: These ones are the scalene ones. They have all sides different and all the angles different.
Cole: These are, I can't think of what they are. They have two sides the same and one different, and two angles the same and one different.
Int: Do you think any of these groups go together?
Cole: No not really, they are all triangles.
Int: No links for any other reasons?
Cole: No.
Int: Do you think I could put these (isosceles) with these?
Cole: No not really, I suppose they do have two sides the same.
Int: Could you put them with that other group?
Cole: No they are separate.

The students responding at this level were able to group the triangles into three mutually exclusive classes. Each class was determined by a specific property. Under prompting the classes remained mutually exclusive although Cole alone indicated a possible link between the equilateral and isosceles triangles based on side properties.

The remaining 13 responses were seen to lie between these two boundary levels. There were three clearly identifiable groups. These groups appeared to have a logical development to them and provide a sequential pathway from Level 1 to Level 2A. For ease they are described as Categories 1 to 3.

Category 1

Only one student's, Hannah (age 9 years), response was identified in this category. Although there were examples to be found elsewhere, in these other cases, they were followed or accompanied by a more detailed response. The main characteristic of this response was a focus on the number of sides. In addition, there was much in common with the responses of the category described previously, i.e., the use of global imagery to support the description. This is shown in the response of Hannah.

Hannah: Well these (acute isosceles, obtuse isosceles, and equilateral) are like the triangles and these ones (right triangles, and scalene triangles) are like the sloped ones.
Int: Int: Tell me about the triangle group.
Hannah: Well they have three sides and a big triangle face there and that one goes up a long way.

Int: What do they all have in common so that they can go together?
Hannah: Well they all go up and they have this long bit there.
Int: Why do these ones go together?
Hannah: Well they go on a slope and I don't know what they are called but they have three sides like a triangle but they don't all go up to that point up the top.

Overall, the response in this category moved away from a sole reliance on a global representation of the figures, as would be expected of a Level 1 response, and started to focus on the number of sides. No attempt was made to consider the length of the sides in any way.

Category 2

This category was a logical extension of the previous response and six student's responses were identified. Four of the students, all aged 9 years, continued the focus on three sides, and, in some cases, three angles (which were referred to as corners), but, in addition, they attempted to bring in some notion of the length of the sides or the measure of the angles. However, significantly they were not able to use effectively ideas of equality (or evenness) to group figures consistently. In the case of Abbey, she was able to mention that one side is longer than another but was not able to group the triangles using this idea.

Abbey: They are the sort of triangles. (acute isosceles, obtuse isosceles and equilateral)
Int: What do you mean by that they are triangles?
Abbey: Because they just look all the same except for the width wise.
Int: What is the same?
Abbey: Well they just look the same sort of. They have sort of got three corners like that.
Abbey: They are the kind of weird sort of ones because one side is longer than another and I haven't seen that before.
Int: These two? (acute scalene and obtuse scalene)
Abbey: That one is sort of a weird one if you have it the wrong way there like that and these ones (right isosceles and right scalene) are sort of like part of a normal triangle if you have it like that. If you have them both like that they can go in there own group.
Int: What do you mean?
Abbey: If you have them up that way like that they are a bit like a triangle but they are not.
Int: In which way aren't they?
Abbey: Well because that one slopes that way and these ones go straight up. I could put one in with the weird and one in with the triangles.

Helen was similar but during the conversation concerning her grouping she only noticed the lengths of sides as a consequence of the groups she had formed. However, there was a lack of consistency in her explanations.

Int: So what does this group have in common?
Helen: They won't come straight up into an apex. They won't have even sides like that one. It has one big side and one short side.
Int: So what does this group have with its sides then?
Helen: They have equal sides.
Int: Are you sure? Have a look.
Helen: Um most of them do.
Int: Does that matter if they don't?
Helen: Um.
Int: Is the apex more important?
Helen: Um I am not sure.

Initially, Jack responded using global criteria typical of a Level 1 response but when probed started to focus on the size of the edges (sides).

Jack: That is the group (acute obtuse and right scalene) that are the more sloped and they are bigger.
Int: This group? (right isosceles, acute isosceles and equilateral)
Jack: This is the group with um they are the ones that are exactly the right way.
Int: What do you mean by that?
Jack: Like um um like they have got all the edges are the same size.
Int: And this one? (obtuse isosceles)
Jack: That is just one that has been pushed down.

Finally, Anthony begins by trying to use lengths of sides but is not consistent with the groupings he established. His attempts to describe the length of sides are drawn from specific examples within the group and he is unable to provide a broad generic description which encapsulates all triangles within the groups formed.

Anthony: They are all triangles.
Int: What does this group (acute, obtuse, and right isosceles and equilateral) have that relates them together?
Anthony: Some of them have all the edges the same size.
Int: What about the others?
Anthony: Um the bottom edge is smaller than the top edge.
Int: What about this next group? (right scalene)
Anthony: It is half of a triangle.
Int: And your last group? (obtuse and acute scalene)
Anthony: They are sort of triangles but one side on the edge is longer than the other.
Int: Are any the same on that?
Anthony: Um one is a lot longer.

The remaining two students, Alisha (age 12 years) and Simon (age 9 years), provided very similar responses to that described above in that they were still inconsistent in their justification of their groupings. However, they were able to move beyond the focus of individual figures to begin to talk in more general terms about the groupings they formed. They used examples related to specific figures only as a means to justify their more global decisions. For example, Simon responded:

Simon: These ones are all even sort of thing. (acute and obtuse isosceles and equilateral)
Int: What do you mean by that?
Simon: Um, they all um, they are the same on each side like on this side it is like 4 cm long and on this side it is another 4 cm long. Whereas on this group it is say 6 cm long, and that one is only about 3 cm long. And also on these it is half.
Int: What part of the triangle are you looking at?
Simon: I am looking at the top because the bottoms are all practically the same.

Here Simon has chosen to use specific lengths to justify his groupings even though the answer he came up with was incomplete.

Overall, these six responses in this category, while still relying heavily on visual cues, are characterised by the addition of attempts to use the length of sides to group triangles. However, there is often a vagueness in the students' comparison of lengths as they have difficulty in indicating spontaneously which sides are equal. In addition, the groupings lack stability as the guiding principle is not applied in a consistent manner across all triangles.

Category 3

There were six students who responded in this category. All students except Daniel (age 9 years) were 12 years of age. The most important characteristic of the responses used by this group is that

a single feature, such as equality of sides, is an appropriate criterion upon which to group triangles. As a result, all triangles with, say, two sides equal, such as isosceles and equilateral triangles, can be linked. This does not imply that the students see these properties as defining the figure but that given this feature certain triangles have this characteristic. Key aspects of the responses in this category include: consistency across groups formed in relation to the principle applied by the student; a strong reliance on visual cues; only one property or feature is utilised at any one time and, hence, the groups form spontaneously, as triangles are seen to have the appropriate chosen characteristic. Different grouping are possible depending on the feature or property chosen.

Two examples to illustrate this category are provided by Jason and James, both aged 12 years.

Jason: These (acute, obtuse, and right isosceles and equilateral) have either got um some of their lines are equal length with the others like those two are there.
Int: So they all have some lines of equal length to the others. Any other reason?
Jason: No right angles.
Int: What is this one? (right scalene)
Jason: Well it has a right angle and it could go with this group here because it doesn't have any sides that are equal.
Int: So why is that second group together? (acute, obtuse, and right scalene)
Jason: Because they all have unequal sides.
Int: Does that group have a name?
Jason: It does but I have forgotten it.

Int: Can you tell me why these (acute, obtuse, and right scalene) are all related together?
James: They are all triangles but each three sides of the shape are different lengths.
Int: Anything else?
James: Um nope.
Int: How come your next group are together? (acute and obtuse isosceles)
James: Because only two sides um ... but these are all wonky triangles (acute, obtuse, and right scalene) but these ones are still triangles but they are um.
Int: So what relates these two together?
James: They are still triangles. They have got three sides, and three corners, and that is all. These ones (equilateral and right isosceles) are just the same length, oh no they are not. These ones are almost all of the same length around the triangle.
James: Well if that one is all the sides are different and this one is almost the same, what is this group? (acute and obtuse isosceles)
Int: I just realised that this one is the same as this one. (added right isosceles to acute and obtuse isosceles)
Int: Are you sure?
James: Yep.
Int: Do they look the same?
James: (pause) In this shape there is only one odd side. In these shapes there is one odd side and on there are no odd sides on that shape and these here they are all odd.

Overall, students who respond in this category are able to form consistent groupings based upon the spontaneous identification of the chosen property. However, this contrasts with those responses coded as Level 2A as in this latter case the properties signify particular figures and are not simply a consequence or an associated characteristic of a figure.

Discussion and Conclusion

The sample interviewed provided an insight into the development from Level 1 to Level 2A. Three broad categories of responses were identified. These categories can be described as:

BEST COPY AVAILABLE

1. a move from a total reliance on global visual aspects to the realisation that there is significance in certain aspects of a figure, such as sides. However, in the early stages this results in students commenting on the number of these features;
2. an attempt to document more than one feature or, alternatively, to try and further clarify a particular feature. However, the attempts were inconclusive with either the student being unable to appropriately articulate the property or unable to move from specific figures and apply the notion across a group of figures; and
3. a successful attempt to group the triangles according to a single property. This grouping is not necessarily unique but it is consistent within the framework adopted by the student. However, the figures chosen within a grouping are simply those which are seen to possess the chosen observable property, hence, there is the possibility of different groupings of triangles being formed depending on the nature of the property selected.

The results of this study have offered an initial framework to describe a developmental path in student cognitive growth in moving from a visual basis for describing figures to one in which properties determine a figure. Due to the exploratory nature of the findings, as much transcript information as possible has been provided. Nevertheless, these results are tentative and require further investigation across different tasks and using other figures. Further research into this aspect of cognitive development is vital. The careful analysis of the process of students' acquisition of properties can offer new insights into teaching during this critical time in a young person's development of geometrical concepts. It is possible that future successes in students' growth will depend on how well a program of instruction addresses this transition phase.

Pupils in lower secondary school solving open-ended problems in mathematics

Erkki Pehkonen & Jaana Vaulamo
University of Helsinki, Finland

Abstract
In spring 1998, eighteen pupils in the lower secondary school took part in research, the aim of which was to clarify how creatively pupils can solve open-ended problems. As a part of the research interview, two open-ended problems were given to the pupils in pairs to solve. Without any hints, all pupils ended with the same simple (addition-based) solution. After the first hint, only one pair of pupils came to the complete solution, and another pair got the right idea, but was not able to follow it. The rest, seven pairs needed, at least, two hints in order to solve the problem completely. The results bring clearly forth the meaning of creativity for problem solving. Some pupils seem to have weak ability to think creatively, i.e. to generate new ideas and ponder different alternatives.

The purpose of this paper is to clarify how pupils in lower secondary school can solve open-ended problems in mathematics. Especially, the focus will be on the role of creativity in problem solving. The paper pertains as a part to the research project "Teachers' conceptions on open-ended problems" which was financially supported by the Finnish Academy (project #162027).

Theoretical background

Conventional school teaching has been accused that it considers the action and the context where learning happens totally different and neutral concerning the topic to be learned. However, psychological studies show that learning is strongly situation-connected (e.g. Brown & al. 1989). Furthermore, the latest research indicates that learning of facts and learning of procedures seems to happen through different mechanisms (Bereiter & al. 1996).

This points out that in mathematics instruction, pupils should be offered different methods to learn on the one hand conceptual knowledge (as facts) and on the other hand procedural knowledge (such as using facts). Conventional school teaching suits very well for learning of facts, whereas learning of procedural knowledge demands other kind of instruction. One possible solution to the latter case is offered by open learning environments, since within them one can deal with real, existing problems, be active and learn in natural settings (e.g. Blumenfeld & al. 1991).

In search for mathematics instruction which is compactible with the constructivist view of learning (cf. Davis & al. 1990), one promising method seems to be the use of open-ended problems. They offer pupils opportunities to explore on their own, make conjectures, to prove their hypotheses, to communicate with their mates, etc

(cf. the papers in Pehkonen 1995 or 1997b) – thus they form open learning environments.

The idea to teach mathematics via problem solving leads naturally to the use of investigations (e.g. Klaoudatos 1999), i.e. a kind of open-ended problems. The ability to generate new ideas, to change flexible one's view point if one gets stuck in the solving procedure, to check obtained results (looking back) and compare them with the problem statements, and all the time to control that one works within the proper problem framework are essential components of successful problem solving (cf. Mason 1982, Schoenfeld 1985).

In problem solving activities, creativity has an important role (e.g. Silver 1997). But in the literature, there is no single definition for creativity that is generally accepted in research (e.g. Haylock 1987, 1997). The most common components of the definitions for creativity are divergent thinking and flexibility. For example, Haylock put forward that "creativity is the capacity to get ideas, especially original, inventive and novel ideas" (Haylock 1997, p. 68). In solving mathematical problems, an individual needs both logical thinking and creative thinking, and large mathematical knowledge with rigid logic is not alone enough (cf. Pehkonen 1997a. Solvang 1998). Therefore, pupils' possibilities to be successful in problem solving are also strongly dependent on their creative capacity.

The sample and methods

In spring 1998, seven teachers with nine teaching groups and from these 18 selected pupils took part in research, the aim of which was to clarify how creatively pupils can solve open-ended problems, i.e. what is the amount and the quality of ideas they produce during the solving procedure. The research was carried out in two lower secondary schools Apia and Tyry with 13-15 year-old pupils in the city of Valkeakoski in southern Finland, using observations and interviews. From each teaching group, a pair of pupils was chosen at random, in order to be interviewed. Additionally, one mathematics lesson from each teaching group was observed. Furthermore, the teachers' conceptions on open-ended problems were gathered with a questionnaire.

At the end of the interview, two open-ended problems were given to the pupil pairs to solve. The problems used were taken from the paper of Reusser & Stebler (1997, p. 312). The selected problems represent mathematically simple problems in everyday context with multiple answers, and the aim of using them was to find out pupils' creative capacity, not so much their mathematical skills. Since the problems selected were similar in their mathematical and creative level, one may suppose that the results obtained support each other.

Here we will concentrate on the results based on the solving procedure of the first open-ended problem, because of the space restriction. Some parts of the interviews and observations are used as background information.

Data gathering process

In the interview before problem solving, the pupil pairs were asked for their conceptions on open-ended problems. And directly in the beginning of the problem solving phase, they were told that following problems are open-ended.

Here we describe the procedure of solving the first open-ended problem which was as follows:

> *Carl has 5 friends and George has 6 friends. They decided to give a party together and they are asking all their friends. How many guests are coming?*

The pupils were asked to read the problem and to answer it, thinking aloud, if possible, in order their solutions and reasoning can be audiotaped. During the solution procedure, the pupil pairs were given only some hints, if they seemed to need some help. As the first hint, they were asked "Are there any other possibilities?" If the pupils have not yet produced the complete solution, they were given another hint: "What about if the boys have common friends?" As the third and last hint, the following completing question was given: "Could there be still more possibilities?"

During the solving procedure, the interviewer gave no comments on the quality of the answers. Her only intervention was to give the hints in the order described. But after the pupils have finished, after the hints, their solving of the problem, the interviewer worked the complete solution of the problem with the pupil pairs together through.

Two examples of the solution procedure

In the first place, we tried to find out, whether the pupils were satisfied with one answer or whether they found (or tried to find) more answers without a hint or after the hints. Additionally, the quality of ideas was noted. In the problem, pupils had to recognize that Carl and George might have some mutual friends, in which case there could be a varying number of persons attending the party.

As the first example, the solution procedure of a pair of seventh-graders, two boys (from Terry's teaching group, see Table 1) is presented. In the beginning of the problem solving phase of the interview, the boys began eagerly to study the given problem. As soon as they had read the question, one of the boys stated: "*I know already, there will be thirteen guests.*" And the other boy responded convincingly: "*Yes, so there are.*" Then the boys put more precisely that one gets 13, if one adds the guests (11) and the boys (2).

Hint #1: "*Are there any other possibilities?*"

After pondering a while with soft mumble, the first boy continued: "*If they have three common friends, then five plus one will be six, and plus boys.*" After a tangled explanation and common discussions, the boys reached a consensus: "*There will be eight guests.*"

Hint #2 was skipped, since the boys have already reached the idea of common friends.

Hint #3: "*Could there be still more possibilities?*"

After discussing a while, the boys passed as a resolution the earlier answer without any alternatives. "*There will be eight guests.*"

The second example is a pair of eight-graders (from Anne's teaching group, see Table 1). In the case of the eight-graders, there seems to be some scepticism against the question. Anne's pupils expressed openly their surprise after reading the question in the problem. One of them said: "*What ...? One cannot say anything on this. All might be possible, because you are not saying....*" And the other one continued: "*They will ask their all friends, and we don't know how many they are ... or we just know about.*" The pupils pondered also the aspect that the party might be arranged in Carl's or George' home, and then the host is not counted as a guest. After long discussions, the pupil pair concluded in consensus that the number of will be eleven.

Hint #1: "*Are there any other possibilities?*"

After a long-lasting silence, one of them answered first with a silent and unsure voice: "*No*". After a while, the other one repeats the same answer more sure and loud.

Hint #2: "*What about if the boys have common friends?*"

After this hint, they began to ponder together other possibilities for answers. At last, one of them states: "*Then there can be ten or less.*"

Hint #3: "*Could there be still more possibilities?*"

The third hint did not improve the given solution.

Results and discussion

Table 1 gives an overview on the development of the solution procedure in the open-ended problem. The first column gives the grade level. In the second column, one can find the pseudonames of the teachers: A for Apia and T for Tyry. Two of the teachers had two teaching groups: Annette and Teo. The third column indicates the interviewed pupils' last mathematics mark, grouped into three categories: A = marks are average level, A+ = marks are above average level, A- = marks are below average level. Results of all interviewed pupils (grades 7–9; 13–15 year-old pupils) are gathered in the four last columns. A dash in the box means that no new answer was given or that the hint was not offered, since the pupil pair has already reached the complete solution.

grade		*marks*	*1. answer*	*after 1. hint (other?)*	*after 2. hint (common friends?)*	*after 3. hint (other?)*
7	Terry's pupils	A	13	8 (3 common friends)	8	8
7	Ann's pupils	A	11	11 plus gatecrashers	6 or 10	5...10
7	Teo's pupils #1	A	11	6 (only guests)	6...11	-
7	Teo's pupils #2	A-	11	2 or 3 (it depends who comes)	10 or less	6...11
8	Anne's pupils	A	11	11	10 or less	-
8	Annette's pupils	A+	11 or 13 (who is a guest?)	6...11 (common friends)	-	-
9	Ted's pupils	A	11	11	6...13	-
9	Alfred's pupils	A	11 or 13 (who is a guest?)	13+ (friends of their friends)	5...13	-
9	Annette's pupils	A-	11	12 or 13 (who is a guest?)	5...10	-

Table 1. Development of the pupils' solutions for the open-ended problem (grades 7–9: 13–15 year-old pupils).

The described problem solving procedure of Terry's pupil pair was typical in the sense that the pupils needed hints to continue in their solving procedure. Characteristic for their thinking was the lack of flexibility – when they got an idea ("three common friends"), they were stuck in it, and were not able to variate the conditions, i.e. to get rid of the arbitrarily set preassumption ("three common friends").

Another example, the solution procedure of Anne's eight-graders showed low level creativity and anxiety in problem solving. Characteristic for the pupil pair was the small amount of speech during the solving procedure and their unwillingness to think aloud (if at all).

In contrast to these two examples, the solution procedure of Annette's eight-graders who were talented was very concise: On seeing the problem, they discussed briefly the question "Who is a guest?" and concluded the answer "*11 or 13*". After the first hint, one of them commented the idea that the boys might have mutual friends, and then they very soon resulted "*all between 6 and 11*".

Without any hints, all pupils ended with the similar simple (addition-based) solution. Some of the pupils discussed the question "Who is a guest?", and therefore, came to two different solutions (11 or 13). After the first hint, four pairs of the pupils began to generate alternative ideas, as gatecrashers or friends of their friends, but only two pairs came without the second hint to the idea of common

friends: Terry's (grade 7) and Annette's (grade 8) pupils. No pair of pupils did give a big variety of alternative ideas. Usually the pupils were satisfied in finding another possibility. All other pairs but one needed, at least, one more hint, in order to solve the problem completely. Two pupil pairs (Terry's and An[illegible]) were not able to find all the solutions.. Terry's pair developed a good idea ("t[illegible]e common friends"), but were not able to generalize the idea, in order to reach the complete solution. Their looking back stage was insufficient. Anne's pupils were satisfied with an about solution".

In the pupils interviewed, two pupil pairs have mathematics marks below average level (Teo's pair #2 and Annette's ninth-graders). Their solutions were in average on the same level as the other ones. Those pupils having mathematics marks above average level (Annette's eight-graders) were essentially better in solving this problem: With one hint they developed the complete solution.

There seemed to be no difference between grade levels in solving this problem. The result is understandable, since in such problems one does not need mathematical content knowledge but more creativity and thinking skills.

In their ability and capacity to generate new ideas, the pupils differed slightly from each other. Two pupil pairs (Annette's eight-graders and Alfred's pupils) begin to ponder the problem context from the very beginning (before the hints), but their considerations were only around the question: Who is a guest? After the first hint, four pupil pairs generated good ideas (as common friends, gatecrashers, friends of their friends), but only one was successful in solving the problem. All other needed the second (or third) hint. Summarizing, the pupils' ability to generate new ideas is weak, they need some hints in order to begin. But with hints most of them are able to produce enough ideas for solving the problem.

Background information

From the questionnaire and the interviews, we have gathered the teachers' and the pupils' conceptions on open-ended problems. Every teacher defines open-ended problems, using slightly different words, as problem tasks which have more than one solution. Almost each teacher has written in the questionnaire an example of an open-ended problem he has used. The teachers consider the use of open-ended problems as a method to foster pupils' thinking.

Before solving the problems during the interview, the pupils were asked for their knowledge on open-ended problems. Most of the pupils answered that they had no idea of this kind of problems. None of the pupils had seen such kind of problems in their mathematics text books. Only Alfred's pupils told that their teacher usually starts lessons by using similar questions. Also Teo's pupils (both pairs) stated that their teacher often asked questions with more solutions.

In this small sample, there seems to be no relationship between the teacher's use of open-ended problems in class (Teo and Alfred) and the pupils' capability to solve the problems (cf. Table 1).

Conclusion

Pupils seem to think rather schematically, although they were informed on the openness of the problems to be solved. Especially the seventh-graders "rushed" on the problem, in order to produce an answer in a hurry. In the case of the upper grade pupils, one can observe some hesitation (which might be interpreted to be thinking) in the beginning of the problem solving, but the results are mainly similar to those in grade 7. Probably, pupils lacked the skill to ponder between different alternatives, they were satisfied with the first solution which came into their mind. After the hints, almost all pupil pairs were able to solve the problems completely.

The word problems in Finnish mathematics text books are usually closed problems with one fixed answer (usually a "nice" number) and one way of solution. Since everyday problems which pupils will encounter later on in their future are not well-defined closed problems, pupils might have difficulties to transfer their mathematical knowledge. The use of open-ended problems in mathematics class, every now and then, might help them to use their mathematics skills in the future.

The results bring clearly forth the meaning of creativity for problem solving. Some pupils seem to have weak ability to think creatively, i.e. to generate new ideas and ponder different alternatives. Since creativity is a central component in problem solving and since problem solving can be considered as the core of mathematics, more emphases for practicing creativity should be given also in mathematics classes. For example, the teacher may use such open-ended problems in the classroom situation, in order to promote pupils' flexibility of thinking. And for this, the use of a proper set of hints might be helpful.

GENDER DIFFERENCES IN PRIMARY PUPILS' MATHEMATICAL ARGUMENTATION

Leila Pehkonen
University of Helsinki, Finland
e-mail: Leila.Pehkonen@Helsinki.fi

Abstract: This paper deals with the gender differences in primary pupils' (N= 185) mathematical argumentation. The theoretical framework is derived from the idea based on social constructivism that mathematical argumentation is regulated by normative aspects. The methodological approach is qualitative, but analysis is supported by some statistics. The results of this study suggest that there are gender differences in the conclusions and in the quality of argumentation.

Theoretical background

Gender differences is a widely discussed topic in the field of of mathematics education. Studies concerning primary school mathematics have found gender differences for example in the strategy use and in problem solving and calculation. In the first grade girls were more likely to count on fingers or use counters, i.e to use overt strategies; boys were more likely to use retrieval to solve addition and subtraction problems (Carr & Jessup 1997). Boys are found to be better at problem solving and girls at calculation (Marshall 1984) and girls make different errors than boys in problem solving (Marhall & Smith 1987). It has also been found that boys show greater self-confidence in mathematics than girls (Leder 1992). These and many other findings give us reason to explore the field of gender differences more thorougly.

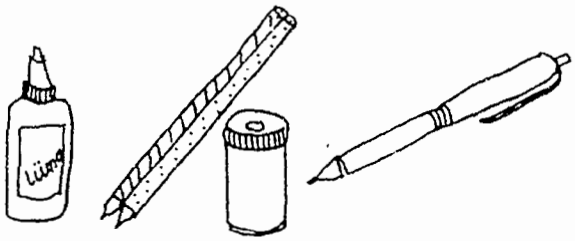
This paper deals with the gender differences in mathematical argumentation. Argumentation in mathematics education has been studied i.a. by Krummheuer (1995). However, we do not know very well whether there are any gender differences concerning the quality of argumentation.

How do primary pupils give arguments in a mathematical situation? Argumentation is understood here as a chain of ideas proceeding from the premises to a conclusion. In a classroom, a common possibility for argumentation is, to show the rationality of one's own action when explaining a solution to a problem.

In the following, the theoretical framework is derived from the idea that mathematical argumentation is regulated by normative aspects (Yackel & Cobb 1996): What kind of arguments are justified, acceptable and valid? Thus the communicative nature of the argumentation is emphasized. It is assumed that the norms are produced in the classroom interaction processes. *Social norms* are general norms which regulate social activity, and they can be applied to any subject

matter. By *sociomathematical norm* Yackel and Cobb refer to the normative aspects of mathematical discussions which are specific to mathematical activity. A sociomathematical norm includes a shared understanding of what constitutes an acceptable and justified mathematical explanation in each community. An example of a classroom's sociomathematical norm is the understanding of what constitutes mathematically elegant or mathematically efficient solutions.

Data collection and analyses



This paper deals with the quality of arguments primary schools pupils gave when they were faced with conflicting or confusing mathematical information. The data was collected by student teachers in nine different schools either in rural areas or in small towns. The total number of pupils was 185 of whom 98 were girls and 87 boys. Half of the pupils were fifth-graders, i.e. 11 years old, but fourth and sixth graders also participated. The following task was posed to pupils:

Pens 7.50

Pencils, 2 in a package 4.50

Glue 35 ml 9.30

Sharper 5.80

Accompanied by the illustration shown here, the following task was given to pupils in one classroom: **Jack buys six pencils. How much must he pay for them?** Arthur says that Jack must pay 27 marks. Lisa thinks that the correct answer is 10 marks and 50 pennies[1]. With which of the children could you agree? Give arguments for your answer.

The pupils were asked to write their answer and argumentation on a sheet of paper. The students teachers read the task aloud as many times as desired to ensure that a pupil's poor reading skills would not prevent him or her from accomplishing the task. The teachers were also asked to make sure that all pupils understood what they were expected to do. In our schools pupils pupils are not familiar with this kind of problems in which none of the suggested answers is correct. The task was mathematically simple, since the mathematic skills were not the main interest. The emphasis was put on the children's reasoning and argumentation process.

A richer and more relevant data could have been collected by recording classroom discussions, but this was not possible in this setting. However, "writing mathematics" is also important. Writing is one possible way to communicate. During the act of writing the writer clarifies and works out his/her thoughts and tries to make them understandable to others (Borasi & Siegel 1994; Shield &

[1] 1 Mark = 100 Pennies

Galbraith 1998). As the data is pupils' written works it is not possible to consider the development of argumentation, but nevertheless, it is possible to see what kind of explanations were used and acceptable in the classrooms' mathematical situations.

Both quantitative and qualitive methods were used in analysing. Statistical analyses were made to calculate the significance of differences. When analysing pupils' arguments I applied the method developed by Stephen Toulmin (1974), in which an argument is seen to consist of different elements. Data provide the starting point on which the conclusion is grounded. This process - from data to conclusion - is legitimised with the help of facts, which are called warrants. The warrants can be supported by some generally known facts, called backing. Krummheuer (1995) also used this method when he investigated the development of argumentation in a classroom.

The whole data (N=185) was analysed qualitatively to seek the patterns in argumentation. First, it was classified by the conclusion and thus three categories (+ blanco category) were formed. Then each of these categories were analysed by the argumentation. All the answers that followed the same-type chain of ideas were classified into the same category. In the beginning there were almost thirty categories, which include inter aliai the categories for work sheets with no answer to the posed question ("With which of the children could you agree?"), without any argumentation and blanco work sheets. In the course of process the categories were gradually reduced. The final analysis include four main categories and eight sub-categories. Each sub-category was described by the terms of Toulmin's model so that the each chain of argumentation was made visible.

Results and typical argumentations

The answers of 50 pupils (27%) were not included into the further analysis, because of the difficulties to follow their reasoning. Half of of them gave no answers at all, some gave answers and arguments without any reasonable logic, and some of students had made so many errors in calculations that it was impossible to them to draw any reasonable conclusions regarding the task. It was not expected that pupils should write their calculation on the work sheet - they were allowed to to do the calculation mentally if the preferred. The main issue was the argumentation. In the course of analysing it turned out that if pupils had made many errors in calculations, in most cases it was impossible to follow their reasonig or at least the intepretations had been very coincidental. So I decided to skip over those pupils. However, minor errors in calculation did not matter. There were exactly as many boys as girls among the skipped pupils. No gender differences were found ($\chi 2$ = 0.11 , df = 1) in this respect.

In the following I will discuss only the responses of those 135 pupils whose reasoning it was possible to follow. Of them 73 (54 %) were girls and 62 (46 %) boys. The task allows three possible conclusions to be arrived. Differences between

boys and girls are significant (χ^2 = 6.85 , df=2 0.05>p>0.02) in the conclusion. Table 1 shows the division of different conclusions among pupils.

Conclusion	*Girls*	*Boys*
I disagree with both	63% (46)	66% (41)
I agree with Liza	37% (27)	29% (18)
I agree with Arthur	0% (0)	5% (3)
Total	100% (73)	100% (62)

Table 1. The precentages of pupils' different conclusions.

Did the gender matter in the quality of argumentation? The main types of argumentation were divided in four categories which were labeled: 1) mathematical logic, 2) I know, 3) Lisa is nearer, and 4) Arthur is reasonable. First, the differences between argumentation and sex were analysed by $\chi 2$ -test. The result of this analysis suggested significant differences ($\chi 2$ = 9.075, df = 3, 0.05>p>0.02). Then a more detailed analysis was made by comparing the differences between proportions.

Most pupils -- 63% of the girls and 66% of the boys – stated they would disagree with both Lisa and Arthur. There were two main routes to arrive the conclusion "I disagree both Lisa and Arthur". Many pupils - and majority of them were girls - used arguments having the nature of mathematical reasoning: "*I disagree with both of them, because if the price for two pencils is 4,50 then for six pencils Jack must pay 3 x 4,50 (Jack needs 3 packages). So althogether 13,50.*" They started from the mathematical information and facts and proceeded step-by-step. The final conclusion was drawn by combining the data known from the solutions given by Lisa and Arthur with their own mathematical reasoning. 34% of girls and 26% of boys used this kind of mathematical reasoning in their argumentation. This difference is not statistically significant (z=1.01, p=0.08).

The less qualified arguments were based on pupil's own performance. This type of argumentation was more common among boys (40 %) than among girls (29 %) and the difference is significant (z = -1.39, p = 0.04). A typical argumentation was: "*I cannot agree either of them, because I got a different answer.*" Figure 1 displays an example of this kind of argumentation.

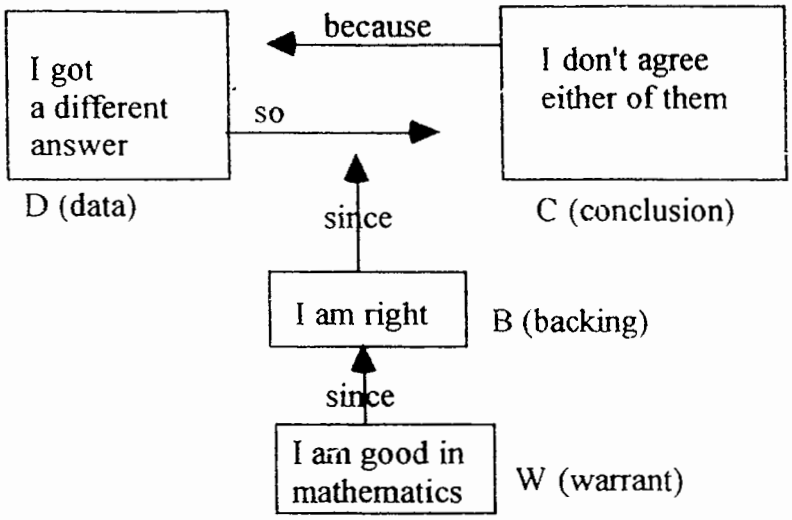


Figure 1. An example of argumentation

The distinctive aspect between the categories "mathematical reasoning" and "I know" was the quality of argumentation. In the first category the arguments had the basis in the mathematical reasoning: The pupils showed how they arrived the conclusion and proved it to be the correct one. It is the kind of reasoning that a mathematician does. In the second one the argumentation is grounded on the authority-based belief. A mathematician would never accept an argumentation: "It must be so, because I have calculated it and I know how to do it:"

32 % (=46 students) wrote they could agree with Lisa. However, majority of them stated that neither Lisa nor Arthur was right, but if they had to choose, they would side with Lisa, because her answer was nearer to the right one. This was the main argument. This conclusion was more common among girls than among boys, but the difference is not statistically significant ($z = 1.01$, $p = 0.08$). However, in this conclusion there were no differences in the quality of argumentation, all the arguments very were similar and so independent of gender. Only a few pupils - and all of them were boys - gave their support to Arthur, and the arguments given by them were very reasonable. They were sympathetic to Arthur and the error he had made: "*He did not notice that there were two pencils in the box. He has calculated the price for six boxes correctly.*"

The normative aspects of argumentation

I distinguished between two sociomathematical norms. The first sociomathematical norm (type i), which is based on the arguments of those students who agreed with Lisa, can be formulated as follows: "*The result which is closest to the right answer,*

is a better one." One third of the pupils used this explanation and regarded it valid and justified. This norm is interesting: Although Lisa's process was not in any way reasonable, pupils - however - though that her answer is better than Arthur's reasonable process but wrong answer. This gives us reason to believe that in classrooms' mathematical discussion products are more valuable than processes. Every pupil who applied this explanation carried out the calculations correctly and stated that, in fact, neither Lisa nor Arthur was right, but they were ready to give their support to Lisa.

The second sociomathematical norm, mathematical reasoning, (type ii) appears in some of those explanations where pupils stated they would disagree with both Lisa and Arthur. These pupils generated their own opinions and their arguments were based in the first place on mathematical reasoning. One third of the pupils applied this norm. This kind of sociomathematical norm gives us reason to believe that mathematical argumentation is practiced in some classrooms.

My hypothesis was that social norms could not be seen in pupils' written products. However this belief turned out to be wrong. I could find three social norms that regulated the nature of argumentation. There were five teaching groups with a great number of pupils who justified their decisions primarily on the basis of their own expertise or the lack of expertise of others (type I). A typical argument was: *"I disagree with both Lisa and Arthur because I got a different answer."* or " ... *because both of them have calculated incorrectly"* (but in our language the meaning of "incorrectly" is stronger). In these teaching groups a valid argument seems to be the fact that the pupil has arrived at a different solution. Some of them have secured their backing by the fact, obviously well-known in their classroom: *"I am right, since I am good in mathematics."*

We could say this norm is social, rather than sociomathematical, because it is grounded more on status or supposed expertise than on the efforts to show the mathematical basis. Furthermore, these explanations are often related to efforts to convince the teacher or the reader that the actor is innocent: *"I don't want to agree with either of them because both of them are wrong."* This kind of explanation has actually nothing to do with mathematics, and it can be applied in any situation to explain the rationality, if it is accepted in the classroom.

The second social norm emerges only connected to the first one. This norm is very gender related. In all those teaching groups where - among boys as well as among girls - the social norm of one's own expertiness or other's inexpertiness was accepted, the norm of unsureness can be identified among some girls. The girls who have very well carried out the calculations and given very elegant mathematical arguments may state in the end: *"Naturally I may have made a mistake too"* or " *Maybe I am wrong"*.

The third social norm was encountered in one teaching group. This norm includes the idea that you should understand other people. Regardless of what kind of

mathematical arguments the pupils in this group applied, they tried to understand the actions of both Lisa and Arthur: "*Arthur has made a little mistake, but it could have happened to anyone,*" or "*I don't know how Lisa got her answer, but it must be some kind of annoying and human mistake.*" The norm was independent of gender.

The quality of arguments was not dependent on pupils' age as I have shown in an earlier paper (Pehkonen 1998). Actually there was more variation across different teaching groups than across grades. Similar results have been reported by Yackel and Cobb (1996). The patterns of argumentation and norms could be very similar among the third graders than among the fifth-graders. But there were teaching groups of fifth-graders (or third-graders) each of whom had its own norms and ways to argumentate. And there were groups where it was not possible to distinguish any norm in the written data.

Some teaching groups were very able to give arguments and others were not. It seems obvious that some teachers have trained their pupils to argue and express their opinions. Argumentation can be seen primarily as a discourse technique (Krummheuer 1995, 238) which can be learnt.

Concluding remarks

Boys based their argumentation on their own expertise more often than girls and girls preferred mathematical reasoning more often than boys did. These findings are in line with results of previous research which indicate that girls are better at calculations and algorithms (Armstrong 1981; Marshall 1984). The findings of this study suggest us that girls are more able to use these skills in their argumentation to make them mathematically more elegant. Further research with more representative samples will be needed to comfirm these suggestions.

Gender influence on the normative aspects of argumentation could be seen in some teaching groups. Gender differences emerged in those teaching groups where the social norm was that acceptable mathematical accounts can be based on one's own supposed expertise or on the lack of others' expertise. In these - and only in these - teaching groups there were girls who were willing to suspect their solutions and reasoning - even when they were mathematically elegant and well grounded in logic. These findings support previous reseach which has pointed out gender differences in self-confidence. Boys are more confident (Leder 1992) and tend to dominate situations in class rooms (Carr & Jessup 1997).

The results of this study help us to get a more detailed picture of the nature of gender differences in mathematics education. The next question is what is the influence of teacher who belongs to the social setting of class room? What is the mechanism how teachers influence to the accepted, valid and justificated explanations in mathematic class rooms and so to the norms that emerge?

OBSTACLES IN APPLYING A MATHEMATICAL MODEL: THE CASE OF THE MULTIPLICATIVE STRUCTURE

Irit Peled - University of Haifa
Leonid Levenberg, Ibby Mekhmandarov, Ruth Meron - Center for Educational Technology, Tel-Aviv
Alexander Ulitsin - Ministry of Education, Jerusalem

Third and fourth grade children, who started learning about multiplication in second grade, do not tend to use multiplication in multiplicative situations. This study looks at children's choice of mathematical models in different non contextual displays: equal groups, rectangular arrays, and a rod model (which they use in class). The findings show that many children do not perceive the displays as representing multiplicative situations. Even children who exhibit knowledge of multiplication facts do not apply their knowledge in these tasks. Instead, they use addition and counting strategies.

An important goal in teaching mathematical operations is the development of schemes, such as the additive scheme or the multiplicative scheme. These schemes, or structures can act as mathematical models of given situations. Usually the situation does not uniquely determine the structure, nor does it easily hint that a certain mathematical model can be used (although conventional school word problems might imply that it does). We teach children basic operations with the intention that they apply them in different situations. We also expect to see progress over time in the choice of a model, i.e. in the ability to apply more efficient models in the relevant cases.

Given a rectangular array of objects with the task of finding their total number, it is expected that a young child will count the objects one by one. An older child will count the elements in each row and then add up the rows. An even older child is expected to realize the size equivalence of the rows, i.e. the repeated addition structure and then add or multiply, or recognize the rectangular array structure, and multiply the number of rows by the number of columns.

The above description talks about different structures, which have been identified by several researchers. A lot of the research on multiplicative structures deals with the categorization of multiplicative situations (Vergnaud, 1983; Schwartz, 1988; Nesher, 1988) and with children's word problem solving (Fischbein et al., 1985; Kouba, 1989; and many other significant works reviewed by Greer, 1992).

Some of these researchers have focused on younger children's work. Carpenter et al. (1993) show that even kindergarten children can solve some types of multiplicative word problems. Kouba (1989) looks at solution strategies of children in grades 1-3, and is interested more in the nature (and quality) of their solutions than in the question whether they can answer a given problem correctly. Kouba uses equivalent set problems (later termed repeated addition problems or mapping rule problems) and finds that children use a variety of counting strategies. She also observes that the intuitive model that children seem to have for equivalent set problems is linked to the intuitive model for addition as both involve building sets and then putting them together.

Similarly, Mitchelmore and Mulligan (1996) show that during their second and third grades children use many different strategies in solving multiplicative problems. These strategies include quite a lot of addition and counting calculations. However, they also find that over time the strategies are chosen more efficiently.

These different research findings suggest that children do not necessarily use multiplication in solving multiplicative word problems. Many children use addition and some choose to use a long counting process.

It is often claimed that children are efficient and use a more effective tool or a shorter route once they possess it. Such a behavior is described by Woods, Resnick, and Groen (1975) in the case of choosing between solution strategies in subtraction (e.g. going two steps backwards in 9-2 while counting up from 7 to 9 in 9-7). This behavior is also evident in Siegler and Shrager strategy choice model (1984), where children choose to retrieve an addition fact rather than count, when they reach a reasonable degree of confidence.

If children tend to be efficient, why do they not use multiplication but instead do quite a lot of counting or adding? Several explanations can be suggested: They are not able to identify the structure of a multiplicative word problem as a multiplicative structure, or they do recognize a multiplicative structure but do not know the relevant multiplication facts. In this work we differentiate between these two obstacles by looking not only at children's solution strategies but also at the way they perceive different situations.

Most of the existing research, including the works described above, involves word problems. In solving word problems children are engaged in text interpretation, a stage which might contribute to the difficulty in identifying the efficient structure (although in some word problem types the verbal description contains clues for identifying a multiplicative structure). In this work we avoid this stage by looking at children's behavior in different non-contextual displays of objects. As we show

below, the use of a multiplicative structure is scarce even in these non-contextual tasks.

PROCEDURE

Fifty four third and fourth grade Israeli children were individually interviewed. The children were chosen from regular classes that use the same curriculum, called "One-two-and three". They were identified by their teacher as having some minor difficulties in mathematics. This curriculum usually introduced beginning ideas about multiplication at the end of first grade, and further develops the concept in second grade. A sequence of concrete models is used in order to represent multiplication: a "train" of equal rods, the same rods in a rectangular configuration, and eventually an array of dots. Using the array model the children discuss the number of rows and the number of dots in each row, and apply the model in different problem solving situations.

The purposes of the interview were: To find what mathematical model children use spontaneously in perceiving a given display, which has a multiplicative structure, to observe which strategy they apply spontaneously in calculating the amount represented in the display, and to find how they calculate multiplication facts in multiplication number problems. Eventually these findings were used to investigate the relation between knowing multiplication facts and recognizing and using multiplication in different situations.

In the course of the interview each child was presented with different displays, asked to describe what she sees, and then requested to find "How many there are". The order was: Equivalent sets, a "train" of equal rods, a rectangular array, and some contextual situations (involving eyes and fingers). Each display was presented several times with different numbers (4x5, 10x5, 4x2, 10x2). Here we present the results for the case of 4x5, (complete results to be presented in an extended article).

The request to describe what they see was intended for investigating how children perceive the display. The child was given a card with a dot configuration and asked to tell the interviewer, who supposedly could not see the card, what to draw.

Several additional tasks included: representing a given expression, such as 4x5, using rods, inventing a story problem to a given expression, and finding some multiplication facts, e.g. 4x5. The questions that mentioned multiplication came only at the end of the interview in order to avoid any hints about the choice of an operation in the different displays.

RESULTS

Children's conceptions were deduced from their display descriptions and explanations during the interview. In several cases a child was considered to be perceiving the display as a multiplicative structure even when an additive or a counting strategy was used in the calculation of the total amount of objects. In the following excerpt a third grader, Lorry, tries to figure out the total amount represented by a "train" consisting of four '5-rod'-s, as shown below:

yellow	yellow	yellow	yellow

I: What do you see?
L: Yellow rods of 5.
I: And what else? (no answer) How many rods?
L: 4.
I: How much is it?
L: Should I do 4 multiplied by 5 [note: In Hebrew 4X5 can be read as '4 multiplied by 5', or as '4 times 5'. Here she used the word 'multiplied'. Further on when she calculates the amount by addition, she uses 'times'].
I: Yes.
L: (Thinks for a while) 25.
I: How did you do it?
L: I did four times five, 5 plus 5 that's 10, and another 5 that's 20, and another 5 that's 25.

Table 1 presents the percentages of students who perceived the different displays of 4X5 as multiplicative situations. It also shows these percentages separately for students who could do a mental calculation of 4X5 (using either fact retrieval or repeated addition), and for those who could not do a mental calculation (e.g. had to use objects). It should be noted that the columns are not disjoint. A child who perceived a multiplicative structure in one display, could also see it in another display.

Table 1: Children exhibiting multiplicative display conceptions.

display / calculation	equal sets		rods		array	
	yes	no	yes	no	yes	no
mental	7	25	5	27	10	22
n=32	(22%)	(78%)	(16%)	(84%)	(31%)	(69%)
non-mental	0	22	2	20	2	20
n=22	(0%)	(100%)	(9%)	(91%)	(9%)	(91%)
all students	7	47	7	47	12	42
n=54	(13%)	(87%)	(13%)	(87%)	(22%)	(78%)

The data in Table 2 shows the different calculation strategies in each of the displays for children who could figure out 4x5 mentally. This subgroup of children includes those who could potentially utilize their knowledge in the different displays.

Table 2: Strategy choice in different situations for children who could mentally multiply 4x5.

Strategy / Situation	multiplication	addition	counting	other	total
equal sets	6 (19%)	18 (56%)	6 (19%)	2 (6%)	32 (100%)
rods	4 (13%)	19 (59%)	-	9 (28%)	32 (100%)
rectangular array	8 (25%)	9 (28%)	9 (28%)	6 (19%)	32 (100%)
contextual cases	7 (22%)	20 (63%)	3 (9%)	2 (6%)	32 (100%)

As can be seen in Table 2, less than a quarter of the children who calculated 4x5 mentally, used multiplication in each of the different display calculations. Our data (not presented here) details this distribution separately for children who did the calculation of 4x5 by retrieval, and those who used addition. Most of the children who used multiplication in the display calculation were those who used it in the calculation of 4x5.

Children's answers and explanations contribute some interesting information on the way they perceive the given representations. The following are two of these examples:

1. Post hoc identification of a multiplicative structure:

Given a rectangular array of 4x5 X-s , Ron (a fourth grader) draws it correctly from memory. The task is followed by this dialog:

How many rows are there? 4
How many X-s are there in each row? 5
How many X-s altogether? (Ron thinks for quite a while) 20
How could you tell? I did 4x5.
Did you do it in your head? No. I counted the X-s.
So why did you say 4x5? Because it's 20.
But 2x10 is also 20. (Ron hesitates a moment) Ah! But here (in the array) we have 4 and also 5.
So why did you count earlier rather than do 4x5? Because I was in a hurry...

This dialog might initially suggest that Ron identified the multiplicative structure, or at least the repeated addition structure of the array. However, the time it took him to figure out the total amount, his own account on his counting, and his surprised discovery of the connection to the 4 and 5 lead to a different interpretation. Ron suggested the expression 4x5 after counting 20 X-s in the display. He might have chosen 4x5 because it is an expression that yields 20. It is probably during the discussion that he suddenly saw how the array dimensions related to the expression.

2. A selective application of multiplication:
Some children used addition or even counting for small amounts, while applying multiplication for larger amounts. Other children had different reasons for the choice of a strategy, such as: *I counted [even though I used multiplication in another situation] because I was in a hurry.... [and would have wasted time if I stopped to analyze the situation].*

DISCUSSION

Third and fourth grade children participating in this study showed very little use of multiplication strategies in non-contextual displays, while multiplication was the more efficient strategy. These findings could only partially be attributed to the fact that most of these children did not know the relevant multiplication facts. This was revealed by investigating the way children perceive the displays. Only a small proportion of children perceived the displays as multiplicative structures. Even among those who could figure out a multiplication fact mentally, only about a third identified the multiplicative structures. The conclusion that the blame does not lie in absent knowledge of facts is also manifested by the choice of strategies in figuring the amount in different displays. Less than a quarter of the children who could figure out the facts mentally used multiplication, a large proportion of them used addition, and some even counted.

The children in this study were identified by their teachers as having some difficulties. Yet the displays presented to them were familiar representations, the same ones through which multiplication was defined to them in first and second grades. If fact retrieval is not the main obstacle in applying multiplication, perhaps the difficulties involve the nature of the displays or the nature of instruction.

The identification of a multiplicative structure is quite complex. In equivalent set situations, for example, one has to be able to perceive all the given sets at the same time and recognize their equivalence. In deriving the number expression one of the factors is an intensive quantity, appearing not just in one set but in each of the sets. The second factor is

not even represented as a simple set. Rather, it is the number of the sets in the display. This complexity makes it difficult for children to identify and apply a multiplicative structure in a given situation.

The interviews disclose some of the display difficulties. In additional tasks, where children were asked to use manipulatives and represent an expression, such as 3x4, some of them tended to represent both numbers. Thus, for example, one of the children used rods and built a train consisting of a single 4-rod and three 3-rod -s, as follows:

(4)	(3)	(3)	(3)

When realizing that something was wrong because it does not measure 12, as expected, he changed it to one 3-rod and three 4-rod -s. He was frustrated upon realizing that it still does not measure 12. Another child represented this expression by building an array consisting of four rows, with three 3-rod -s in each row.

In the course of class instruction children are directed to those elements in the display which represent the multiplication factors. If we want them to develop the ability to look at a given display and choose an efficient mathematical model, we need to teach them to analyze situation structures and detect relevant features of these situations. Our instruction should include tasks that give them the opportunity to develop the ability to analyze and apply the mathematical models which are available to them.

A SCHEMA-BASED MODEL FOR TEACHING PROBLEM SOLVING

George Philippou and Constantinos Christou
Department of Education, University of Cyprus, Nicosia 1678

In this report, we develop a model for teaching mathematical problem solving based on schema knowledge. The model makes extensive use of the graphical representation of problems to enhance students problem-solving schemas. Instruction proceeds through four successive phases: the recognition, interpretation, strategy development, and application. The design extends for about twenty-four teaching periods that spread over ten weeks. The model was field-tested in Grades five and six. The results presented in this report refer to students in Grade 5 and showed significant differences between pre-test and post-test scores in favor of the experimental group. This is an encouraging indication that the model is effective in improving students' problem solving ability.

Introduction and aims

In recent years problem solving has been constantly at the heart of mathematics learning and plays a central role in mathematics education. During the past decades, considerable progress has been made in understanding the mathematical and linguistic structure of several types of word problems and many of the factors that affect their difficulty were specified (De Corte & Verschaffel, 1987; Riley & Greeno, 1988; Nesher and Hershkovitz,, 1994). Research has developed three different types of "instructional models" for teaching word problems. Models of the first type emphasize explicit teaching of the distinct phases of problem solving and some general problem-solving strategies and heuristics (Polya, 1973). A second type of models focuses on the linguistic structure of the problems to make it explicit and less difficult, aiming at facilitating students to classify and connect the new to existing in the memory schemata (Rudnitsky, Etheredge, Freeman, & Gilbert, 1995). A third approach draws attention to problem posing i.e., to the process by which pupils are guided to develop understanding by actively working out given information to synthesize their own problems (NCTM, 1989). These efforts have done little to improve pupils' ability to solve mathematical problems (Lester, 1994); word problems continue to be the cause of frustration to teachers and students alike.

Though schemas knowledge is expected to enhance problem solving ability, Cooper, Baturo, and Dole (1998) found that instead of the expected schema based classification, proficient solvers of percent problems used computational proficiency. Marshall (1995) developed a comprehensive proposal for teaching and assessing problem solving, which is grounded on schema theory and the acquisition of basic schemas by the learners. Our goal was to develop and field-test an instructional approach of problem solving by extending Marshall's ideas to encompass in an integral form the basic characteristics of the three instructional models mentioned above. Furthermore, the proposed model incorporates some of the ideas of concept mapping which have been used successfully in language, arts, and social studies for years, as a way to teach students how to organize information in these subjects.

Theoretical background

From a developmental perspective, children's thinking about problem solving is part of a more general way of knowing. Of particular relevance to this research are the schemas proposed by Marshall (1995) that form a major foundation for problem solving in the primary grades.

"Schema" is a Greek word with multiple meanings most of which derive from Plato and Aristotle. The literal meanings of schema include form, figure, shape and diagram, while the metaphorical meanings refer to a means of organizing characteristics that might be used as frameworks unifying objects of the same structure. Marshall (1995) argues that the two main dimensions of the construct of schema focusing on memory and action might be reconciled. The schema is structured by our experience and it also structures it. Though we do not fully understand how memory works, schema is one means by which related information is retained in human mind. Schemas from the same domain are connected to each other and they are frequently displaced as networks of cohesive units. Thus, schema may be thought of as a storage and consequently retrieval mechanism.

Figure, the literal meaning of schema, is a geometrical representation of information. Figure understanding is an expression of problem thinking and, as such, it is a natural function of the human mind. It is a powerful visual technique, which provides a key to understanding the structure and the linguistic forms of a mathematical problem and helps students to construct understanding of mathematical problems, clarify their thinking, and justify their ideas.

The first steps toward a successful solution of a problem involves understanding the semantics of the problem, producing a mental representation, and relating this structure to existing schemata; a solution plan can only subsequently be formulated. Mayer (1987) breaks down the phase of problem representation into problem translation, which involves converting each sentence into an internal mental representation, and problem integration, which involves combining the information into a coherent unified structure. The final outcome of repeated similar problem experiences is the formation of a relevant mental schema, which subsequently becomes part of the solver's repertoire. Relating a new problem to an existing schema, the solver analyzes the features of a problem by transcribing the main ideas with the purpose to learn through organizing his thoughts. A problem schema could function as a means to describe and classify the elements of a story problem and hence conceptualize the relationships and connections among them. In other words, the problem schema serves as a teaching and learning activity.

The real value of mapping a problem onto a schema lies in the visual representation of the relationships among the elements of a word problem. Via this tool, the linguistic form of the problems is explicitly depicted and is visible to the students constructing the maps as well as to the teachers. A student-constructed

schema is the "hard copy" of his/her understanding of the syntax and relationships of the problem.

The instructional process leading to problem schemata constitutes a practical form of analyzing (conceiving) the particulars of the problem and next connecting (integrating) the parts into a holistic mental representation. Schema construction may be viewed as a natural function of the human mind, it is a process of transforming the script into a more tangible graphic form, which may provide a key to understanding the mathematical structure of the problem. Schema serves as a vehicle for developing problem solving abilities, offers pupils an opportunity to encounter various linguistic forms and situations. It helps pupils to construct deeper understanding of mathematical problems, clarify their thinking, and justify their ideas. It further provides teachers and students a useful tool to monitor progress of students' understanding of the process. The schema enables students to investigate their own solutions, and it allows them to feel successful at the end of the lesson, as long as they have tried valid strategies. Problem schemas may lead to rich discussions among students, as they explore relationships among the pieces of information comprising a problem, clarify misconceptions, and develop understanding in a meaningful way.

An overview of the intervention program.

A number of instructional programs emphasizing problem solving have been developed in recent years (Lester, 1994; Nesher and Hershkovitz,, 1994). For the most part these programs encouraged an active role for both students and teachers, promoted the learning of problem solving strategies, and drew attention to solving problems of different schemas. In addition to these characteristics, the present program had the following characteristics:

- It focused on the schemas and diagrams of arithmetic word problems based on the work reported by Marshall (1995).
- It emphasized extensive experience with word problems by asking students to identify the essential parts of a story, specifying the complete and incomplete elements of the problem.
- It emphasized the development of students' abilities to recognize, apply, select and create a schema.
- It incorporated a specific teaching strategy for problem solving by integrating the diagrammatic representation of a problem.

According to the main targeted abilities the problem solving experiences were organized in four distinct though overlapping phases: The identification or recognition phase, the elaboration or interpretation phase, the strategy planning phase, and the application or execution phase.

Phase 1: The identification of the main elements and features of a problem is the most important knowledge for schema activation; it is this understanding that contributes to the initial recognition of a situation or a story. The structure of each category of word problems involves some essential features that are repeated in all

similar situations and problems. Thus, pattern recognition occurs as a result of the simultaneous cognitive processing of many features (Marshall, 1995). The objective of this phase was to help students develop the basic identification knowledge. The students were expected to learn at this phase that there are four basic problem-situations (change, compare, group, and analogy schemas), and to identify the essential nature of each schema. To this end, during the first few lessons students were introduced to problems that underlie the four basic situations and were asked to discuss the salient features of each situation as well as the relationships among the elements of the problems. After all the situations had been introduced students were encouraged to identify problems and classify them into one of the four schemas.

Phase 2: The elaboration knowledge contains discussion of the main characteristics or features that are essential for the development of each one of the specific schemas. The students explain in their own words the details that are distinct to each schema. Through the elaboration knowledge, the students were expected to create relevant mental models about the problems. The identification and elaboration knowledge constitutes a framework that allows students to form a hypothesis about the schema into which a problem belongs, and tests it.

During the second phase teachers introduced the idea of representing the relationships of problems through a diagram aiming at helping students develop the elaboration knowledge. A schema diagram used in the study for the change problem is shown in Figure 1. Each schema can be represented in its own unique way. Thus, teachers spend about lessons on each schema discussing with students the three necessary components of each diagram. A broad description for each part of the diagram was undertaken so that students perceive what the shapes represent in each schema and what is the function of the arrays (see Marshall, 1995). Several examples were treated in the classroom, to help students understand the various situations that arise according to which part of the problem is the unknown. Both phase 1 and phase 2 dealt with one-step word problems to acquaint students with the structure of each schema

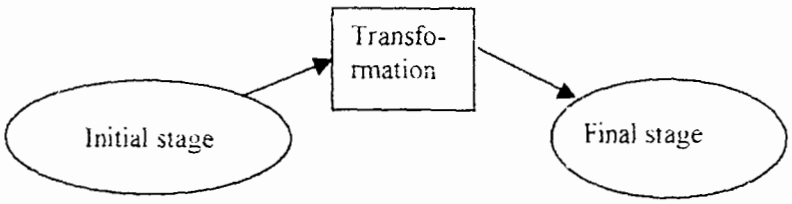

Figure 1: Diagrammatic form of the Change schema

Phase 3: The evaluation of the hypothesis is the result of the process of elaboration. The planning knowledge refers to ways through which students make decisions about the schemas that are appropriate for the solution of the problems at hand. Phase 3, which is the planning phase, involved students in two-step word problems, which are combination problems. Instruction in this phase focused on the need to identify the

two situations that compose each two-step problem and on the way each problem can be mapped. Given the presence of two situations in a single problem, the students are expected to acquire the necessary knowledge for selecting which one to examine first and to examine how two situations are related within a problem. Figure 2 illustrates the instruction for one two-step problem, which involves two change schemas. The two diagrams emphasize that one of the values from the first situation will of necessity be part of the second situation. This is graphically demonstrated by drawing both diagrams and linking the parts that contain the same value with an arrow. This is the most crucial phase, since the students must acquire the skills needed to formulate a plan of action (about twelve lessons were devoted to this phase).

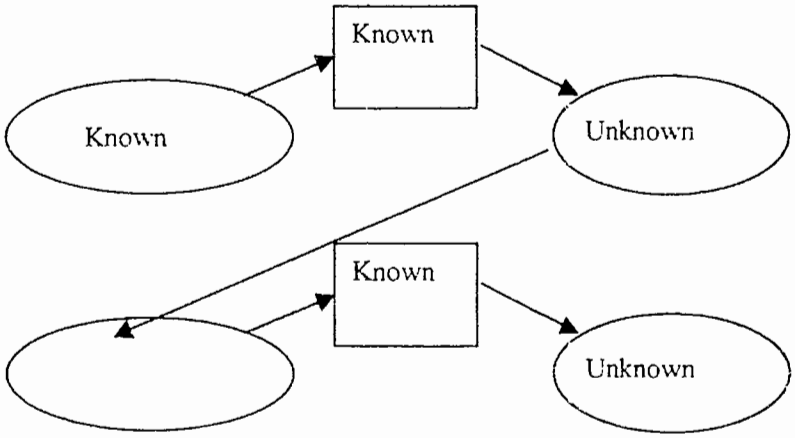

Figure 2: Diagrammatic form of the Change-Change schema

Phase 4: The execution or application knowledge consists of the techniques and skills that are necessary for carrying out the selected schemas. In the case of word problems, the execution knowledge is limited to the four arithmetic operations of addition, subtraction, multiplication and division. During this phase students developed their ability to execute the appropriate operations to give reasonable solutions to the problems.

Procedure

We used an experimental-control design. The subjects were 310 fifth graders from ten intact classes. Five classes of students comprised the experimental group, and the rest comprised the control group. The study took place during the first term of the 1997-98 school year. The intervention program was taught to the experimental classes during the regular mathematics sessions allocated in the weekly timetable. During the same period the control classes continued to follow the regular instruction on the same problems as those involved in the experimental program

The teachers who taught the experimental classes had a short course at the University just to get acquainted with the basic constructs of schema theory, and the way they were expected to work with their students. All the classes were given the

same pre-test and the same post-test, which measured students' ability in solving one-step and two-step word problems. These tests contained items designed to measure learning as well as transfer of knowledge. The pre-test and the post-test comprised of two parts each, the first one consisting of ten one-step word problems and the second one consisting of twelve two-step word problems The subjects completed a retention test one month after the post-test. All writings of the pupils during these lessons were collected and will be analyzed in a later stage. However, the results that follow refer only to the twelve two-step problems of the pre and post-tests.

Results

For the analysis of the data a structural means model was used. The model is a representation of the two samples of students; the first sample is the experimental group, while the second is the control group. Figure 3 shows the path diagram used in the present study, where the pretest scores can be conceived as indicators of the latent variable F1. Ability at post-test was represented by the latent variable F2, which was also a function of the ability at the pre-test. The right part of the figure gives the constant V999, which was presumed to affect each of the twelve two-step problems in the pre and post-tests, reflecting their intercept (see Bentler, 1995). V999 also affects directly the factors F1 and F2, representing the intercepts of these factors. Factor loadings, factor regressions, and variable intercepts were constrained to be equal across experimental and control groups. Factor intercepts were fixed at 0 for identification in the control group, and were free to be estimated in the experimental group.

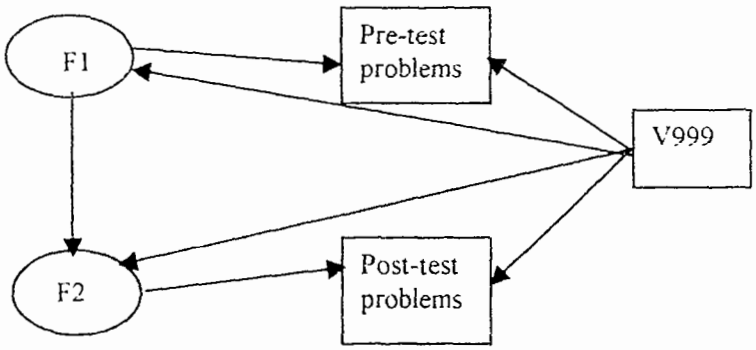

Figure 3: The Structural Means Model used in the Study

As reflected by the iterative summary, the solution converged quite smoothly, and the goodness-of-fit statistics showed the model to be a very good fit to the two-group data, as indicated by a CFI (Confirmatory Factor Index) of .934. To answer the primary question of whether the latent construct means for the two groups are significantly different, we turned to the construct equations, which are presented in Table 1. The parameters of interest in answering this question were the factor intercepts that represent the latent mean values. Because the control group had their

parameters fixed to zero, we concentrated solely on estimates for the experimental group (Table 1).

The regression of F2 (post-test scores) on F1 (pretest scores) was significant indicating that the experimental group did better than control group on the post-test (.971, Z=10.036). The experimental group students were higher in pre-test to begin with, when .078 was compared to control's value fixed to zero. However, the difference between the two groups at the pre-test was found to be non statistically significant, (Z=0.875) and thus we could conclude that both groups were initially equal in ability to solve problems at the beginning of the study. Thus, the experimental program produced a positive significant impact (.275) on students ability to solve word problems (Z=2.124).

Table 1

Construct Equations with Standard Errors and Test Statistics

F1 =	.078*V999	+ 1.000 D1	
	.089	(SE)	
	.875	(Z -score)	
F2 =	.971*F1	+ .275*V999	+ 1.000 D2
	097	129	(SE)
	10.036	2.124	(Z -scores)

Conclusions

We began with the premise that schemas are basic mechanisms for learning and therefore, instruction ought to facilitate students develop strong schemas (Marshall, 1995). The proposed instructional model for problem solving was based on schema theory. Throughout the instructional phases students were encouraged to construct meaning and knowledge by analyzing and synthesizing the problem text, on the basis of schematic representation, and to develop the ability to work with various linguistic forms and become acquainted with the mathematical structure of relevant problems. Much of the process involves visual representation that enhances connectivity of the common characteristics of the problem. Thus, we may hypothesize that individual student and group activity with visual forms can anchor the schema development. The schematic representation of a problem could be used as a means of getting pupils make sense and communicate their understandings to make it open to inspection and scrutiny.

The results of the present study provide us an encouraging indication that the instructional model for problem solving based on schema theory, is effective in improving students' problem solving ability. The study provided evidence that the students in the experimental group acquired knowledge about problem solving in a rather short period of time. Another advantage of the model is the possibility to monitor student's abilities and weaknesses. By simply looking at the drawing

constructed by the student one can pinpoint misunderstandings about the mathematical relationships in the problems, possible misinterpretation of concepts, deficiencies in the problem representation or the strategic planning of a solution. For example, the teacher can identify the pupils who are unable to solve a problem of a specific structure when they use the inappropriate figure.

In light of the differences in performance observed between the experimental and control groups, pertinent research questions need to follow up. First, further analyses of the data will follow to provide us with insight of what categories of problems contributed most to the development of students' ability to solve problems. Second, which of the four phases was of greater importance in developing the problem schema. In addition, several points might be examined concerning involvement and relevant characteristics of participant teachers.

*This paper describes an analysis of student constructions of formal theory in university mathematics. After a preliminary study to establish initial categories for consideration, a main study followed students through a twenty-week Real Analysis course, interviewing individuals at regular intervals to plot the growth of their knowledge construction. By focusing on the students constructions of definitions, arguments and images, two distinct modes of operation emerged—**giving meaning** to the definitions and resulting theory by building from earlier concept images, and **extracting meaning** from the formal definition through formal deduction. Both routes may be successful or unsuccessful in constructing the formal theory.*

Advanced mathematical thinking is so vast an enterprise that different individuals focus on different kinds of activities. One mathematician might focus on "thinking hard about a somewhat vague and uncertain situation, trying to guess what might be found out, and only then finally reaching definitions and the definitive theorems and proofs." Another may extend formal theory already developed by "getting and understanding the needed definitions, working with them to see what could be calculated and what might be true to finally come up with new 'structure theorems'," (MacLane, 1994, p. 190–191). The division of labour between those "guided by intuition" and those "preoccupied with logic" was noted by Poincaré (1913), citing Riemann as an intuitive thinker who "calls geometry to his aid" and Hermite as a logical thinker who "never evoked a sensuous image" in mathematical conversation (p, 212).

So how can we expect students to fully understand all the processes of advanced mathematical thinking when mathematicians themselves must specialise in only part of the total enterprise? This research project began with a preliminary study analysing written work and interviews with students to establish basic categories for analysis. It was founded on theory in the literature of advanced mathematical thinking (e.g. Tall, 1991, and subsequent developments). Few of the students concerned proved to have a grasp of the formal theory, exhibiting imagery already studied in the literature. The main study was designed to cover a wider spectrum of students, including highly successful ones. Students were interviewed at intervals on seven occasions through a twenty week first year course on Real Analysis. The methodology uses a form of theory construction following the style of Strauss (1987), Strauss & Corbin (1990). It begins by reviewing data and attempting to categorise it, re-evaluating the categorisations to fit the data collected until it falls into a natural structure that is grounded in the available data.

1230

Preliminaries

A preliminary categorisation was considered in which students:

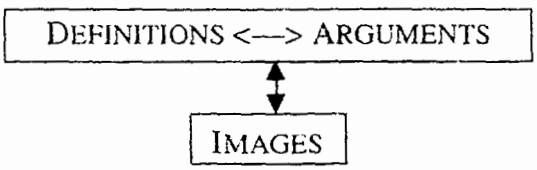
1. become acquainted with the definition,
2. use the definition to deduce results,
3. use the results in further theorems to build up systematic theories.

This may be summarised under the successive headings:

1. DEFINITIONS,
2. DEDUCTIONS,
3. SYSTEMATIC THEORY.

However, the cognitive processes proved to be more intimately interconnected. To truly understand the nature of a definition requires the use of deductions to construct its implications. There is therefore an important interplay of the form

DEFINITIONS <—> DEDUCTIONS.



To take account of this observation, Bills & Tall (1998) defined:

> A (mathematical) definition or theorem is said to be *formally operable* for a given individual if that individual is able to use it in creating or (meaningfully) reproducing a formal argument.

In a preliminary study, Pinto (1998) analysed the final assessments of twenty student trainee teachers. Only *three* based any arguments on definitions and only *one* used a formal definition in an operable manner. The remainder gave informal justifications often based on a particular case. To take account of this spectrum, the heading DEDUCTIONS was modified to ARGUMENTS to include all types of justification, and the main study focused on DEFINITIONS, DEDUCTIONS and underlying MISCONCEPTIONS. The negative tone of the third category was later modified to focus on:

- DEFINITIONS,
- ARGUMENTS,
- IMAGES.

The first two headings were analysed in turn with each being related to underlying concept images as follows:

The students chosen for the main study were selected using a test designed to provide a full spectrum of students following a first year pure mathematics course including potential high and low achievers. The students were interviewed on seven occasions throughout a twenty-week course. All interviews were transcribed from the tapes and significant episodes selected to be coded and organised into a classification system. The initial coding system followed the plan of themes highlighted by the exploratory study:

- DEFINITIONS given by each student were classified as descriptive, correct formal or distorted formal,
- ARGUMENTS were categorised as being based on concept images or based on the formal theory presented,
- IMAGERY, as evoked by the students, was classified as to whether it was apparently constructed from the formal theory or not.

Given the differences between the informal approaches of the students in the preliminary study and the desired formal theory, the responses initially were classified as follows:

Approach:	DEFINITIONS	ARGUMENTS	IMAGERY
informal	descriptive	based on concept image	not constructed from definition
formal	formal (correct or distorted)	based on formal theory	constructed from definition

Table 1

This analysis, however, was revised when two distinct approaches were found to occur:

- ***giving meaning*** *to* the concept definition from concept imagery,
- ***extracting meaning*** *from* the concept definition by making formal deductions.

Although reminiscent of the earlier-mentioned approaches of research mathematicians, they differ because students are given the definitions as starting points. However, there are certain parallels. *Giving* meaning involves using various personal clues to enrich the definition with examples often using visual images. *Extracting* meaning involves routinising the definition, perhaps by repetition, before using it as a basis for formal deduction. This led to a new categorisation (table 2) where giving meaning could lead to formal theory or fail by remaining image-based, while extracting meaning could be done either reflectively or mechanically, leading again to a spectrum of success or failure.

Approaches	Concept Construction			
Strategies	Characteristics	DEFINITIONS	ARGUMENTS	IMAGERY
Giving meaning (building from *informal* ideas)	1. Reconstructing old knowledge to give new 2. Interpreting new knowledge in terms of old	1. Formal: • correct • distorted 2. Descriptive: • general • prototype • specific	1. Based on thought experiments: • formally presented • image-based 2. Rote-learned	1. Reconstructed with the formal theory 2. Old images retained 3. New ideas added as extra information 4. Conflict between old and new
Extracting meaning (building from *formal* theory)	Routinising: • reflective • mechanical where either may remain compartmentalised or later be linked to old knowledge	Formal: • correct • distorted	Based on formal theory: • meaningful • rote-learned	Based on formal theory: • compartmentalised • linked

Table 2

1232

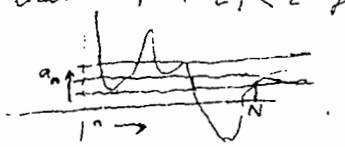
Students building operable definitions through giving and extracting meaning

In the main study some individuals used both approaches at different times, but many showed a distinct preference for one approach. For instance of two highly successful students, Ross was categorised as an *extractor* of meaning and Chris, a *giver* of meaning.

In his first interview, Ross wrote down the definition as follows (Pinto, 1998):

(a_n) Sequence tends to limit L if, $\forall\ \varepsilon>0$, $\exists\ N(\varepsilon)\in\mathbb{N}$
s.t. $\forall\ n\geq N$; $|a_n - L| < \varepsilon$. (Ross, first Interview)

He explained that he coped by:



> "Just memorising it, well it's mostly that we have written it down quite a few times in lectures and then whenever I do a question I try to write down the definition and just by writing it down over and over again it get imprinted and then I remember it." (Ross, first interview)

Throughout the course he constantly attempted to prove results from formal definitions, seeing links with earlier established results until towards the end when he began to slip behind the pace of the lectures. At such times he might consider imagistic ideas but then always attempted to base his ideas on *extracting meaning* from the definition.

Chris, on the other hand, used imagery to support his thinking, drawing pictures to represent his main ideas. He wrote down the limit definition as he drew a picture, saying:

> "I don't memorise that [the definition of limit]. I think of this [picture] every time I work it out, and then you just get used to it. I can nearly write that straight down." (Chris, first interview)

~~If $a_n \to L$ then that~~ exists
For all $\varepsilon>0$, there exists $N\in\mathbb{N}$
such that $|a_n - L| < \varepsilon$ for all $n \geq N$

> "I think of it graphically ... you got a graph there and the function there, and I think that it's got the limit there ... and then _ once like that, and you can draw along and then all the ... points after N are inside of those bounds. ... When I first thought of this, it was hard to understand, so I thought of it like that's the *n* going across there and that's a_n. ... Err this shouldn't really be a graph, it should be points." (Chris, first interview)

The slip in drawing a curve revealed him concentrating on more important ideas and (temporarily) neglecting others. He always seemed to be negotiating with his ideas. For instance, he considered an alternative definition in which increasing N caused ε to become small before rejecting it and settling on the standard form. He seemed to enjoy the tension of challenge and was constantly *giving* meaning from his concept images whilst reconstructing them to take account of the formal theory.

Both students could use the definition of limit in an operable manner in different ways. For instance, when asked about "non-convergence", Ross wrote down the limit definition and negated the quantifiers, while Chris wrote down the definition immediately as if thinking the ideas through in a mental experiment. Ross practised and thought through his proofs formally, Chris wrote formal proofs linked to thought experiments.

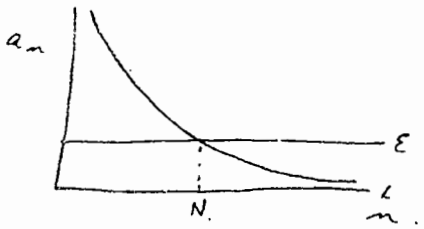
Less successful students

Many students on the course had difficulty with definitions. Robin tried rote learning:

> "It's just *memorising* the exact form of it, making the actual idea sort of *understandable* ..."

Despite this, he could not write the definition of convergence accurately:



A sequence (a_n) tends to a limit L if $\forall \varepsilon > 0$ $\exists$ there exists $N \in \mathbb{N}$ s.t. $|a_n - L| < \varepsilon$ provided $n \geq N$. (Ross, first interview)

He attempted to extract meaning from the definition, but was unable to remember it accurately, let alone make it operable. For instance, in one problem he set $N=5$ without mentioning any relationship between ε and N.

Colin was also unsuccessful with the definition, writing:

If $a_n \to l$, then there exists $\varepsilon > 0$, such that $|a_n - l| < \varepsilon$ for all $n \geq N$, where N is a large positive integer. (Colin, first interview)

He often attempted to support his ideas using a diagram:

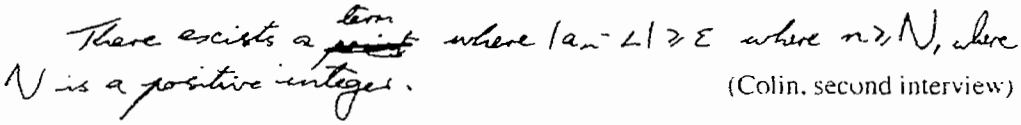
(Colin, first interview)

However, his pictures were highly specific and seemed to imprison him in their implied detail rather than provide the flexibility of thought available earlier to Chris. For instance, he denoted the limit by l yet wrote ε instead of $l+\varepsilon$, and considered the limit as a *lower bound* (a common concept image noted by Cornu, 1981, 1991). He explained:

> ". umm, I sort of imagine the curve just coming down like this and dipping below a point which is ε ... and this would be N So as soon as they dip below this point then ... the terms bigger than this [pointing from N to the right] tend to a certain limit, if you make this small enough [pointing to the value of ε]." (Robin, first interview)

Neither student could cope with non-convergence. Robin wrote:

A sequence a_n does not tend to the limit L if for any $\varepsilon > 0$, there exists a positive integer N s.t. $|a_n - L| > \varepsilon$, whenever $n \geq N$ (Robin, second interview)



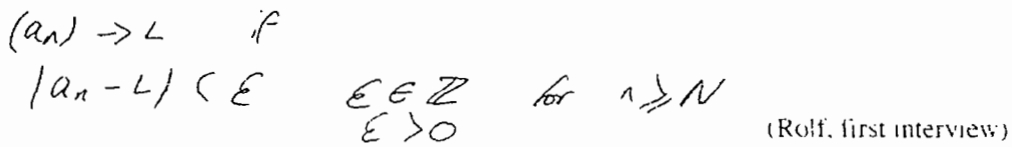
BEST COPY AVAILABLE

He leaves the original quantifiers unchanged, and only modifies the inner inequality $|a_n-L| < \varepsilon$ incorrectly to give $|a_n-L| > \varepsilon$. He is unable to treat the whole definition as a meaningful cognitive unit (Barnard & Tall, 1998), focusing instead only on the inner statement as something which he can attempt to handle.

Meanwhile Colin, said:

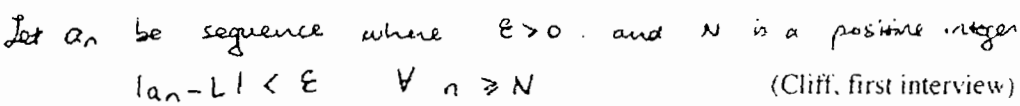
> "Umm ... I would just say there doesn't exist a positive integer because we can't work it out ... no ... you cannot find an integer N ...".

and wrote:



(Colin, second interview)

Both students used pictures and symbols in their work, giving meaning on some occasions and attempting to extract it from the definition on others. However, Robin's main preference was to extract meaning from definitions which were regretiably often erroneous, whilst Colin preferred to attempt to give meaning using concept images which were too limited to build the general concept.



Other unsuccessful approaches

Two other classes of students were considered—*users of mathematics*, including those studying physics, statistics, economics, etc and *future teachers of mathematics*. Some of the users of mathematics were successful, others were more interested in mathematics only for its use, having little interest in formal proof which appeared too complex, even alien. Rolf (an applied mathematics student) wrote the definition as:

(Rolf, first interview)

Cliff (a statistics student) wrote:

(Cliff, first interview)

Both definitions are distorted and restricted to the inner statement, with total absence of the two external quantifiers and the functional relation between ε and N. Rolf saw the definition as a process. which he attempted to memorise, and use as a criterion to check if a sequence is convergent or not. He tended to try to *extract* meaning from it, but failed. Cliff seemed to think of it as a dynamic *description* of convergence which he imagined occurring in time as N increases and ε decreases. He attempted to *give* meaning but is unable to do it successfully. Given their inadequate definitions, neither student could define non-convergence. Both subsequently resorted to rehearsing routine computations requested in previous examinations and tried to rote-learn them to pass the course.

BEST COPY AVAILABLE

The student teachers in the main study all replicate the imagistic meanings of those in the preliminary study. They have dynamic images of convergence with terms getting "arbitrarily close" which have often been reported in the literature (Cornu, 1991). For instance, Laura evoked many personal images for the idea of a limit with built-in conflict:

> "The number where the sequence gets to, but never quite reaches."
>
> Let a_n be the sequence and L is the limit which it tends to. Then when some initial values are placed into the formula of the sequence the answers will never reach the value of L (negative or positive).
>
> "... oh, yes, I put 'never reach', and it *can* reach, and that will be the limit of it. ..."
>
> "... But it won't never get bigger than the limit. The limit is like the top number it can possibly reach. And I put never reach." (Laura, various sayings, first interview)

She was unable to write down the definition in any formal sense, although she had mental pictures that gave her imagistic meaning for some of the theorems. Any justifications she made involved attempting to *give* meaning using images. She was unsuccessful with the formal aspects of the theory as were all the other teacher-training students. Essentially, the idea of formal proof in analysis was alien to their day-by-day routine in teaching practice. As Laura explains:

> "I'm on another planet when it comes to Analysis. It seems just completely surreal to me. ... it sparks in a lot of people in the group ... a lot of people. I don't think there is anybody who understands it. And a lot of people are getting very frustrated, with it. I just want to throw books around the room and ... get up and leave." (Laura, first interview)

Summary

In this paper we began by noting that mathematicians use different cognitive techniques to generate new theorems. Some work with formal definitions, carefully extracting meaning from them by deducing from them and gaining a symbolic intuition for theorems that may be true and can then be proved. Some have a wider problem-solving approach, developing new concepts that may be useful before making appropriate definitions to form a basis for a formal theory.

Students learning mathematics have a different problem. They come from elementary mathematics, deeply ingrained in the computation of arithmetic and the symbol manipulation of algebra using standard algorithms to solve certain types of problems. The forms of proof at this level (often called "demonstration" or "justification") usually either involve algebra to give a symbolic description for a general arithmetic statement, or some kind of thought experiment focussing on a "typical" or "generic" case.

The transition from elementary mathematics to formal proof is a huge chasm for many students whose underlying concept image is unable to sustain the formalism. Many (including the majority of those in our sample preparing to teach mathematics) have informal images which dominate their thinking. Some remain entrenched with their old images and those that attempt to use the definition may only be able to cope with part of the structure, giving a personal definition that is not formally operable.

Success comes to those who achieve it in (at least) two ways, either *giving* meaning by working from the concept image, or *extracting* meaning by working formally with the definition. These two techniques can each be successful or unsuccessful. For the successful student, *giving meaning* involves constantly working on various images, reconstructing ideas so that they support the formal theory. The successful student who extracts meaning from the definition has a different task of building up a formal image based mainly on the proof activities themselves.

Those who fail to cope with formal proof but try to give meaning from their concept imagery may be able to imagine thought experiments which give generic proofs and an intuitive insight into some of the ideas, others may fail completely. And become extremely frustrated. Those who fail to extract meaning are unable to cope with the complexity of the definitions and be totally confused. A fall-back strategy to attempt to pass exams is to learn proofs by rote.

Teaching and learning formal proof remains an important component of theory building in advanced mathematical thinking. For future mathematicians it is essential. However, in using different approaches through giving or extracting meaning involves quite different sequences of construction. *Giving meaning* from concept images requires ongoing reconstruction of personal ideas throughout the course to focus on essential properties of the definition and to construct an integrated formal theory. *Extracting meaning* builds up ideas mainly from formal deductions with fewer links to other concept images and so avoids some possible conflicts at the time. However, this formal approach has its own difficulties and may end up with a formal theory unconnected to informal imagery. These different developments suggest that it may not always be possible to deal with different student approaches within a single teaching method.

The most serious finding is the negative effect caused by teaching formal proof in analysis has on future teachers which may have an implicit effect on their teaching of mathematics to the next generation.

DISCONTINUITIES REGARDING THE SECONDARY / UNIVERSITY TRANSITION :THE NOTION OF DERIVATIVE AS A SPECIFIC CASE

Frédéric Praslon, Equipe DIDIREM, University Paris 7

ABSTRACT :

The mass phenomenon regarding university teaching today makes high school/college transitional problems bigger. We carry out a didactic analysis of these multiform problems in a specific mathematics field i.e. the analysis, and concerning a more precise topic, the derivative. A parallel study on the way each teaching institution deals with the derivative notion, and on student's personal relationship coming out from them, highlights the existence of two very distinct cultures. Finally, we will study the consideration of this institutional break and its management through adapted workshops.

I. INTRODUCTION

The mass phenomenon of university teaching as well as new requirements imposed to universities make the transition between high school and college a crucial issue today (ICMI, 1997). This transition involves very different facets, discontinuities and changes, and not only academic ones. For instance, one cannot deny that the evolution in students' social status and life plays an essential role. From an academic point of view, forms and contents of knowledge are affected by this transition, as well as assessment modes and relationships between teachers and students. In our research project, we address these transition issues from a didactic perspective, by focusing on one mathematical domain known as playing an essential role in the transition failure : Calculus. Moreover, in this mathematical domain, we focus on one specific area : the notion of derivative which, in France as in many countries, is the core notion of high school Calculus courses. Our aim is to understand the discontinuities and changes occurring within the high school/college transition regarding this notion and its environment, the way they are dealt with in standard university teaching practices with the corresponding cognitive effects on students. It is also to build didactic designs which could help to make both teachers and students more sensitive to these discontinuities and able to face them more effectively.

In this report, we will first present our theoretical frame and methodology. Then we will briefly describe the multidimensional grid we have built in order to analyse the institutional and personal relationships linked to the notion of derivative and its environment. before focusing on the analysis of one specific task proposed to

students. Finally, we will analyse the results obtained through this specific task when considering the more general outcomes of the research project.

II THEORETICAL FRAME AND METHODOLOGY

II.1 Theoretical frame

The research project relies on different theoretical frames. At a global level, it relies on the anthropological approach of didactic phenomena developed by Y.Chevallard (1991). This is specially useful for one major reason : we are here studying the transition between two different mathematical cultures : high-school culture and university culture. Chevallard's approach stresses the relativity of mathematical knowledge and the fact that the personal relationship such or such individual develops with respect to such or such mathematical object is shaped by the institutional values, relationships and norms the institutions he or she lives in, develop with respect to that object. These are conveyed by mathematical practices or "praxeologies" which, according to Chevallard, can be analysed in terms of tasks, techniques (the word bearing here a very general meaning), technologies which have to be understood as discourses with explanatory or justificative aims, and finally theories which can be seen as technologies of the technologies. In order to understand discontinuities and changes, we have thus to analyse the praxeologies relevant to both cultures concerning the derivative notion, in a very precise way. Another important point is the following one: Chevallard stresses that the knowledge development within one given didactic institution supposes what he calls the "routinisation" (routine process) of some tasks and official techniques which tend to become "naturalised", and then transparent to the actors of the institution.

At a more local level, we rely on different theoretical frames relevant to Advanced Mathematical Thinking (Tall, 1991), especially to what is now known as the "theories of reification" (Dubinsky, 1991), (Sfard, 1992) as we make the hypothesis that the transition between process and object views of mathematical concepts is a key point in the high school/college transition process in Calculus. We also rely on some epistemological distinctions introduced by A.Robert concerning the generalising, unifying, formalising dimensions of concepts or relationships to concepts at stake at university level and the cultural gap these epistemological characteristics necessarily introduce in the transition. We also rely on a recent synthesis of the same author where she tries to describe in a very detailed way the characteristics of mathematical practices at a university level and situates the latter considering high school mathematics culture (Robert, 1998).

When looking at Calculus and results obtained so far in this area more specifically, we refer to two articles recently published by M.Artigue (Artigue, 1996, 1998) which offer an integrated view of the different perspectives mentioned above, of their respective potential and limits as well as a synthesis of the results each of them was able to produce up to now.

II.2 Methodology

Relying on this theoretical frame, our methodology aims at investigating the discontinuities and lacks in the high school/college transition, both from an institutional and personal points of view. For this purpose, we have built a multidimensional grid allowing us to analyse in a detailed way the practices involving the notion of derivative, both at high school level and during the first university courses.

Regarding the institutional dimension, this multidimensional grid has then been used in order to analyse systematically the tasks proposed to students in most current French textbooks for grades 11 and 12, and Baccalauréat assessments for scientific sections. It has then been applied in the same way with worksheets used with students in their first semester at university in Calculus courses, in different universities.

As regards the personal dimension, students' relationships with the notion of derivative has first been investigated through a written test taken at the entrance at the university by students. The tasks elaborated for this test cannot be considered as familiar ones for these students. Taking into account the institutional analysis, they appear more as transitional tasks between the two mentioned above cultures. Secondly, we have designed and experimented specific workshop sessions where students, working in small groups, have to face mathematical problems representative from the main discontinuities previously identified (status and role of definitions, role of conjectures and counter-examples, work on classes of functions defined by general properties...). In the research project, these sessions have a diagnostic role, helping us to understand the difficulties met by students as well as their resources and evolution all along the academic year, but they also want to be the source of the engineering part of the research project mentioned above.

Validation is classically based on the triangulation of the results obtained through these different methodological approaches.

III. THE MULTIDIMENSIONAL GRID OF ANALYSIS

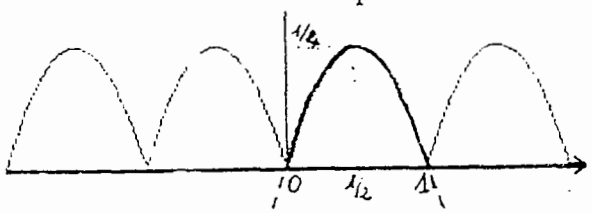
The analysis of the practices involving the notion of derivative is organised around a multidimensional grid of analysis of the tasks arising at least in one of the two cultures. Tasks are firstly classified according to themes, and for each theme the analysis is organised around five main components :

a) autonomy given to students in the resolution (eventual decomposition into subtasks, given hints ..),
b) status of the notion of derivative in the task (according to the "tool" and "object" dimensions, the "process" and "object" dimensions..),
c) nature and context of the task (mere application of standard techniques, technical adaptations possibly required, level of generality, degree of reflexivity...)
d) settings and flexibility between settings required by the resolution of the task
e) semiotic registers present in the text of the task and/or required by its resolution.

For each of these components, both qualitative and quantitative data are collected. Moreover, when using this grid for analysing textbook tasks, for each theme (for example, the "finite increments inequality"), we define a rate of repetition "t" for the corresponding tasks. This rate allows us to measure what kind of tasks and techniques generates important and specific training in a given institution and identify important differences and lacks between tasks, even when they seem part of the two cultures.

IV. FOCUSING ON ONE SPECIFIC EXAMPLE

In this part of the report, as announced above, we focus on one specific task proposed to students in the entrance test.



IV.1 Description and a priori analysis of the task

This task formally introduces the notion of symmetric derivative, and explores its relationships with the standard notion of derivative, firstly on one specific example : the periodic function (period 1) defined on [0,1[by the expression f(x)=x(1-x) then in general. More precisely, they are asked to analyse the continuity and differentiability of the function f and calculate (if they do exist) its derivative and symmetric derivatives at the following points : 0, ½ and ¼. Then they are asked to examine the three different following conjectures :

i) Every par function defined on R has a symmetric derivative at 0.
ii) Every par function defined on R has a derivative at 0.
iii) If one function, defined on R, has a derivative at x_0, then it necessarily has also a symmetric derivative at x_0, and $f_s'(x_0)= f'(x_0)$.

Note that students are also given the following graphical representation of the function f. In this text, due to space restrictions, we focus on the first part of the task, the second part will be addressed in the oral report.

Graphic scheme:

This task is far from being a familiar task at high school level : it deals with a function which is only implicitly defined through an algebraic expression, with a new notion formally introduced, it includes general conjectures... So, from students, it requires a kind of mathematical reflexivity and practice which goes beyond standard institutional relationships to the derivative. Nevertheless, this task can be considered at the interface between high school and university culture, at least for French scientific students : it doesn't require heavy technical work, it begins with the exploration of some particular case, which can help the transition to the more general part, and even provides a counter-example, students just have to identify as such. Moreover, the given graphical representation can help students to visualise the

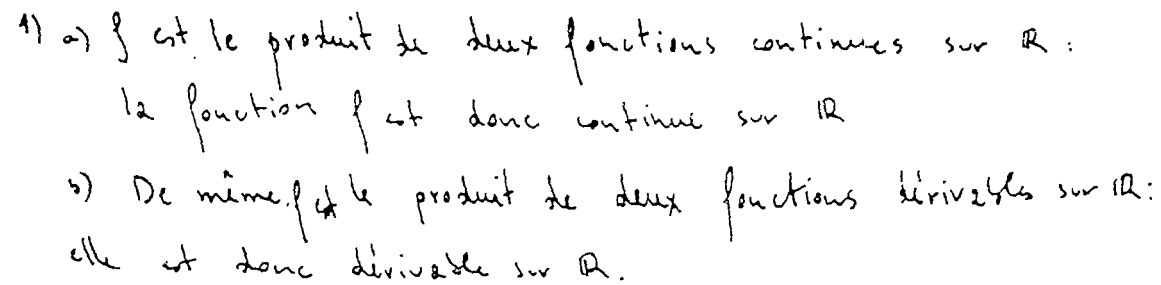
properties of f : continuity, non differentiability for x=n with n∈Z, parity, and thus favour a more economical management of the necessary calculations in proofs. Let us add that one of the aims of this task is therefore to test the level of cognitive flexibility between the algebraic and graphical settings, in a situation where information in the two settings is simultaneously given.

Nevertheless, as mentioned above, this task presents serious difficulties and we would like to point out some of those ones relevant to the first subtask :

a) In order to study the differentiability of f, it is necessary to come back to the definition of the derivative, definition which, at high school level, has more a cultural status than an operational one. In order to succeed, students also have to overcome the obstacle associated with the possible amalgam between f and the polynomial function P defined by P(x)=x(1-x). So they have to clearly distinguish f from its algebraic expression on one particular interval and consider it as a specific object. We can reasonably expect that a lot of students entering the university are not able to overcome this obstacle and will say that the function f is continuous and differentiable over R, as it is given by a polynomial expression on [0,1[and periodical. In the following, we will label such arguments as those of level 0.

b) Students may be aware that there is a problem in 0 and try to develop a local analysis, but unaware of the necessity of distinguishing right and left limits, taking the same expression for negative and positive x, especially if there is a semiotic trap : the bracket is closed in 0 in the definition of f. We will generally label this kind of behaviour as a level 1 behaviour.

c) Students can be aware of the problem for integer values of x and define conditions for smooth connection, without using the notion of limit, still in a construction phase, for instance by checking if f(0)=f(1) and f'(0)=f'(1) by using periodicity and the given algebraic expression for f. No doubt that such a solution is not a correct one but it seems to us unreasonable to expect that, with the scope of experience they have, high school students can go beyond that point. We will label such a behaviour as a level 2 behaviour.



d) As regards the specific calculation of derivative values asked for, we can expect that students will correctly evaluate the derivative at ½ and ¼ , but also that a lot of them will use the same expression 1-2x for the derivative in 0, falling into the semiotic trap mentioned above. It will be interesting to notice if, in that case, they denote some contradictions with the characteristics of the graphical representation and, if so, how they manage them.

e) The calculation of the symmetric derivative values doesn't not obey the same pattern. Students may be blocked by the formal definition which is given there and unable to exploit it. Limit calculations at ½ and ¼ , if they are undertaken, are not beyond high school technical abilities, at 0 the result can be immediately obtained if parity is used, but if not the calculation becomes more complex.

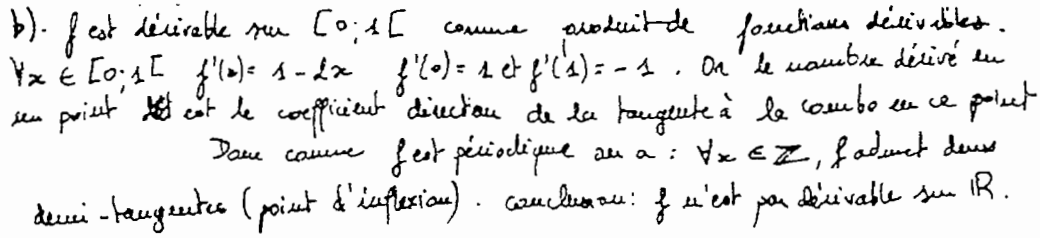
f) The interpretation of the results obtained may raise specific difficulties : students are faced with a new notion they cannot easily interpret; it seems to coincide with the notion of derivative at ½ and ¼ , why such a discordance at 0 ? Students are not obliged to be specifically confident in their formal calculations. It is only through the second subtask that they are seriously required to adopt a reflexive attitude.

IV.2 Main results obtained :

As far as the continuity and derivability of f are concerned, about 1/3 of the students involved can be situated at level 0 (and in most cases they don't even invoke the periodicity of f in their argumentation), 1/3 undertakes a local analysis at points 0 or 1 (levels 1 and 2), 1/3 develops a mixed approach (level 0 for continuity and 1 or 2 for the derivative, or less often the opposite way). 16% clearly develop a strategy relevant to level 2. When there is some local analysis, the graphical point of view is only evoked by 20% among students and it then acts as the essential argument, never as a way of checking algebraic calculations. So the level of flexibility between the two settings appear to be poor, in this specific context at least.

1) a) f est le produit de deux fonctions continues sur ℝ :
la fonction f est donc continue sur ℝ
b) De même f est le produit de deux fonctions dérivables sur ℝ :
elle est donc dérivable sur ℝ.

General procedure, level 0, expression of a typical high school "ritual":



As was anticipated, students massively succeed in calculating the derivatives at ½ and ¼ (95%), see more easily the situation as a problematic one in 1 than in 0, as the bracket is open in 1, and only use x(1-x) as an algebraic expression for f. Continuity, which is a very marginal notion in French high school syllabus, is not dealt with in the same way as differentiability, which is the notion at the core of high school Calculus courses. Most students feel the necessity to come back to the formal definition of the derivative when checking the differentiability in 0 or 1 and 60% of students distinguish between right and left limits in that case. No doubt that the institutional role of functions such as the absolute value function plays an essential role here. Nevertheless, the degree of familiarity with such functions is not enough to make what we could call "the angular point icon" something operational in that context and would allow them to overcome the difficulty generated by the limited validity of the given algebraic expression.

BEST COPY AVAILABLE

Visibly, students try to give some meaning to this unusual situation. This leads to a diversity of strategies, which even if they don't succeed are not at all deprived from interest and show that students have some mathematical resources, of course strongly shaped by their mathematical field of experience in terms of functions, a very limited one in terms of possible pathologies at the end of high school.

The same thing occurs with the notion of symmetric derivative. Unexpectedly, students in their great majority are not blocked by the proposed formal definition. The rate of success is even 75% for the calculations at ½ and ¼. The main error reveals an inadequate relationship with the notion of "undetermined form" which plays an important role in their relationship with the limit concept : obtaining the expression $\lim_{h\to 0}$ 0/2h for $f_s'(1/2)$ some students declare that the symmetric derivative cannot exist as 0/2h is an "undetermined form". But the calculation of the symmetric derivative at 0 is only correct for 3% of students; in that case, 88% of students calculate f(-h) by substituting –h to h in the given expression of f, and thus obtain the value : 1 for the derivative.

86% of students use the expression 1-2x in order to calculate f'(0), obtaining f'(0)=1. 26% of these had previously perceived the non differentiability of f in 0, by using the definition or graphically, but visibly there is a cut for them between the familiar and ritual calculation of derivatives, and the unfamiliar analysis of differentiability they were asked for in the first question. The following excerpt clearly illustrates this cut:

b). f est dérivable sur [0;1[comme produit de fonctions dérivables.
$\forall x \in [0;1[$ $f'(x) = 1 - 2x$ $f'(0) = 1$ et $f'(1) = -1$. Or le nombre dérivé en
un point est le coefficient directeur de la tangente à la courbe en ce point
Donc comme f est périodique en a : $\forall x \in \mathbb{Z}$, f admet deux
demi-tangentes (point d'inflexion). conclusion: f n'est pas dérivable sur $\mathbb{R}$.

Finally, the comparison between the two notions in that particular case remains unproblematic for the majority of students as, due to the errors mentioned above, they have found the same value: 1 for the two derivatives at 0.

V. CONCLUDING REMARKS

This example is quite representative of the strong tendencies we observed in the test results and, beyond that, in the experimental part of the research. Results attest the attempts made by students in order to adapt their mathematical resources to the problematic and complex situations proposed to them in the test and in the workshops. These attempts most often lead to oversimplifications, favoured by their reduced field of experience. They also often lead to a disconnected treatment of continuity and differentiability issues which becomes more understandable if one takes into account the respective role of the two notions in the high school culture. They also appear strongly dependent on the context as well as on the form of the

BEST COPY AVAILABLE

questions themselves and, in spite of the obvious directions given in the syllabus, they are poorly operational at connecting their different settings of mathematical work (algebraic, graphical) and show little cognitive flexibility. Nevertheless, if we consider that the proposed tasks are really out of their high school culture, that they put at stake some important characteristics of the new relationships they will have to develop with respect to the notion of derivative and more generally with respect to Calculus at university, we have to consider these attempts, even clumsy ones, as very positive starting points, sources of adaptation, potential for a didactic work. It doesn't seem reasonable to think that the complex cognitive activities required here can be mastered at high school level, even if they deal with simple objects. They have to be seriously taken in charge in the high school/college transition, which cannot only be seen as a transition from some experimental and pragmatic Calculus towards a formal one. The institutional analysis we have developed in our research work clearly demonstrates that it is not presently the case in most university courses. There is some didactic gap and we hope that, modestly, our research work will contribute to better understand how it could be didactically managed.

THE ROLE OF PICTORIAL IMAGES IN TRIGONOMETRY PROBLEMS

Lisa Pritchard and Adrian Simpson

Mathematics Education Research Centre, Institute of Education
University of Warwick, Coventry, CV4 7AL, UK

Year 10 pupils were involved in two task-based, semi-structured interviews after a short revision course on basic trigonometry. The tasks explored the pupils' use of pictorial images in solving traditional trigonometry word problems. This paper reports that a general pattern of use was discerned in which pupils moved from different types of diagram construction, to information extraction and finally to symbolic manipulation with little subsequent reference to the image of the trigonometric situation. The possible reasons for this unidirectional picture to symbol flow are discussed in relation to some fundamental difficulties in learning trigonometry.

Introduction

Trigonometry may be seen as the confluence of a number of streams of mathematical difficulty. It is a topic area in which students first meet functions which are not direct numerical manipulations of the functions' arguments: $\cos(30^\circ)$ is not a direct manipulation of the number 30. It is one of the first areas where mathematical objects are given by definition: sine is given as the ratio of the lengths of the opposite and the hypotenuse in a particular type of right angled triangle. Curriculum designers see it as an area in which visual elements are naturally associated with word and symbolic problems: questions with and without attached diagrams are interspersed from the beginning of the topic. Problems often involve the abstraction of information from 'real world' situations: ships, buoys and lighthouses abound in trigonometric word problems.

All of these mathematical difficulties are compounded by the difficulties pupils have in moving flexibly between images of trigonometric situations and algebraic/numerical symbolism.

In this paper, we report on a research project which directly examined the roles pictorial images played for students in solving traditional, basic trigonometry problems.

The implicit assumption of the various UK mathematics schemes (and, indeed, of the UK national curriculum) is that trigonometry is a topic in which pupils can flexibly move between visual and symbolic ways of working. Despite earlier research (Blackett, 1990) suggesting the importance of a flexible approach to linking numerical and visual domains in trigonometry so as to give a better conceptual

understanding, most schemes follow the suggested pattern of development in national curriculum documents. Following a grounding in Pythagoras' theorem, the notion of similar right angled triangles are used to define sine, cosine and tangent functions in terms of ratios of appropriate side lengths. Pupils then find angles or lengths of sides in abstract situations in which the right-angled triangles are drawn for them. They progress to 'real world' word problems, such as finding heights of trees from a given angle of elevation and distance in which diagrams are sometimes given, but are expected to be constructed by pupils as an aid.

It is widely claimed that the use of diagrams or pictorial images is useful in helping pupils solve problems. It is claimed (Nickerson, Perkins and Smith, 1985) that

> Once a graph or diagram is drawn, the problem solver can bring perceptual processes to bear on it. Also, a visual representation of a problem can make apparent certain relations among parts that might otherwise go unnoticed.

It seems clear, then, that trigonometry is an excellent place to explore the ways in which pictorial images are used in the solution of problems.

Trigonometric problems

The research was an attempt to get a sense of some of the possible ways in which pupils might use pictorial representations as part of the process of solving trigonometry problems, having had only a basic introduction to it. Six pupils, two girls and four boys, were chosen from a top-set year 10 class who had just revised the basic concepts of trigonometry. They were tape-recorded solving some 'real world' word problems of the type (but not precise form) they were familiar with, during two different interviews. The questions which the data presented in this paper relate to were:

a. A ship is 10km due south of a lighthouse. It is sailing on a bearing of 60° towards a buoy which is due east of the lighthouse. How far is the lighthouse from the buoy?

b. A flagpole is hung horizontally, suspended from the wall by two ropes which are attached to the end of the flagpole. The angle between the ropes at the end is 60° and at the wall the ropes are 1m apart. How long are the ropes?

c. A 5m ladder rests against a wall, with the foot of the ladder 1.2m from the bottom of the wall. What angle does the ladder make with the ground and how far off the ground is the top?

d. A cuboid has dimensions of 5m by 12m by 15m. Calculate the angle made between the diagonals from the bottom of one corner to the top of the diagonally opposite corner and the 5m by 12m base.

The method of solution was left entirely to the students, no diagrams were provided, neither were the pupils directly encouraged to produce them, though such encouragement would have been given in an ordinary classroom situation.

The pupils' spoken protocols, their diagrams and their written work were analysed revealing three different useful categories for exploring their use of pictorial images:

- The creation of diagrams
- The use in solving problems
- The use in checking and making meaning

The Creation of Diagrams

For the typical 'real world' word problems, all of the pupils, in all of the problems drew a diagram. What stood out from this, however, was that there were qualitatively different ways in which the pupils used their mental imagery to produce them. The data showed three different ways in which they appeared to construct them: getting a whole mental image of the real scene and then effectively copying that image on to paper; getting a whole mental image and copying an abstraction on to paper or constructing the diagram piece by piece by taking one phrase from the question at a time.

Andrew, who seemed to be a strong visualiser throughout the tasks, talked of "thinking about the diagram in my head and what I would see if that happened" when drawing pictures. His also drew pictures with quite realistic properties - ladders that were an attempt to look like ladders, as seen in fig 1.

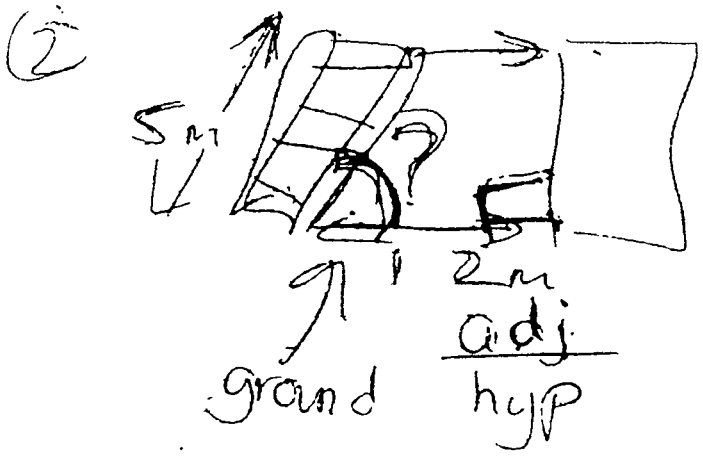

Figure 1

BEST COPY AVAILABLE

In Sophie's case, she spoke similarly about some form of complete mental image which she was struggling to manipulate (in this case, trying to draw the space diagonal of a cuboid for question d)

> "I can't see a diagonal from the bottom of one corner, it's confusing. I'm trying to get in my mind which corner which diagonal ... [the cuboid is] square, no, rect..., no it was square actually"

However, her diagrams, such as in fig 2 were more abstract than Andrew's.

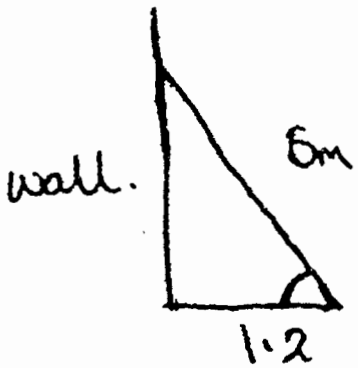

Figure 2

Most pupils, however, drew the diagrams by repeatedly taking the next piece information from the question and adding it to the drawing. They did not seem to construct a mental image and copy it - they directly constructed a drawing. Keith, for example, seems to take the information as instructions to be followed in a logical order. When asked how he drew parts of the diagram for question b he said

> Well I made it into sections, one thing at a time. I didn't just pinpoint 3 dots. I had to think about each thing at a time. I pinpointed the lighthouse and then thought that the ship's 10km south so I didn't do it in proportion. I drew 60^0 angle which I thought was about 60^0 and I drew a line straight down. I drew a line east until it met the other line and I drew the other dot there.

Uses in Solving Problems

The research showed only two main uses in solving problems for the pupils' diagrams: identification and extraction. They were used to sort out the information in the question, identifying the objects in relation to each other: as Sophie put it "as you're drawing it out you can see which one's opposite and which one's not". Once the drawing had all of the information arranged on it, the pupils then used it to extract

the appropriate information and choose which of the trigonometric ratios they would need to use.

This two stage process of identification and extraction was seen in all the pupils' solution strategies, but was put most succinctly by Sarah:

> Sketch out the triangle, label it and then work out what the question wants

All the pupils followed the same procedures for solving the problems. They recalled the mnemonic they had been taught to enable them to recall the basic ratio definitions ("sohcahtoa" for "sine = opposite/hypotenuse; cosine = adjacent/hypotenuse and tangent = opposite/adjacent"). The relevant information was substituted in to the 'formula' and the symbols were rearranged in an attempt to find a solution. As expected, it was when this attempt initially failed that the most interesting data was seen.

One problem was the reliance on memory – if a student could not remember the process, they could not proceed easily. In particular, when pupils were asked to find an angle in the problem (rather than the more familiar task of finding the length of a side) many could not recall the procedure they needed to follow after having reached, for example, $\cos(x) = 0.24$. Most, perhaps for want of any other interpretation to hand, thought of this as the product of 'cos' and 'x' being 0.24, even if, for some pupils, they knew this was not the case:

> Int: How would you find x?
>
> Sophie: 0.24 divided by cos
>
> ...
>
> Int: Does cos x mean cos times x?
>
> Sophie: cos is x is the cos. What cos is, like x belongs to cos.

This problem was quite common and highlights a further problem in the nature of trigonometry at this stage of schooling. In terms of the development of the function notion in the sense given by APOS theory (Breidenbach et al., 1991), the functions pupils will have been familiar with to this point will generally have been seen as processes: the direct numerical manipulation of their arguments. For many of the pupils, even in a good year 10 class, functions as objects may not yet have developed even in simple cases. It is reasonable to suggest that the trigonometry functions can not yet be seen even as a process: $\cos(30^\circ)$ is not a numerical manipulation of 30 in any obvious way. It is more likely to be seen as no more than an action: one based on procedure implicit in the definition and which is quite convoluted ('draw a right angled triangle with a 30° angle, measure the adjacent and the hypotenuse and find the ratios of their lengths'). In the pupil's nascent understanding of familiar functions, the inverse can often be associated with a reversed procedure. It seems much harder to get a sense of reversing the procedure above to find x given $\cos(x)$.

The use in checking and making meaning

The checking of solutions was not a natural procedure for any of the pupils. If they found an answer, they generally considered the task completed. As part of the process of gathering data, however, the pupils were explicitly asked if their solutions 'seemed reasonable'.

An interesting aspect of this data is that the checking followed the same flow as the solution, even if that flow was not complete. Some pupils did refer to their diagrams and the data from the diagram, whereas others checked only the symbolic/numerical calculations. None of the pupils seemed to put their solution back into their pictorial or mental image, to get a sense of whether the solution was of roughly the right size.

Discussion

Presmeg (1986) categorised solutions as visual if they involve

> imagery, with or without a diagram, as an essential part of the method of solution, even if reasoning or algebraic methods are employed

and non-visual if they do not involve such imagery. The research reported here shows that there may be layers of complexity within that definition of a 'visual solution', at least in the context of these trigonometric problems. Even though no pupil used it throughout the solution of a problem different pupils used imagery to different extents.

In the research data presented here, we can see a general flow to the methods of the pupils' solutions: construction of a diagram, identification and extraction of data, choice of ratio and symbolic manipulation to a solution (or until stuck). The genuine use of visualisation in the sense of Solano and Presmeg (1995) seems only to play a part in the first aspect of this flow and only for those few pupils who constructed the diagram by first building a whole mental image and then copying it on to paper (either 'realistically' or more abstractly). For most of the pupils, there was much less use of visualisation even here: they transferred the information, a piece at a time, from the word problem to their diagram without, it seems, constructing a whole mental image. Even in checking, this general flow from (possible) visualisation to diagram to calculation was followed.

One of the problems with the construction of images in the case of trigonometry at this stage of schooling may be the reversal of the usual concept image/concept definition development (in the sense of Tall and Vinner, 1981). It has been argued that the majority of mathematics at school proceeds from getting a familiarity with concept images without any real reliance on concept definitions and that one of the difficulties with the transfer to advanced mathematical thinking is that this flow is reversed. In higher mathematics objects may be defined prior to any other aspects of a concept image being constructed. Probably for the first time, pupils are given definitions of the trigonometric ratios (often in shortened forms like 'sine is opposite

over hypotenuse') before they have formed any significant concept image of them. Indeed, these definitions do not lend themselves to the development of clear images: while the objects of the definition ('opposite side' and 'hypotenuse') are easily identified as part of a picture, the ratio itself is not. The objects within the definition and the object which is defined are quite different and are susceptible to quite different modes of reasoning - the former visual and the latter numeric/symbolic.

In this research we can see pupils who are able to move between these two modes of reasoning, but in one direction only and at only one point in the solutions to the problems given. They can extract from their diagram the information they need to begin the symbolic reasoning they use to handle the ratio itself.

This is quite at odds with the findings of Nunokawa (1994) where a mathematically more sophisticated student was asked to solve a problem and was seen to move more flexibly between pictorial and symbolic representations, modifying diagrams as the work on the problem progressed. Simpson and Tall (1998) distinguished between passive, organisational, conceptually generative and formally generative imagery. It appears that while Nunokawa's mathematically gifted student used diagrams in ways that fit all four of these categories, the pupils in this research are using their pictorial images in, at most, an organisational way. They are using the diagrams to organise and to allow them to extract the information they need for a symbolic calculation, but they do not use them to suggest solution strategies, hint at expected results or embody the formal definition of the mathematical objects under consideration.

It may be that the more sophisticated use of pictorial images comes from a more developed understanding of the topic. The student in Nunokawa's research had developed a much richer network of connections that constituted his understanding (in the sense of Hiebert and Carpenter, 1992) and it can be suggested his concept image and concept definition were more closely linked. With pupils beginning their encounters with trigonometry they inevitably can only draw on a sparse network of knowledge and with this, one of their first encounters with a defined object, they have dissociated concept images and definitions.

Clements and Battista (1992) suggest:

> At van Hiele Level 2 and higher, one's use of visual images is constrained by one's verbal/propositional knowledge. Images and transformations of images incorporate this knowledge and, as a result, might behave differently at different levels.

In this research we have seen that the verbal/propositional knowledge does indeed take precedence over the images and it may be that the paucity of such knowledge makes the images they produce such poor generators of subsequent thinking.

THE RHETORIC OF GENERALIZATION
A Cultural, Semiotic Approach to Students' Processes of Symbolizing

Luis Radford
Université Laurentienne
Ontario, Canada

Abstract: Taking generalization as a cultural semiotic problem, that is, a problem about meaning co-construction occurring in the overlapping territories of writing and speech, this paper attempts to study generalization as a mathematical action unfolding in a classroom discursive Bakhtinian 'text' jointly written by teachers and students in the course of mediated activities. In the case that we shall consider here, what is at stake is the construction and the meaning, in a grade 8 classroom, of a new mathematical object —that of the general term of a sequence or pattern. We shall focus on the problem of how generalization finds expression in processes of sign use (particularly sign understanding *and* sign production*)*

1. Introduction

This paper is part of an ongoing research program dealing with the students' processes of symbolizing in algebra[1]. By students' processes of symbolizing we mean the different ways in which students come to *understand, use* and *produce* signs. Our work is embedded in a post-Vygotskian semiotic theoretical framework that we elaborated elsewhere (Radford 1998, in print) in which signs are seen as psychological tools, symbolically loaded and intimately linked to the actions that the individuals carry out in their activities. Within this theoretical context, ways of symbolizing (Nemirovsky 1994) are not considered as acultural, pre-given processes. Instead, we consider them as instances of the general modes of signifying resulting of the juncture of sign-mediated activities of the individuals and the *Cultural Semiotic System* (e.g. beliefs, patterns of meaning-making; see Radford 1998) in which activities are subsumed. Mathematical generalizations as well as other mathematical activities are framed by specific and culturally accepted ways of symbolizing. This point can be made clearer if we consider sign use in the historical example of the study of numbers in Antiquity. While mathematicians in the Pythagorean tradition, legitimately used pebbles to investigate some properties of numbers, in Euclid's *Elements* not only the actual pebbles but also any iconic representation of them was completely dismissed and replaced by a referential, non-operational sign-segments/letters language couched in a deductive line of reasoning. The deductive Greek mathematical style was linked, as A. Szabó suggested, to the Eleatan distinction between true knowledge and appearance and the consequent rejection of the sensible world as carrier of knowledge. Moreover, and most important for our discussion, the Eleatan beliefs legitimized new ways of symbolizing which authorized certain rules of sign use and excluded others. How the Euclidean "mathematical generality" could be expressed depended on the Greek conception of the concrete and the abstract, the historical availability of the Phoenician letter-based alphabet adopted by the Greeks (a letter-based written language which was completely different from, for instance, the syllabic Akkadian cuneiform language of the Babylonian scribes) and on the accepted cultural normative dimension in which the use of signs was caught. Let us consider a short example. Proposition 21, Book IX of Euclid's *Elements* reads as follows

If as many even numbers as we please be added together, the whole is even.
For let as many even numbers as we please, AB, BC, CD, DE, be added together; I say that the whole AE is even For, since each of the numbers AB, BC, CD, DE is even, it has a half part; [VII Def 6] so that the whole AE also has a half part.

But an even number is that which is divisible into two equal parts [id], therefore AE is even (Heath 1956, Vol II, p 413).

Euclid expresses here "generality" in natural language as a volitive potential action rendered by the comparative formula "as many even numbers as we please". And, within the Euclidean semiotics, the letters allow combinations (in fact assemblages, e.g. AB) which denote segments that stand for non-particular numbers. Interestingly enough, the proof was not recognized (either by Euclid or his later commentators) as lacking generality despite the fact that a drawn segment unavoidably has a particular length as well as the fact that it was actually based on only *four* numbers. As far as we know, the proof was considered completely general by the canons of Greek mathematical thought. As in contemporary classrooms, modes of symbolizing and expressing generality in Antiquity were shaped by the master's and students' beliefs about mathematics, and their mutual understanding and acceptance of legitimizing procedures about mathematical symbolization.

In this paper we shall deal with a problem which arises in the algebraic study of patterns, namely, that of generalization. Ordinarily, in such cases, because of curricular requirements (as is the case in the current Ontario curriculum for Junior High-School), generalization is expressed through the semiotics of the algebraic language. Of course, a great deal of experimental research has shown that the algebraic expression of generalization is very difficult for students who are still acquiring the mastering of the algebraic language (see e.g. Rico *et al.* 1996). In accordance with our theoretical framework (Radford 1998, in print), we will attempt to explore generalization as a semiotic problem, that is, a problem about meaning co-construction by teachers and students in the course of mediated activities. We shall focus on the construction and the meaning, in a grade 8 classroom, of a new mathematical object—that of the general term of a sequence or pattern. We are particularly interested in the problem of how generalization finds expression in processes of sign use. Since the general term cannot be ostensively pointed to as one can point to a door or to a desk, the semiotic construction of such a mathematical object acquires a particular didactic interest.

2. The methodology

In our research program we are accompanying for three years some 120 students and 6 teachers in the teaching and learning of algebra This task includes the teachers', researcher's and assistants' joint elaboration of general and particular goals, the joint elaboration of teaching and learning settings, the video-taping of the lessons, discussions, and feedback The teaching settings have been elaborated in such a way that the students (who are presently in Grade 8) work together in small groups; then the teacher conducts a general discussion allowing the students to expose, confront and discuss their different achieved solutions. In general terms, we are interested in investigating the students' processes of symbolizing in specific teaching settings about patterns on the one hand, and equations and inequations on the other In this paper, however, we shall focus solely on the students' and teacher's co-constructive semiotic expressions of the "general term" of a sequence or pattern. The results that we shall present here come from an interpretative, descriptive protocol analysis (Fairclough 1995, Moerman 1988) Because of the length requirements of the article, we

shall limit ourselves to the protocol analysis of one of our student groups. The protocol analysis will attempt to disentangle texture forms underlying the process of sign use (particularly *sign understanding* and *sign production*) in terms of the conveyed meaning and of the classroom use of utterances genres (e.g. reading, confronting, requesting, informing). Our question can then be explicitly formulated in the following terms: how do students' and teachers' voices and writings find their way in the construction of the new object (from the student's perspective) of the general term of a pattern or sequence? How do teacher and students deal with the concrete and the abstract in pattern problems? In its most general terms, and taking the term 'rhetoric' as a mode of discourse or text making, the question is: How does the rhetoric of generalization take place in the classroom?

3. Results

The students were asked to work in groups to solve some problems about patterns. In previous activities they investigated some patterns and had to provide answers to questions like *a* and *b* shown below. Questions *c* and *d* required a new kind of symbolic understanding. For the sake of brevity, we will consider here only some excerpts of the episode concerning one 3-student group discussion of questions *c* and *d*. Let us nevertheless mention that, although questions *a* and *b* led to different understandings of how to investigate patterns, the students did not raise problems concerning issues on generalization. The students kept focused on concrete issues raised by those particular questions. The case for questions *c* and *d* was very different.

Observe the following pattern:

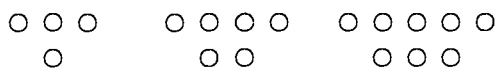

Fig. 1 Fig. 2 Fig. 3

a) How many circles would you have
* in the bottom row of figure number 6?
* in the top row of figure number 6?
* in total in figure number 6?

b) How many circles would you have
* in the bottom row of figure number 11?
* in the top row of figure number 11?
* in total in figure number 11?

c) How many circles would the top row of figure number "n" have?

d) How many circles would figure number "n" have in total? Explain your answer!

Time	*Line*	*dialog / remarks*
1.41	(21)	student 2: *(he writes the answer to the third part of question b while saying)* in total that comes to 24. Wow! This is easy! *(Now he reads question c)* How many circles would the top row of figure number . What? OK Somebody else!
1.59	(22)	student 1: *(reads the question.)* How many circles . [.] What does it mean?
2:07	(26)	student 2: I don't know. *(hitting the sheet with his pencil)*
2.13	(27)	student 1: What's figure n? / *(inaudible)*
2:22	(28)	student 1: (*talking to student 2*) Shut up! I'm going to kill you .. n is what letter in the alphabet?
2.33	(29)	student 2: (*talking to student 1*) Ask the teacher

In this passage the students are trying to make sense of the expression "figure number n" contained in question *c*. As we noticed elsewhere (Radford 1996), the general term of a geometric or arithmetic pattern cannot be explicitly expressed within the semiotic system (SS) of the objects of the pattern itself. Even to pose the question, it is necessary to go "out"

of the first SS (which will include, in the case of elementary school arithmetic, the basic "well-formed" expressions using the ten digits and certain signs like those required for the elementary numerical operations, equality and so on) and to rely on another richer SS (e.g. a meta-language). In the case of our text, we had recourse to the algebraic language to talk about the general term. As the engineering of the problem given to the students suggests, the idea of generalization that we decide to use resides in an experiential dynamics attempting to go beyond the concrete terms of arithmetic. As expected, the transcript indicates, however, that the students' understanding of the question remained circumscribed to their arithmetical experience. We reach here a nodal point in the development of the classroom activity whose unraveling will require the elaboration of new meanings. While student 2 bluntly abandons the quest for meaning (an action accompanied by exasperation as line 26 suggests), student 1 started a cardinal-arithmetic plan: to display the letters of the alphabet and to figure out what position n occupies in that order:

2:54 (32) student 1: How many circles would the top row of figure 14 have? n is fourteen
3.00 (33) student 2: No it's not!
3:01 (34) student 1: Yeah it is!
3.02 (35) student 3: What is n? *(asking the teacher who coincidentally is walking by)*
3.04 (36) student 2: *(talking to the teacher)* What is n? We do not know
3:08 (37) teacher: *(turning the page and reading the question aloud)* How many circles would the top row of figure number n have?
3:13 (38) student 3: What is n?
3.15 (39) student 1: n is fourteen because n is the fourteenth letter of the alphabet. Right?
3.20 (40) student 2: *(counting aloud the letters that student 1 wrote on the table previously)* one, two three, four, five, six, seven, eight, nine, ten, eleven, twelve, thirteen, fourteen.

Student 2 does not agree with student 1's interpretation about what n is and his arithmetical rephrasing of the question ("confronting" utterance in line 33). The arrival of the teacher serves as a potential way to overcome the conflict. The teacher, nevertheless, offers as an answer a re-reading of the question only. Interestingly (and probably because of the teacher's laconic answer) student 2 seems to change his mind and to agree in investigating student 1's idea; thus he starts counting the letters of the alphabet. Noticing that the students are taking an unexpected path that may take them away from the intended algebraic meaning, the teacher consents to explain a bit further:

3:28 (41) teacher "n" is meant to be any number.
3.32 (42) student 2. OK
3.33 (43) student 1: n is what?
3:35 (44) teacher: Any number *(in the meantime student 3 comes back to question a.)*
3.39 (45) student 1. I don't understand.
3.41 (46) teacher. You don't understand?
3.42 (47) student 1: No [.]
3.44 (49) teacher. *(talking to student 3)* Do you understand what n is?
3.45 (50) student 3 Which one? *(pointing to the figures on the sheet)* this, this or this?
3.46 (51) teacher: It does not matter which one

The rhetoric of generalization has now taken a different turn. The teacher launches the understanding of "n" as "*n being any number*". The students reactions show that there is a tremendous difficulty in constructing this specific meaning. Student 3's answer (line 50) suggests that this difficulty is linked to a very specific semiotic problem that we will term as

the "multiple representation problem". Since sign-numbers, in the semiotics of arithmetic, generally refer to a single object (i.e. although in some contextual instances the number five may be represented as e.g. -1, nobody will agree that, in the base 10 arithmetic, two different 'basic' representations like "7" and "5" represent the same number) it appears very hard to conceive "n" (which by the way as sign has a similar 'basic' iconicity as "7" or "5") as representing more than one number (see line 50). This is corroborated by the following lines:

4 10 (53) teacher: *(talking to student 2 after a long period in which the students remained silent)* OK. There, do you have an idea what is n?
4 12 (54) student 1: Fourteen.
4:13 (55) teacher: It may be fourteen ...
4:14 (56) student 2: *(interrupting)* any number?
4:15 (57) teacher: *(continuing the explanation)* ... it may be 18, it may be 25. .
4 18 (58) student 1: Oh! That can be any number?
4 19 (59) student 2: *(interrupting)* The number that we decide!
4 20 (60) student 1: OK then, *(taking the sheet)* OK, n can be uhh
4:26 (61) student 2: Twelve
4:27 (62) student 1: Yeah.
4:28 (63) teacher: But . yeah What were you going to write?
4 31 (64) student 1: 12.
4:32 (65) student 2: 12.

The teacher's attempt failed. The proposed meaning for n as being "any number" is interpreted as an arbitrary but *concrete* number ("informing" utterances, lines 61, 64-65). The teacher tries to give meaning to the expression conveying the generalization by re-investing the students' arithmetic point of view in a way which is still coherent with the global plan to introduce the general term in the context of the classroom setting. The teacher's voice hence acquires a specific tone made up of the pedagogical plan and the students' contextual voices. The Bakhtinian text in which generalization is being written appears to be heterogeneous in its meaning. Realizing that things had not turned out as expected, in the next line the teacher launches a rescue mission from where the wanted meaning could properly arise:

4:33 (66) teacher: And if you leave it to say any number How can we find . how can we find the number of circles for any term of the sequence *(making a sign with the hands as if going from one term to the next)*
4 51 (67) student 2: Figure n? There is no figure n!
4 54 (68) student 1: *(talking to student 2)* He just explained it! N is whatever you want it to be
4.57 (69) student 2: *(talking when student 1 is still talking)* What is it?
5.01 (70) student 1: OK Umm ... seven. *(writing on the sheet)*
5 10 (71) student 2: Not on top! It's seven circles *(taking the sheet and looking at the figures)*
5 13 (72) student 1: Yeah! And in the bottom is 5 circles!
5 21 (73) student 2: *(writes the answer and starts reading the next question)* How many circles would . . *(inaudible)* ... 12 circles *(writing the answer)*

Speech does not unfold alone. Speech unfolds accompanied by other semiotic systems, for instance systems of gestures that we make with our hands and arms (see e.g. Leroi-Gorhan 1964). When we make gestures, the hands can be used to produce signs by e.g. sketching objects (Kendon 1993), while in certain cases concrete objects can be used as metaphors of absent objects (an instrumental strategy generally employed and which becomes a

cornerstone in the development of sign systems with deaf children). Gestures form a sign system with its own syntax and meaning that afford the production of texts. In previous activities, we frequently saw our students pointing to a concrete figure (the third figure of a pattern, for instance) to refer in fact to the 100^{th} figure. And in the case of the episode that we are discussing here, the teacher makes an intensive use of gestures (line 66) to try to complement the sense of the expression "any number" —an expression whose even most forceful utterance cannot reach the students' understanding yet. Indeed, the students keep the arithmetic meanings for the relation between "n", "figure n", and "any number". We should note at this point that student 2 is clearly uncomfortable with their general understanding of "figure n". There is something that does not fit the modes of meaning generation as being used in their classroom culture. In the subjective understanding of student 2, the order of discourse (Foucault 1971), as legitimized by the discursive practices of the classroom cultural institution and instantiated here by the teacher's remarks seems to point to a different way to interpret "n". We may say that, for him, if n is meant to be any concrete intended number, as student 1 is proposing, then, according to the classroom culture, the teacher could have stated this clearly instead of using such a complicated phrasing. Student 2 is doubtful and this doubt appears as something very important for the future of the meaning negotiation process. Notice that the conflict between students 1 and 2 seen in lines 27-28, 32-34, arises differently here. In line 68, student 1 re-interprets the teacher's previous explanations as confirming his own arithmetic interpretation and challenges student 2 with an authoritative argument ("[the teacher] just explained it!"). Seeing this, the teacher decides to intervene again:

5 42 (74) teacher: So, uh... *(looking at the sheet)* Wait, wait, wait! But for any number . There you did it for seven circles, but if seven.. for any . .

5:52 (75) student 2: *(showing the sheet with his pencil)* You add 2 to the number on the bottom .. subtract ...oh no, you add 2 to the number on top If it is seven, the number like this what I *(inaudible)*

As the dialog suggests, the opening towards a new understanding is not made possible through a discussion on a concrete example but through the *prise de conscience* of an action previously undertaken (in solving question *a* and *b* but also in many lines of the dialog presented here, e.g. lines 71, 72). The action is now formulated *not* as a *concrete action* within arithmetic (which would give as a result a concrete number, as in lines 71 and 72) but as a *potential action* in the metacode of natural language. As we can see, the new mathematical object is constructed with words: "You add 2 to the number on the bottom...". What we call "generality" is trapped here in the expression "the number on the bottom" —an expression that keeps all the sensuality of the figures in the space— and the operation of adding ("You add 2") to which is submitted this unutterable number ("the number on the bottom") within the elementary semiotic system of school arithmetic.

But what is it that finally made possible the negotiation of meaning? The answer resides not in the students' suddenly grasping the teacher's intentions but in the teacher's continuous (polite, encouraging but always clear) rejection of the students' solutions and the students' will to search for alternative understandings The construction of the potential action with words is pushed further by the teacher in order to end up with a mathematical formula

6.01 (76) teacher. OK Could you put this in a formula?

6 04 (77) student 3 Uhhh

6 05 (78) teacher using n

6 06 (79) student 3: Uhh . . it's the term times two plus two
6 10 (80) student 2. The term times two plus two?
6 12 (81) student 3: *(showing the figures with his pencil)* Uhhh . . 2 times 6 2 times 3 is 6, plus two . .
6 21 (82) teacher: Could you say that again, please?
6 23 (83) student 3: Yeah. The term times two plus two *(student 2 writes the explanation)* / [. .]
6 37 (86) student 1: *(reading the answer)* OK. The term times two plus two

The students finish by writing: "n2 + 2 = ".

4 Concluding Remarks

The word "term" (which emerges as a sign representing the previous term "the number on the bottom") is not used correctly by the students from a mathematical point of view. There is a confusion between the term and its rank. Nevertheless, the attempted meaning was functionally clear. It is worth noticing that the word "term" comes first to be used by the students as a tool that allows a refinement in the construction of the object. The use of words seems to be similar to that of concrete tools in apprentices. At first the tool (in terms of the "specialist's norms") is used awkwardly and only later can one use it with progressive mastery.

The concept of general term appeared as a potential action bearing the concrete characteristics of actions previously carried out in the social plane undergoing an internalization (in the neo-Vygotsky's sense given in Radford 1998) *through* and *by* signs (in this case words and mathematical signs, whether iconic or arithmetic ones). Such a potential action —which seizes the actual form of the generalization— is the particular expression of concrete actions as afforded by the students' mediated activity (not only by speech but by writing and the related cultural artefacts allowing it, e.g. the sheet and the pencil, the latter functioning as a key instrument in deictic gestures, as in the crucial line 75) arising in the course of their reflections to solve the problem. The students' reflections and their understanding and production of signs are embedded in discursive schemes and discourse orders prevailing in the classroom according to its own culture.

As we have seen, the potential action making possible the overstepping of concrete arithmetic thinking and the reaching of generalization finds expression in the semiotics of the concrete actions and the mode of thinking thus produced. Contrary to the traditional idea, generalization is not something dealing with the abstract and its evacuation of the context but a different contextual semiotic expression of previous actions, which afford the potential action (for instance, giving sense and virtually existence to it). It is enlightening to remark at this point of our discussion that Euclid's proposition quoted in the introduction also bears this distinctive trait of generalization as a potential action that, figuratively speaking, still has the sent of the concrete Pythagorean actions from where it emerged. Generalization is not a mere act of abstraction from the concrete; indeed, generalization keeps a genetic connection to the concrete according to the mediated system of individuals' activities and the epistemic and symbolic structure of these. In turn, as paradoxical as it may seem, the generalizing potential action, even without being *there*, is already producing the concrete actions. Indeed, without being explicitly there, the potential action is already present, making possible that the sixth, seventh or any other term be investigated in the very same form. Beyond their synchronic temporal dimension, the concrete and the abstract bear a dialectical relation, in which they mutually condition each other within the limits traced by the historical and cultural rationality

of the individuals and the semiotic systems that the individuals are continually re- and co-creating.

As we saw, the web of possibilities from where generalization takes place is co-formed and revealed in the texture of the text that the teacher and the students deploy in their search for meaning. In the particular case studied here, we saw how meaning shifted from "figure n" to "n" to "any number" to "any arbitrary but concrete number" until they overcame the "multiple representation problem" and reached an algebraic "public" (Ernest 1998) standard meaning. We also saw that this was done by using different utterance genres ranging from reading ("R" e.g. line 22), requesting ("Q" e.g. line 36), confronting ("C" e.g. line 33), explaining ("E" e.g. line 44), acquiescing ("A" e.g. line 42), informing ("I", e.g. line 45)[2] . The students' production of signs in the formula was mediated by speech and its written form. After uttering the formula, the students wrote it in natural language as "the term x 2 + 2" and then as "~~n x 2~~ n2+2 = " . It is worthwhile to note that Vygotsky suggested that " [u]nderstanding written language is done through oral speech, but gradually this path is shortened, the intermediate link in the form of oral speech drops away and written language becomes a direct symbol just as understandable as oral speech." (1997, p. 142). The fate of the students' understanding of algebraic language seems to be the same, that is, it will be couched in speech (and the accompanying semiotic systems) and only later will it become a kind of autonomous semiotic action. Indeed, signs (like "n" in the students' formula), we would like to insist in closing this paper, are but the result of semiotic contractions of actions (concrete or intellectual as outer or inner speech) previously carried out in the social plane.

UNDERSTANDING DATA TABULATION AND REPRESENTATION

Chris Reading
Centre for Cognition Research in Learning and Teaching
University of New England, Armidale, Australia

Statistics has received increased recognition in mathematics school curriculums in Australia partially due to the strand status assigned to statistics (within Chance and Data) in ***A National Statement in Mathematics for Australian Schools.*** *Consequently, research has focused on considering what 'statistical thinking' really means. To assist teachers to plan and assess the teaching of statistical concepts more needs to be known about students' statistical understanding. This paper takes up the theme by considering students' responses to two open ended tasks, one of which presents the data in table form and the other graphically. Both tasks require students to describe what they understand by the data representation. A developmental sequence of eight levels was identified and the responses to the two different data presentations were analysed. The SOLO Taxonomy was used as the theoretical framework to assist this process.*

Introduction

More statistical ideas are being incorporated into mathematical syllabuses across Australia but poor awareness of students' statistical understanding on the part of teachers (Watson, 1998) may well be a contributing factor to the poor treatment of statistical components in the curriculum. Truran (1997) identified lack of knowledge of statistical understanding as a concern when trainee teachers had difficulty in interpreting and applying concepts in the Chance and Data strand to create well structured sequences of lessons. In encouraging teachers to give students a chance to show what they *can* do statistically Shaughnessy (1997) stressed the need for research into students' thinking about chance and data.

A recent development in investigating student understanding has been the use of the SOLO Taxonomy (Biggs & Collis, 1982) as a framework, in both probability and data handling. SOLO levels have been used to classify student responses concerning uncertainty (Moritz, Watson & Collis, 1996), data representation (Chick & Watson, 1998), data reduction (Reading & Pegg, 1996) and data interpretation (Reading, 1998). This paper contributes by exploring students' responses to questions concerning the understanding of data tabulation and representation, using the SOLO Taxonomy as the theoretical framework.

The SOLO Taxonomy

Detailed descriptions of the SOLO Taxonomy can be found elsewhere (see for example, Biggs & Collis, 1991; Pegg, 1992). The model, which allows students' responses to be categorised, consists of five modes of functioning, with levels of achievement identifiable within each of these modes. The two modes relevant to the research being reported are the ikonic mode (making use of imaging and imagination) and the concrete symbolic mode (operating with second order symbol systems such as written language). Although these modes are similar to Piagetian stages, an important difference is that with the SOLO Taxonomy earlier modes are not seen to be replaced by subsequent modes and in fact are often being used to support growth in the later modes.

A series of levels have been identified within each of these modes, three of which are relevant to the this report. These are: *unistructural* - with focus on one aspect, *multistructural* - with focus on several unrelated aspects and *relational* - with focus on several aspects in which inter-relationships are identified. These three levels form a cycle of growth which recurs within modes and in different

modes. Within a mode the relational level response in one cycle is similar to, but not as concise as, the unistructural response in the next. A similar cycle of levels is identified in different modes but the nature of the element on which the cycle is based is different. This taxonomy is particularly useful because of the depth of analysis which can be achieved when interpreting students' responses.

Research Design

One hundred and eighty secondary students, selected randomly over gender (male, female), mathematical ability (low, middle, high) and academic years (7 to 12) were tested on a range of statistical questions. This paper reports on the responses to a two part question concerning the understanding of data tabulation and representation, an important step in the process of data analysis. The question was not testing the ability to arrange data into a table or a graph, but aimed at presenting students with some data and allowing them to describe what information they were able to gather from the representation. Part I of the question presented the data in a table, while in Part II the data presentation was graphical. The two parts were used in the question to investigate whether the form of data presentation influenced student understanding. The open-ended question allowed the student to respond with as much information as he or she felt was necessary.

Analysis of Responses to Part I

The question, as presented to students, is shown in Figure 1. Investigation of student responses showed that it was possible to divide the responses into a number of levels based on the statistical quality of the answer given. Three major groupings of the levels were identified based on the depth to which the response indicated the ability of the student to understand the representation of the data.

Part I Question

A class teacher wanted students to practice collecting data. One Year 8 student decided to collect data concerning the number of ice creams that she ate during a week for a seven week period. The table the student came up with is given below.

Week 1	3
Week 2	5
Week 3	7
Week 4	4
Week 5	2
Week 6	7
Week 7	5

What does the table tell you ?

Figure 1

First Group (No Data Use)

Responses in the first group dealt with only the requirements of the question and three broad levels, coded as 0, 1 and 2 were observed. These responses attempt to rationalise the requirements of the question but appear to make no use of the data when formulating the response.

Level 0 These responses indicate that the question has not been considered or the requirements were not clear. For example:

(7201) *Its like a graph.*

Level 1 These responses indicate that not all aspects of the question have been considered sufficiently to produce an answer. Usually, some key fact from the wording of the question is reproduced in the response. For example:

(7111) *The table tells us about the ice cream eating habits of a year 8 girl.*

Level 2 These responses indicate that all aspects of the question have been considered and a reasonable answer attempted but still no use is made of the data. For example:

(8213) *The table tells you in column one: what week it was and in column two: how many ice creams were eaten in that week.*

Second Group (Data Item Use)

Responses in the second group are concerned with attempting to understand the data, with three levels, coded as 3, 4 and 5, being observed. However, attempts to describe the data are produced in non-statistical terms.

Level 3 These responses indicate that, although students have considered the data, focus is directed back to the key facts in the question usually indicating in some way that weekly data is available. For example:

(11105) *It tells me how many ice creams she ate in 7 weeks, how many she ate each week.*

Level 4 These responses indicate an awareness that features of the data need to be mentioned in the answer. However, restricted experiences at data description result in the information in the table being quoted verbatim. For example:

(12207) *The table tells me that for week 1 the student ate 3 ice creams, in week 2 she ate 5 ice creams, week 3 she ate 7 ice creams etc.*

At this stage there is a divergence of the responses into two distinct paths which appear to develop at seemingly parallel rates. These are labelled:

Path A for responses which describe statistical features of the data

Path B for responses which make judgements about the data.

Level 5 These responses describe the data by making a simple observation. They suggest readiness to engage in data description but a lack of experience and appropriate tools to produce a statistically sophisticated response. For example:

Path A (11111) *Some weeks she ate more than other weeks.*

Path B (8108) *That the girl is very unhealthy.*

Third Group (Data Feature Use)

The final group of responses indicate a readiness to describe the information contained in the data in a more acceptable statistical form. Only two levels of responses, coded as 6 and 7, were identified. Both levels are split into A and B paths, with Level 7 also having some responses incorporating elements from both paths.

Level 6 These responses indicate the use of data from the table to make one detailed observation. They show more sophistication than those at Level 5, linking the observations to features of the data, rather than making broad statements. For example:

Path A (10109) *The table tells me that the amount of ice creams eaten varies from 2 - 7 over the 7 weeks.*

Path B (9201) *The table tells you that she likes ice cream for a couple of weeks then she gets back into them again.*

Level 7 These responses indicate a more in-depth understanding by presenting more than one observation related to the data. For example:

BEST COPY AVAILABLE

Path A (9112) *She ate the most ice creams in week 3 and 6. And the least in week 5. On average she ate 4.7 or 5 ice creams a week.*

Path B (12212) *The student likes ice cream or it is summer and she wants to keep cool.*

Some responses showed features of both Path A and Path B,

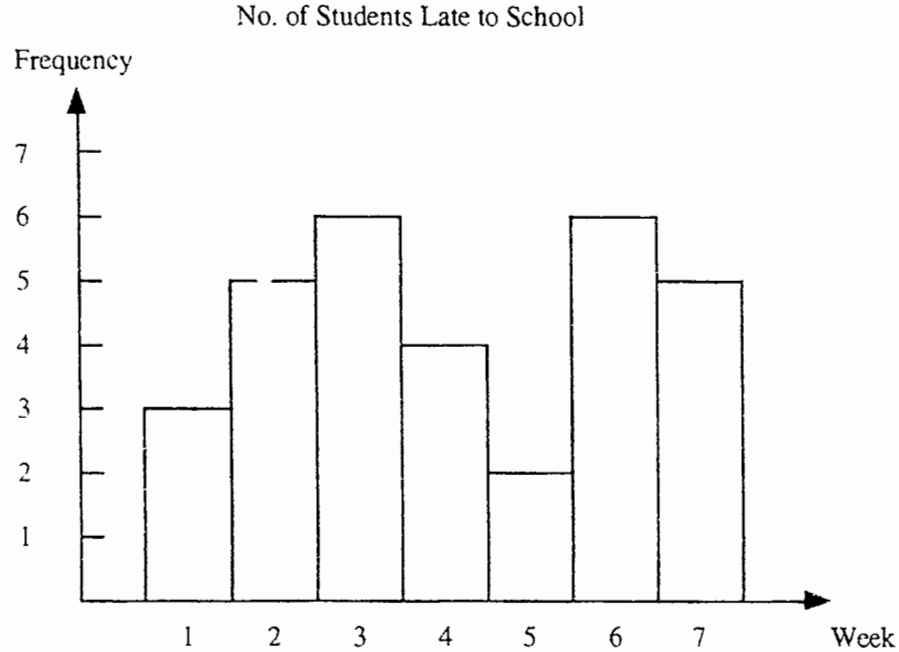
(10212) *The table tells you that the girl ate 33 ice creams in 7 weeks and that she must have liked ice creams.*

A third level in this group was not found but it is anticipated that such a level may contain responses which not only mention statistic(s) and judgement(s) but use the statistics as evidence for the judgements made.

The results, arranged by academic year, appear in Table 1 and a number of interesting points become apparent. First, there are only eleven students (18%) from the two senior years whose responses fall within the first group, compared to twenty five (42%) from Year 7 and 8. Second, there is a larger number of senior students compared to junior, noticeably twelve in Year 12, whose responses were coded as Level 7. Third, there is a large bulge in most years at Level 2. Fourth, there appears to be a larger number of responses in the last level of each of the first two groups (that is Levels 2 and 5), than in the previous two levels of the group. This is more noticeable in the junior years. Last, there appears to be a balance in the number of students whose responses reflect Path A and Path B.

Table 1
Response Level and Path by Academic Year for Part I Question

Level	Year												Total
	7		8		9		10		11		12		
0	1		0		0		0		0		0		1
1	4		1		0		1		0		2		8
2	4		5		10		11		6		3		49
3	14		3		3		2		7		2		20
4	0		5		0		3		0		2		10
	A	B	A	B	A	B	A	B	A	B	A	B	
5	1	5	3	6	4	3	2	4	4	2	3	3	40
6	1	0	3	2	1	4	2	2	2	3	1	2	23
7	1	0	1	0	3	1	1	0	5	0	4	3	
	0		1		1		2		1		5		29
Total	30		30		30		30		30		30		180



These results suggest that, for the process of understanding data presentation, the level of response improves progressively with academic year, although, the bulge at Level 2 suggests that many students have difficulty actually describing the data at all. Further, there appears to be no particular preference for descriptions using statistical features or judgemental observations.

Analysis of Responses to Part II

The second part, II, of the question is shown in Figure 2. Answering this question meant that students needed to be able to read the graph before describing the data. Examples of responses to Part II are not given because they are similar in form to those given for Part I and were coded into similar levels. The results, arranged by academic year, are presented in Table 2 and some interesting features emerge. First, while twenty one students (35%) from the two senior years gave responses in the first group, there were thirty four (57%) from the Years 7 and 8. Second, Level 7 contained thirteen Year 11 and 12 students but only three Year 7 and 8 students.

Part II Question

The deputy in the school kept a record of the number of students who were late to school each week. He decided it would be useful to draw a graph to illustrate the information. The graph is presented below.

What does the graph tell you ?

Figure 2

Third, there appears to be a larger number of responses in the last level of each of the first two groups (Levels 2 and 5). Last, there are almost twice as many students coded in Path A as Path B, with Path A more popular in all but Year 7 and Year 10.

Table 2
Response Level and Path by Academic Year for Part II

Level	Year												Total
	7		8		9		10		11		12		
0	0		0		0		0		0		0		0
1	8		7		1		0		2		3		21
2	11		8		11		14		12		4		60
3	2		1		3		4		4		1		15
4	0		0		0		1		0		2		3
	A	B	A	B	A	B	A	B	A	B	A	B	
5	0	7	3	3	5	3	0	7	4	2	7	3	44
6	1	0	6	0	5	0	4	0	1	0	2	0	19
7	1	0	1	0	0	2	0	0	4	0	6	2	
	0		1		0		0		1		0		18
Total	30		30		30		30		30		30		180

These observations suggest a slight improvement in the quality of responses with increasing academic year and a preference for describing the data using statistical features rather than judgements. Difficulties were experienced making the step to actually describe the data and also in the step to describe the data in more statistical terms.

Comparison of Part I and Part II

The framework developed appears to be adequate for explaining students' understanding, as far as the basic description of data presentations is concerned. There is a slight upward shift in the trend of

1268

the responses over the academic years as would be expected. All but one student felt that he or she understood the question sufficiently to attempt an answer and those few who had the most problems responding (Level 1), including misinterpreting the graph, were mostly in Years 7 and 8.

Testing the hypothesis that the level of response is independent of the part of the question yielded $\chi^2 = 13.53$ (6 d.f) which is significant ($p < 0.05$) and indicates that the level of a response is associated with the part of the question being answered. Many more responses than expected were coded at the lower levels in Part II, while Part I had more responses than expected in the uppermost levels. This suggests that students exhibit a higher level of understanding when the information is presented in a table rather than as a graph. Considering the number of responses that were graded into each path for Parts I and II, a test of independence resulted in $\chi^2 = 2.39$ (1 d.f.) which is not significant ($p > 0.10$) suggesting that the choice of path is not associated with the part of the question being answered. This means that the path, A or B, used by a student in Part I does not indicate which path will be used in Part II. For example, giving a judgemental response when describing tabulated data, does not necessarily mean a judgemental response will be given when describing graphed data.

Three noticeable trends emerge when comparing the results of the analysis of Part I and Part II. First, there are more Year 7 and 8 students in the first group than there are Year 11 and 12 students. Second, there are more senior students than junior students in Level 7. Third, there is a large bulge in the numbers at Level 2 in most years. So, irrespective of the form of data presentation there is a general trend for a slight increase in the level of performance of the students over the six academic years and an unexpectedly large number of students repeating key facts from the question and not using the data in any way in the description. The better quality responses from Years 11 and 12 could mean that by this stage most students are ready to describe the data in more detail, despite the fact that little statistical work is actually undertaken in their curriculum studies.

The comparison of results also highlights three differences. First, the number of Year 11 and 12 students in group one is much larger for Part II (21) than for Part I (11). Second, the overall number of responses at Level 7 is much larger for Part I, (29), than for Part II (18). Lastly, similar numbers of responses are categorised as Path A or Path B in all years for Part I but most years show a predominance of Path A type responses for Part II. These differences suggest that although there is an increase in level with academic year, the overall range of performance is better when data are presented in table form than as a graph. Also, that when presented with data in graphical form younger students are more likely to use judgements in their descriptions while older students are more likely to use statistics.

SOLO Taxonomy Framework

The SOLO Taxonomy is now used, along with the groups of levels described earlier, to develop a framework which can be used to assist with the interpretation of student responses. The first group of responses exhibit ikonic features, while the second and third groups represent two different cycles in the concrete symbolic (CS) mode.

Ikonic mode responses show no evidence of linking the required task with any sort of symbolic representation. Level 1 responses were coded as a mixture of unistructural (U) and multistructural (M) responses, while Level 2 responses were relational (R).

Second and third group responses have been able to link the concepts in the question to concrete experience. The answer, which suggests that the question has been understood, links directly to aspects of the data. These responses are in the CS mode, with two cycles, of U, M and R levels.

The first cycle involves appreciating that it is possible to describe data. The elements in the first cycle are the actual pieces of data themselves (data items). A relational response in the first cycle is not achieved until the student is able to consider all data items as a functioning set, and the data items as capable of being described in another form. The U, M and R levels in this cycle correspond to the Levels 3, 4 and 5 described earlier, with the R level showing the split into two parallel paths.

The second cycle involves showing an appreciation for the need to refer to the features or behaviour of the data as part of the description. The elements in the second cycle are the various features (or properties) of the data which a statistical description could include. A relational response in the second cycle is not achieved until the student is able to present both statistical facts and judgements, and also some relation between them. In this cycle, the U and M levels correspond to the Levels 6 and 7 as outlined earlier. These two levels still contain the separate A and B processing paths, while some M level responses show evidence of elements from both paths. No responses were observed at the R level.

In summary, the main feature which distinguishes the concrete-symbolic mode responses from those in the ikonic mode is the retrieval of facts from the recorded data. Ikonic mode responses go no further than recognising from the question the variables which are being measured. CS mode responses show that the data items have been considered. Within this mode, the first cycle responses suggest that the data items have been considered as separate items while the second cycle responses indicate an overview of the data, in the form of a statistic or judgement.

Conclusion

Three major findings have evolved as a result of this study. First, presenting data in graphical form alters the way students describe data, as compared to tabular presentation. The differences in approach to data description include an overall lower level of understanding and a greater likelihood to discuss statistics rather than make judgemental comments.

Next, the three broad grouping identified, namely, *No Data Use*, *Data Item Use* and *Data Feature Use*, assist in determining the stage a student has reached in understanding data representation and tabulation. *No Data Use* responses are dealing with aspects of the question and not the data, while in the other two groups use is made of the data, *Data Item Use* responses in a less statistically sophisticated fashion than the *Data Feature Use* responses. These groupings offer teachers a means to follow better student thinking when planning lesson sequences within the curriculum and assessing specific student outcomes.

Last, the groups of levels identified can be categorised as cycles of U-M-R levels, based on the SOLO taxonomy. The *No Data Use* group is a U-M-R cycle in the ikonic mode where the elements of focus are the facts in the question. The other two groups represent two U-M-R cycles in the CS mode. The elements of focus in the first cycle, the *Data Item Use* group, are the actual data items

while the focus in the second cycle, the *Data Feature Use* group, is on the various features (or properties) of the data. The identified levels in the CS mode are consistent with the U, M and R levels described in more general terms by Chick and Watson (1998, p. 156). Using this framework to assess responses, teachers can gain a greater awareness of students' understanding which will allow them to better prepare lessons based on the curriculum and to assess what students really know, understand and can do.

NEEDING TO EXPLAIN: THE MATHEMATICAL EMOTIONAL ORIENTATION

David A Reid

Acadia University

Explanations are accepted or rejected within a community on the basis of an emotional orientation. Examination and description of students' explanations in mathematics classes are used in this report to clarify the nature of the mathematical emotional orientation. The report also provides elements of a language for describing students' explanations as a contribution to the difficult task of conducting research into students' mathematical proving.

Proving in mathematics is a complex activity and research on students' learning to prove must employ a rich descriptive language to capture it. Lakatos (1978) and Polya (1968) offer language to describe two elements of proving: the formality of written proofs and the relationship between deductive reasoning and other types of reasoning. Classifying kinds of deductive and inductive reasoning has also been an area of much research (e.g., Bell 1976, Harel & Sowder 1996). Another element of proving, the formulation of reasoning, has been described by Mok (1997) and Reid (1995a) but further work is needed in this area. A further element, the need or purposes served by mathematical reasoning, has been receiving considerable attention (Balacheff 1991; Bell 1976; Hanna 1989; Lampert 1990; de Villiers 1991), especially the need to explain deductively in mathematics (Hanna 1989, 1995; de Villiers 1991, 1992; Reid 1995). This report elaborates on the language used to describe students' explaining, and discusses the central role deductive explaining plays in the "mathematical emotional orientation."

The mathematical emotional orientation

Maturana (1988a, 1988b) uses the phrase "emotional orientation" to describe the bodily predisposition that underlies individuals' decisions to accept some things as explanations and to reject others. An emotional orientation defines a domain of explanations, of which mathematics is one. Mingers (1995), in his discussion of Maturana's work, identifies three aspects of an emotional orientation:

> Each domain is constituted in three interlocking dimensions — the *criteria* for accepting explanations, different *operational coherencies* structuring such explanations, and the *actions* seen as legitimate (p.98, emphasis added).

In mathematics the *criteria* for accepting explanations include the use of deductive reasoning, a basis in agreed upon premises, and a formal style of presentation. There are many *operational coherencies* (shared experiences and assumptions) in mathematics, the most obvious of which is the language used to talk about it. There are also many *actions* that are seen as appropriate to mathematics (drawing diagrams, generalising statements, making conjectures, etc.).

The nature of the mathematical orientation may be clearer if we consider what is *not* mathematics. Explaining by reference to authority (as in the non-explanations discussed below) is not mathematics. Neither is focussing closely on procedural steps in mathematics classes, although this is the experience of many students. Finally, actions such as the use of abuse to establish authority are not legitimate in mathematics. On the other hand, feeling a need to explain conjectures, and preferring deductive reasoning as the means to do so, are a part of the mathematical orientation.

Ways of explaining

Most of the examples I provide in this report come from observations in grade 10 mathematics classes in which students were studying coordinate and Euclidean geometry. The students engaged in a series of activities, working in groups, and reported their conclusions to the class as a whole on a regular basis.

Behaviours which could be called "explaining" occurred in two kinds of contexts: activities in which there was an explicit demand to "explain" and contexts in which students engaged in what observers saw as explaining without being prompted to do so by a teacher or activity prompt.

In these two contexts several different modes of explaining were observed:

- Non-explanations;
- Explaining *how*;
- Explaining to someone else (in response to a question);
- Explaining to someone else (spontaneously);
- Explaining as part of social activity in a community where explaining is a social norm, i.e., part of the community's emotional orientation;
- Attempting to come to a personal understanding (explaining to oneself).

Individuals operating from a mathematical orientation are likely to use deductive reasoning in any of the last four modes of explaining listed here.

Non-explanations

Personal or institutional authority is a common mode of "explanation" in schools, especially for students and teachers who can't explain something and see that inability to explain as a negative reflection of themselves as people. In the following

---

In this report I will sometimes omit the word "emotional" from the phrase "mathematical emotional orientation" for brevity. This should not be taken as an indication that the role of emotions in defining a mathematical orientation is unimportant. Emotions are central to defining mathematics

These examples are taken from an ongoing research project on the psychology of reasoning in school mathematics, funded by SSHRC grant # 410-98-0085, Acadia University and Memorial University of Newfoundland.

example Stu both refers to the teacher's authority to verify and falls back on his own authority when asked to explain.

1.	Stu:	[To teacher] That one and that are complementary right?
2.	Teacher:	Why?
3.	Stu:	Because.
4.	Jill:	None of them are complementary.
5.	Stu:	They are.

Abuse can be used to establish the authority to explain. In the following example Stu replies to Christy's questions with a question of his own, perhaps to help her reflect on her own mathematical activity, or perhaps to evade her question. When he and Jimmy do reply to her they provide only the procedure she is meant to use with an implicit reference to an outside authority ("you're supposed to"), followed by abuse from Stu. Stu's opinion that he is in a position to declare Christy "stupid" suggests that he is establishing authority over her.

1.	Christy:	How'd you get that?
2.	Stu:	How'd you get 6?
3.	Christy:	I don't know.
4.	Jimmy & Stu:	You're supposed to add them together.
5.	Christy:	Oh—
6.	Stu:	3 minus 5 equals 8 ... Man you're — you're stupid.

Explaining *how*

Jimmy and Stu, in the previous transcript, offer Christy a procedural explanation, in response to her question ("You're supposed to add them together."). Many of the explanations offered in mathematics classes are not explanations of *why* something is the case (as would be expected from a mathematical orientation), but simply explanations of *how* something is calculated (which is consistent with what might be called the "school emotional orientation"). This happens not only when students ask each other how to do something (as in the previous example) but also when teachers ask students to explain. For example, this is Jill's response to the written prompt, "Which equation describes the graph on the left? Explain why."

In transcripts I use the following conventions: An em-dash (- –) indicates a short pause. Several indicate a longer pause. Ellipses (...) indicate omissions (usually "um"s, etc.) to improve readability. Three asterisks (***) are used to indicate an omission of several lines of speech. A hyphen (-) ending a line indicates an interruption of speech at that point.

The reason the equation I've marked describes the graph is because I took the points from the graph and made up a table of values then I did the equation with the table of values I made.

Jill does not explain why in any way that would satisfy a mathematician. Instead she describes what she did.

Explaining to someone else (in response to a question)

Another context for explaining, the first in which deductive reasoning is likely to occur (suggesting a mathematical orientation), is responding to another person's question. The other person might be a teacher or written prompt (like the one offered to Jill in the previous example) or, in this case, another student (CH is a research assistant).

1.	Melinda:	I have one.
2.	CH:	What do you have?
3.	Melinda:	Triangle ABC and BDC.
4.	Jill:	Why?
5.	CH:	They're congruent?
6.	Melinda:	'Cause they have a shared side and alternate angles.

Here Melinda uses notation specific to mathematics and makes implicit use of a shared experience of theorems and definitions in geometry to provide a deductive explanation.

Explaining to someone else (spontaneously) and as a social activity.

In the following transcript four grade 10 boys are trying to work out a generalisation concerning the sum of the interior and exterior angles of polygons. Their class has been studying Euclidean geometry (parallel lines and congruent triangles) for about a month, in a style similar to the exploratory methods described by Fawcett (1938). In this context the students in the class have come to adopt explaining as a major focus in their mathematical activity, and have come to value well formulated, deductive explanations. The following transcript offers a number of examples of spontaneous explanations, embedded in a social context that values explaining. (Bold indicates such explanations.) These explanations suggest that the boys were operating from a mathematical orientation at this time.

1.	Wane:	The exterior angles of them all — **because when there's more sides you can make more triangles.**
2.	Mick:	Which one is he talking about?
3.	Wane:	**So** it keeps going up by 180!
4.	Clark:	Here's what I was thinking. This one is 360. That triangle there and that one -- exterior angles.
5.	Wane:	Oh yeah, that's true too.

6. Mick: That angle there is 360 and this angle here — Now they all equal 360, right?
7. Clark: You see, we got this thing here — a common vertex. That means we have to subtract some angles. 360 and 360 which is 720, right? Correct? Okay. Now we got to subtract some. Okay?

***

8. Mick: So what do we got?
9. Clark: We got four angles, right? Now — uhhhh — uhhhh - They're all counter-clockwise — Yeah they are. CCW.
10. Wane: No they aren't.
11. Mick & Clark: Yes they are because the way they goes up that way.
12. Clark: Okay. Now we got the four angles.
13. Wane: Four times 180.
14. Mick: But they're not all 180.
15. Clark: How do you know they're not 180?
16. Mick: **Because they're not all straight lines**. The angles aren't straight lines — I was just looking at that one.
17. Clark: **And they're all supplementary to an angle inside here**, right?
18. Mick: Oh, deadly!
19. Wane: And it has something to do with — if you know the interior angles — the sum of the interior angles — then they'll all wind up to be the same thing **because they're all supplementary to an angle.**

The behaviour of Mick, Clark, Jacob and Wane in the above transcript suggests that they have a mathematical orientation. The passages in bold show Wane, Clark and Mick responding to a felt need to explain their conjectures, which is an action in keeping with mathematical practice. Their explanations make reference to geometrical concepts, definitions and theorems that are a part of the shared experiences of their mathematical community. They propose explanations using deductive reasoning (an operational coherency that structures mathematical explanations) and they expect others to explain things deductively and with reference to the same definitions they use, indicating that at least two of their criteria for accepting explanations are consistent with a mathematical orientation.

Explaining to oneself.

The last mode (explaining to oneself) can be described in still gre - detail, but in the interests of space I will limit myself here to one example, of . university undergraduates working on the Arithmagon problem (see Reid 1995a or 1995b for a more detailed analysis):

1. Stacey: What happens if you add the middle numbers together? —

2.	Kerry:	Well I guess we could, hmm.
3.	Stacey:	I just want to try something. If you take 27, 18, and 11 2, 4, 5, 56. Right?
4.	Kerry:	Sure.
5.	Stacey:	And you have — So you add each of those twice, right? — Yeah you do. That's not going to help you either. That's what you end up doing right?
6.	Kerry:	What'd you do?
7.	Stacey:	You add A, B, C. Then you multiply them by 2. You get this answer. —
8.	Kerry:	Do you add?
9.	Stacey:	22, and 34. Yup. Do you know what I mean?
10.	Kerry:	Sorry. So you add this and multiply by 2 so, like, the sum of this is 28 times 2. And it's 56. Good one. What's that mean?
11.	Stacey:	[laughing] Nothing.

In spite of the linguistic indications that Stacey was explaining something to Kerry ("Right?" "Do you know what I mean?") she is really explaining to no one but herself. Kerry, in spite of being involved in the same problem solving activity as Stacey, was unable to follow her explanation. It is clear however that Stacey *was* explaining something to herself, and elsewhere I provide a possible interpretation of the deductive reasoning involved in her thinking (Reid 1995b, Kieren, Gordon Calvert, Reid, & Simmt 1995) which suggests she was operating from a mathematical orientation.

Conclusion

Researching proving involves dealing with complexities. Many types of reasoning are involved, there are degrees of formality of written proofs and formulations of reasoning, and the needs which motivate proving are many and their importance is only beginning to be understood. The examples I offer in this paper are intended to help clarify one need to prove: the need to explain. In exploring the need to explain I also address the features that qualify explanations as mathematical explanations, which is an important part of defining a mathematical emotional orientation. The criteria for acceptance of explanations in mathematical communities include the use of deductive reasoning and reference to shared experiences of notation, definitions and established theorems. Observation of these characteristics in students' explanations suggests progress in their adoption of a mathematical orientation.

MONITORING OF DYNAMICS OF STUDENTS' INTELLECTUAL GROWTH IN MPI-PROJECT

Sam Rososhek
Algebra Department
University of Tomsk – Russia

The system of tests, which allows to follow the dynamics of intellectual growth of students aged 10-15, has been worked out within the frames of MPI- project Accomplishment of test tasks corresponds to a certain level of organization of individual mental experience, which is considered as the level of intellectual growth. Student's accomplishment of every test allows to receive a multidimensional vector, characterizing the state of his/her individual mental experience at the moment of doing the test. Totality of such vectors for all the tests during the whole period of studies makes up the individual trajectory of a student's intellectual growth in multidimensional space. We propose to discuss the tests themselves as well as some results obtained in Tomsk schools.

The system of the tests, which allows to follow the dynamics of intellectual growth of students aged 10-15 has been worked out within the frames of MPI-project (MPI: "Mathematics. Psychology. Intelligence."), the head of the project is Prof. E.Gelfman. The project is directed at the development of students' individual cognitive experience. Fulfilling test tasks corresponds to a certain level of organization of individual mental experience of a child, in other words, a certain level of a child's intelligence. The theoretical foundation of the paper includes Kholodnaya's conception about intelligence as individual mental experience [1] and Weyl-Shafarevich conception about Algebra as the collection of coordinatizing quantities systems [2-4].

Let us have a look at basic pivotal lines, which cross the whole system of the tests and which correspond to certain components of individual mental experience of a child. They are: 1) a line of comparing numbers which by the end passes into a line of inequalities; 2) a line of equations; 3) a line of operations with numbers which by the end passes into a line of algebraic structures; 4) a line of word problems, which by the end passes into a line of mathematical modeling; 5) a line of search for regularities in a row of numbers which passes into a line of functions; 6) a line of visualization of abstract mathematical notions.

We shall dwell on some of these lines in a more detailed way. Let's begin with a line of comparisons. Here is a mid-year test for the 1st year of studies in MPI-project, which along with skills of comparing decimal fractions, checks the ability of transformation of one way of recording numbers into the other one.

Task 1 from a mid-year test for 10-11 year old students. Insert the omitted sign of comparison for the following numbers: "seven integers seventy nine thousandths" ... "seven integers eight hundredths. a) <; b) >; c) =".

A corresponding task which is given at the end of the 1 st year of studies (age 10-11). Insert the omitted sign of comparison for the following numbers:

"thirteen of tenths"... "one hundred and three hundredths". a) <; b) >; c) = ; d) another answer (point out, which one)".

Complication of task of the test which is given at the end of a school year is made simultaneously along several directions: first of all, if in a mid-year test it is presupposed that the right answer is given among the variants of the answers, it is not obligatory for the final test at the end of the school year. Secondly, besides transformation from verbal form of record of numbers into sign form, here transformations of a decimal fraction into a standard form is necessary and that requires comprehention of the notion of a decimal fraction, but not only formal habits of actions. It should be noted that a notion of a common fraction in MPI-project is given after a notion of a decimal fraction, that's why children are not

acquainted with formal transformation of fraction $\frac{13}{10}$ into decimal fraction 1.3.

Let's have a look at a corresponding task for the 2^{nd} year of studies. Here is an example of a mid-year test for students aged 11-12. Insert the omitted sign of comparison into the following numerical expressions: "thirty one minus fifty"... "forty nine minus seventy. a) <; b) >; c) =".
A task which is given at the end of a school year to students aged 11-12.
Insert the omitted sign of comparison into the following numerical expressions: "minus one hundred eighty nine of twenty sixths"... "minus seven integers twenty six hundredths. a) <; b) >; c) =; d) the other answer (which one)".
Complication of a final test in comparison with a mid-year test for children aged 11-12 lies in the following: integers are compared in a mid-year test and in the final test we compare rational numbers (represented in different forms: common and decimal fractions).

Now let me give an example of a comparison task for students of the 3d year of studies, aged 12-13:
"Compare the values of numeric expressions and insert the omitted sign of comparison: $\left(0.04-\frac{3}{72}\right)...\left(\frac{1}{6}-\frac{1}{8}-0.04\right)$. a) <; b) >; c) =" .

This task is directed at exposing students' ability to make a generalized numeric reasoning. The majority of students who were doing this task tried to transform common fractions into decimal ones and they had to pass to approximate values of numbers and, as a result, couldn't get the correct answer. Some of the students transformed decimal fractions into common ones, and having done the required operations with the fractions, they compared the fractions, which they have got as the result. Maximum number of points was given to the students who, having transformed the numerical expressions into the form

$$\frac{1}{25}-\frac{1}{24} \text{ and } \frac{1}{24}-\frac{1}{25}.$$

didn't start to calculate their concrete values, but compared a negative number to a positive one.
Another task from a test, which is given at the end of the school year to 12-13 year old children: "compare the numbers and insert the omitted sign of comparison: 2^{100} ... 1000^{10}. a) <; b) >; c) = ; d) another answer (which one)".
In this task a generalised numerical reasoning was in transformation of numbers into the form $(2^{10})^{10}$ and $(1000)^{10}$ with the consequent comparison of 2^{10} and 1000.

Let us pass over to the task of the 4th year of studies (children aged 13-14).
Here is an example of a mid-year task: "compare numbers and insert omitted sign of comparison:

$$\frac{\sqrt{2}}{3} \ldots \frac{\sqrt{3}}{4}.$$ a) <; b) >; c) =".

A task which is given at the end of the 4th year of studies (13-14 years): "compare the numerical expressions and insert the omitted sign of comparison:

$\left(\sqrt{8} - \sqrt[3]{22}\right) \ldots \left(\sqrt{10} - \sqrt[3]{32}\right)$. a) <; b) >; c) = ; d) another answer (which one)".

If in a mid-year test a generalized numerical reasoning is given in the form of a numerical expression with consequent comparison of subradical expressions, then in a final test the reasoning is complicated by the usage of transformation of numerical expressions, which allow to establish that they have different signs.

In the tests for students of the 4th year of studies there appear numerical inequalities (inequalities and systems of two inequalities with one variable). Finally in the 5th year of studies we include quadratic inequalities and inequalities with a modulus in the test. Success in work with this material largely depends on success of work along the whole line of comparison task, beginning with the 1st year of studies.
Now let's consider the line of algebraic operations. Here is a task from a mid-year test for students, aged 10-11: "Calculate using the properties of arithmetic operations (point out, which ones): $92(57 - 39) + 18 \cdot 208 = \ldots$ a) 7100; b) 7200; c) 7300".
If the correct answer has been got without using properties of operations, one point was given. If the properties of operations have been made use of for getting the correct answer, but they were not named, two points were given and only usage of properties of operations for getting the correct answer with naming these properties was estimated by three points. Here is an example of a test, given at the end of a school year to 10-11 year old students: "Make calculations using the properties of arithmetic operations (point out, which ones): $1.71 \cdot 0.18 + (3 - 2.982)2.29 = \ldots$ a) 7.2; b) 0.72; c) 0.072; d) the other answer (which one)".
Complication of a task of a final test in comparison with a mid-year test lies in the fact, that, firstly, there was the correct answer among the given answers in a mid-year test but in a final test it is not obligatory and, secondly, numerical domain with natural numbers is widened to decimal fractions.
In MPI-project we give two tasks to 2nd year students, aged 11-12. One task consists of using familiar properties of arithmetic operations and the 2nd task is aimed at

checking some of the properties for operations of subtraction and division in different numerical domains.

Here is a mid-year test for students, aged 11-12: "Make calculations using the properties of arithmetic operations (point out, which ones)

$39 \cdot (-2) - (14 - 16)(-111) = \ldots$ a) 300; b) –300; c) 144".

Another task from a mid-year test for 11-12 year old students: "we may say about property of commutativity for subtraction of whole numbers $a - b = b - a$ that it is ... a) always fulfilled; b) never fulfilled; c) fulfilled for some numbers and not fulfilled for the other numbers".

Tasks which are given at the end of the 2^{nd} year (11-12 year old students):

1) "make calculations using properties of arithmetic operations (point out, which ones):

$$\left(6\frac{1}{4}\cdot(-32.4)-(-32.4)\cdot 8\frac{1}{8}-60.75\right)\cdot 3.4-15\frac{3}{5}=\ldots$$

a) –15.6; b) –199.2; c) –428.7 ; d) the answer is different (point out, which one)".

2) "we may say about property of associativity for division of rational numbers that it is: $a : (b : c) = (a : b) : c$. a) always fulfilled; b) never fulfilled; c) fulfilled for some numbers and not fulfilled for the other numbers; d) the other answer (which one)".

Now, let's consider tasks of tests which are refered to the line of algebraic operations (third year of studies).

Tasks for a mid-year test for students aged 12-13:

I. "We may say about property of "right" distributivity for division of rational numbers relative to addition $(x + y) : z = x : z + y : z$ that it is. a) always fulfilled; b) never fulfilled; c) fulfilled for some numbers and not fulfilled for the other numbers".

II. "We may say about property of "left" distributivity for division of rational numbers relative to addition $x : (y + z) = x : y + x : z$ that it is. a) always fulfilled; b) never fulfilled; c) fulfilled for some numbers and not fulfilled for the other numbers".

Tasks from the test, given by end of a school year to students aged 12-13:

I. "We shall define the operation on a set of whole numbers according to the following rule: for any pair of whole numbers m and n, let $m \Theta^2 n = (m - n)^2$. We shall call operation Θ^2 "quadratic difference" of numbers m and n. We may say about property of commutativity for quadratic difference of whole numbers $m \Theta^2 n = n \Theta^2 m$ that it is. a) always fulfilled; b) never fulfilled; c) fulfilled for some numbers and not fulfilled for the other numbers; d) another answer (which one)".

II. "We shall define an operation on a set of whole numbers according to the following rule: for any pair of whole numbers m and n let $m \Theta^3 n$ mean the following: $m \Theta^3 n = (m - n)^3$. We shall call this operation Θ^3 "cubic difference" of numbers m

and n. We may say about property of commutativity for cubic difference of whole numbers $m \Theta^3 n = n \Theta^3 m$ that it is: a) always fulfilled; b) never fulfilled; c) fulfilled for some numbers and not fulfilled for the other numbers; d) the answer is different (point out, which one)".

Now let's pass over to the test for the 4th year of studies. Here is an example of a mid-year test for students of the 8th form (13-14 year old):
"We shall say that natural number n is the order of permutation g if multiplication of permutations $\underbrace{g \cdot g \ldots g}_{n \text{ times}} = g^n$ is equal to identical permutation and that n is the smallest number with such property. Order of permutation $g = \begin{pmatrix} 1 & 2 & 3 & 4 & 5 \\ 3 & 4 & 1 & 5 & 2 \end{pmatrix}$ is equal ... a) 6; b) 5; c) 3".

Here is an example of a final test for the 8th form students aged 13-14:
"Let us consider a set of A numbers in the form $x + y\sqrt{2}$ where x and y are whole numbers. Then, relative to addition of real numbers, this set is: a) noncommutative group; b) commutative group; c) not a group; d) the other answer (which one)".
Finally, in tasks for the fifth (concluding) year of studies, according to MPI-project, the lines of algebraic operations and visualization of abstract mathematical notions are absent as they are united on a new level in work according to computer program on visualization of algebraic structures (groups, rings and so on) and are tested separately.

In conclusion we shall give development of one more line — word problems, which by the end passes into mathematical modelling.
Here are examples of mid-year test for the 5th form (10-11 year old).
I. "What is the price of an ice-cream if the box with ice-cream costs 16 thousand roubles and there are 32 pieces of ice-cream? a) 5 thousand roubles; b) 2 thousand roubles; c) 500 roubles".
II. "Put down the expression for definition of the price of an ice-cream in roubles, if the price of a box of ice-cream is c roubles and the number of pieces of ice-cream in a box is k. a) $k \cdot c$; b) $c : k$; c) $k : c$".
It is interesting to note that while answering the proceeding task, many students give a wrong answer of 2 thousand roubles. But some of them, having got the correct answer to the second task, turn back to the 1st task and get the correct answer.

A task from the test given at the end of the 5th form (10-11 year old):
"Introduce additional information and define the distance which a boat covers in t hours if the speed of the boat is equal to u km/h and the speed of the river-stream is v km/h. a) $(u + v)t$; b) $(u - v)t$; c) $(u - v) : t$; d) the other answer (which one)".
A task from a mid-year test for the 6th form (11-12 year old).

"At the beginning of the year a company issued k shares and by the end of the year got profit of n roubles. At a general meeting of shareholders it was decided that a part of the profit (namely, m roubles) should be used for development of the company and the part of profit, which is left, should be paid to shareholders. Then, shareholders will have per one share...a) $(n - m): k$; b) $n : k - m$; c) $k :(n - m)$" .

A task from the test, given by the end of the year in the 6th form (11-12 year old):

"During interurban bus route one bus stops every 40 minutes and the other bus-every 18 minutes. Both the buses began the movement simultaneously. What is the smallest period of time when both the buses reach their destinations? (It is presupposed that the time which they spend at the bus-stops may not be taken into account).

a) 3.5 hours; b) $5\frac{1}{3}$ hours; c) 6 hours; d) the other answer (which one)".

A task from the final test in the 6th form:

"A set of game device for TV-sets includes the cartridge, the price of which is n roubles, which makes 8% of the whole set price. What is the price of the game device without cartridge?

a) $\frac{8n}{100} - n$; b) $n - \frac{8n}{100}$; c) $\frac{100n}{8} - n$; d) the other answer (which one)".

A task from a mid-year test for the 7th form (12-13 year old):

Define an average speed of an automobile on the part of the road from point A to point B and backwards, if the distance from A to B is equal to S km and it took u hours to cover the distance from A to B and it took v hours to cover the distance from B to A.

a) $\frac{1}{2}(S : u + S : v)$; b) $2S : (u + v)$; c) $(2S : u) + (2S : v)$".

A task from a final test in the 7th form (12-13 year old):

"There are two sectors in the stadium with n seats all in all. Receipts from selling tickets to the match were: to the 1st sector — x roubles, to the 2nd sector — y roubles. How many seats are in the 2nd sector if all the tickets were sold at the same price and there remained no tickets unsold?

a) $y:\left(\frac{x+y}{n}\right)$; b) $y:\left(\frac{n}{x+y}\right)$; c) $\frac{x+y}{ny}$; d) the other answer (which one)".

We should note that the word problems given above were among the most difficult tasks for students of the 7th form.

Here are two variants of the tasks of final test for the 8th form (13-14 year old).

I. The area of a right triangle with cathetuses h_1 and h_2 is B and the area of a square, one side of which is the hypotenuse of this triangle, is A. Define h_1 and h_2.

a) $h_1 = \sqrt{A+2B} + \sqrt{A-2B}$, $h_2 = \sqrt{A+2B} - \sqrt{A-2B}$;

b) $h_1 = \sqrt{A+4B} + \sqrt{A-4B}$, $h_2 = \sqrt{A+4B} - \sqrt{A-4B}$;

1283

c) $h_1 = \frac{1}{2}\left(\sqrt{A+4B} + \sqrt{A-4B}\right)$, $h_2 = \frac{1}{2}\left(\sqrt{A+4B} - \sqrt{A-4B}\right)$;

d) the other answer (which one)".

II. "A raft and a motor boat started simultaneously with the stream from city A to city B. While the raft was on the way, the motor boat, after arriving to city B turned backward and came to city A at the same time with as raft came to city B. In how many times is the speed of the motor boat larger than the speed of the raft? a) 1; b) 2; c) two decisions: $1-\sqrt{2}$ and $\sqrt{2}+1$; d) the other answer (which one)".

In word problems of the final year of studies according to MPI-project, the line of word problems is passing into the line of mathematical modelling. As this line is very important, I shall give corresponding tasks from final test for the 9th form (14-15 year old).

I. "A businessman made up his mind to buy shares of three companies. All in all he wanted to buy 12 shares for 61 dollars and not less than two shares of each of the companies. How many variants there exist on these conditions if the price of shares of these three companies is \$7, 5 and 4? Solve the problem by means of making and analyzing a corresponding mathematical model. a) one variant: 3, 4, 5; b) two variants: 3, 4, 5 and 3, 3, 6; c) three variants: 3, 4, 5; 2, 6, 4 and 5,2,5; d) the other answer (which one)".

II. "In city N in the flour market there is the following situation (tabl.1):

Table 1: Flour market situation

Quantity of flour required during a week (*tons*)	Price per a ton of flour (*mln. roubles*)	Quantity of flour, supplied during a week (*tons*)
100	1.5	20
70	1.7	40
50	1.8	60
30	1.9	90
10	2	100

Construct a mathematical model of the given situation and give the answer to the question: what is the equilibrated price and the equilibrated quantity of flour for the given market? a) 1.7 mln roubles per a ton and 55 *t*; b) 1.8 mln roubles per a ton and 50 *t*; c) 1.7 mln roubles per a ton and 53 *t*; d) the other answer (which one)".

III. "In conditions of a standard model "foxes-rabbits" let's assume that at a certain period of time there were 120 rabbits and 50 foxes on an island. Find out short-term and long-term consequences of the administrative decision to shoot 10 foxes and 25 rabbits during the 1 st year. In particular, can this decision destroy the ecosystem of foxes-rabbits?"

Now we shall consider how, with the help of the tests, to define the individual trajectory of a student's intellectual growth during the period of studies. According to MPI-project, as it is seen from the examples given above, their complication from year to year (and from mid-year to final) demands more and more various in volume

and structure individual mental experience of a child. That's why we may suppose that the quantity of the points which a student gets for the tests of one line for the half or for the whole year, correspond to the level of development of one component of individual mental experience at a given moment. Then a set of points, which have been got for all the lines of the test system in a mid or final test is a vector in a certain multidimensional space. Totality of such vectors for all the tests during the whole period of studies makes up the individual trajectory of a student's intellectual growth. Preliminary results of the tests showed that, if maximum summary number of points is from 25 to 30 for different tests, there may be pointed out some ranges of summary number of points, which may be interpreted in the form of a certain current estimator of state of a child's individual mental experience.

If summary number of points for a test is less than 10, then current state of individual mental experience is considered unsatisfactory. If summary number of points is within range from 10 to 14, then current state of individual mental experience is considered satisfactory and for the range from 15 to 19 is considered good. Finally, excellent mark corresponds to the range of 20 points and larger. A key question: how should we evaluate different individual trajectories? This question requires a separate investigation, taking into account test materials in different schools. So far, on the basis of the results of preliminary tests we can move forward hypothesis: if in a certain test a definite range for summary number of points was achieved, then we may speak of intellectual growth, if in the following tests the summary number of points remains within the same range or higher. It should be noted that besides summary number of points, we should taken into account different components of the vector of points for each of the tests. In practice, the results of a test in any concrete group are recorded in the form of a matrix, in the columns of which we record different tasks of test and in the rows we record the students of this group. Following the results along different lines of a the tests, we may find out the dynamics of development of different components of individual mental experience.

In conclusion, a few words about psychological aspects of the given system of tests. Students who worked with these tests were asked to write reflections where they could express their thoughts and impressions about the search for decision or about the tasks themselves. Even, these reflections which we have now, contain such interesting psychological material that demands a separate discussion.

STUDENT-GENERATED MULTIPLICATION WORD PROBLEMS

Denise W. Rowell
Karen S. Norwood, Ed.D.
North Carolina State University

This study examines sixth graders' attempts to generate multiplication word problems. Twenty-eight students were interviewed and were asked to write a story problem which could be solved by multiplication. Less than 40% of the students could write a problem which was multiplicative in context, yet most of the students used multiplication to solve the problem. In spite of the interviewer's attempt to promote disequilibrium, the students never understood that their problems were not multiplicative in context. This research report discusses the students' attempts to generate problems, their refusal to be put in disequilibrium, and their inability to recognize that context determines the operation.

Introduction

There has been a considerable amount of research done recently on children's ideas of multiplication. Multiplication is much more difficult than addition because it is a binary operation. (Anghileri, 1989; Clark & Kamii, 1996; Simon & Blume, 1994; Vergnaud, 1983) Addition is unary; it only requires thinking in one dimension. Multiplication, however, requires the "coordination of two dimensions". (Simon & Blume, 1994)

The difficulty that children encounter with multiplication is quite surprising considering that students tend to learn the facts and the algorithms at an early age. (Clark & Kamii, 1996; McIntosh, 1979; O'Brien & Casey, 1983) The problem is that there is more to multiplication than just facts and algorithms. In fact, there are two different aspects of multiplication: computational and contextual. (O'Brien & Casey, 1983) Many students can compute products without understanding multiplication in context. (Clark & Kamii, 1996; O'Brien & Casey, 1983) The focus of this paper is on children's *contextual* understanding of multiplication.

Several activities have been done to determine multiplicative reasoning in children. Clark and Kamii (1996) had students in grades 1 through 5 perform a Piagetian "fish task" to determine the ideas that children have about multiplication. They found that multiplicative thinking begins early in some students, but is slow to develop. Graeber & Tirosh (1990) had students give a definition of multiplication and found that most students define multiplication in terms of repeated addition. Dorwaldt (1989) and Anghileri (1989) found that many students do not understand the language of multiplication and thus have trouble understanding multiplication in context. In several studies (De Corte et al., 1994;

1286

Graeber & Tirosh, 1990; McIntosh, 1979; O'Brien & Casey, 1983), students were asked to write multiplication word problems. O'Brien and Casey found that many of the students wrote problems that were additive in context, but used multiplication to solve them. De Corte et al. found that most students who wrote appropriate multiplication word problems used the repeated addition model. Graeber and Tirosh also found that the students who were successful in writing multiplicative problems used either the repeated addition model or the union of equivalent groups. McIntosh found that many younger students could not write a problems that was multiplicative in context, and that some of the students who did write multiplication problems wrote problems which were checks for division. (For example, "6 boys climbed up a tree and collected 18 acorns each boy had 3 acorns." (McIntosh, p. 14))

Children have an informal intuition about multiplication, but often they cannot match their informal knowledge with the formal instruction they receive in school. (Resnick, 1986) Even when teachers try to promote disequilibrium (Simon & Blume, 1994), students tend to rely on their formal ideas instead of their intuition (even when their formal ideas are erroneous).

Theoretical Framework

The theoretical framework for this study is based on a constructivist view of learning. "[C]onstructivism holds that all knowledge is constructed and that the instruments of construction include cognitive structures that are...themselves products of developmental construction." (Noddings, 1990, p. 7) In addition, most constructivist mathematics educators believe that children enter school with some informal knowledge of mathematics. (Baroody & Ginsburg, 1995; Resnick, 1986) The role of the mathematics teacher is to determine what knowledge they have constructed and provide them with the experiences that allow them to construct more logical or more efficient methods for doing mathematics.

In particular, the authors framed the study using the theories of Piaget, Vygotsky and Resnick. Like Steffe and Cobb (1988), we interpret children's cognitive development using Piaget's concept of schema, assimilation, and accommodation, and we agree with Vygotsky's concept of the zone of proximal development. However, in addition to this, we subscribe to Resnick's ideas about children's errors, as well as their intuition about mathematics.

According to Piaget, children adapt to the environment and organize their experiences using what Piaget calls *schema*, *assimilation*, *accommodation*, and *equilibration*. (Wadsworth, 1996) A child's *schema* is the cognitive or mental structure he uses to organize the environment. As he receives new bits of information, he tries to integrate that information into a previously existing schema. Piaget calls this process *assimilation*. When the child receives

information that will not assimilate into a previous schema, he is said to be in *disequilibrium*. This child has to create a new schema or modify an existing schema in order to make the new information fit. This process of modifying cognitive structures is *accommodation*. *Equilibrium* is reached when there is a balance between assimilation and accommodation. Finally, *equilibration* is the process of moving from disequilibrium to equilibrium.

In addition to the theory of Piaget, the authors agree with Vygotsky's zone of proximal development (ZPD). Vygotsky describes the ZPD as "the gap between the child's level of *actual development* determined by independent problem solving and her level of *potential development* determined by problem solving supported by an adult or through collaboration with more capable peers." (Dixon-Krauss, 1996, p. 15) It is through adult or peer collaboration that children can make constructions that they might otherwise have been unable to make.

The piece that seems to be missing in the theories of Piaget and Vygotsky is that they neglect to discuss the "gaps" in constructions. In other words, Piaget fails to describe what happens when children create new schema, or modify existing schema, incorrectly. Vygotsky does not discuss what happens when children are in their zone of proximal development, but fail to develop to their potential. Lauren Resnick addresses these issues. When students perform mathematical tasks, many of them make similar errors. (Resnick, 1986) Some constructivists call these errors "weak constructions". (Noddings, 1990) Resnick calls these errors "buggy algorithms". She claims, "Buggy algorithms are ... clear examples of inventions that are unsuccessful." (Resnick, 1985, p. 274)

Resnick also claims that children enter school with an intuition about mathematics. (Resnick, 1986; see also Carraher, Carraher, and Schliemann, 1985) However, the instruction they receive rarely makes use of this informal knowledge. Students have formal instruction in mathematics which is full of algorithms and is unrelated to everyday life. Typically, children who do well in mathematics are able to make the connection to real life; whereas, "weaker mathematics learners seem very prone to allow mathematical symbols to become dissociated from their quantity and situational referents. . . . [they] try to memorize and apply the rules that are taught, but do not attempt to relate these rules to what they know about mathematics at a more intuitive level." (Resnick, 1986, p. 191)

Methodology

The participants in the study were 28 sixth graders taken from an intact class. The students were enrolled in a small public school in central North Carolina. To collect data, we conducted clinical interviews with each student individually. The interviews were done in April of the school year, (after the

1283

students had reviewed multiplication). Each interview was videotaped. The students were asked to complete seven different multiplication tasks, one of which was to write a story problem. Each student was given the following directions, both verbally and in written form:

Write a multiplication problem that follows these rules:

(1) The problem must end in a question.

(2) The question must be one that is possible to answer by multiplying.

(3) Solve your problem in as many ways as you can.

The interviews were conducted by one of three researchers. A pilot study was done with fifth graders to insure that the researchers were consistent in their questioning techniques. As a result of the pilot study, minor revisions were made with the interview protocol.

During the interview, the student had access to paper and pencil. Each question was read to the student by the interviewer. The interviewer then placed the written instructions in front of the student for reference. The interviews lasted from 20 to 45 minutes.

This paper focuses on the story problem task. After the student wrote a problem, the interviewer asked probing questions such as "Can you draw me a picture of your problem?" and "Can you think of another way to solve your problem?" In the cases where students wrote problems which were not multiplicative, the interviewers asked additional questions in an attempt to promote disequilibrium. In some of the interviews, after attempting to promote disequilibrium, the interviewers asked the students to write another word problem.

We coded the data using an adaptation of a coding scheme used by O'Brien and Casey. (1983) We chose to code our data as follows:

1. Wrote a problem involving multiplication
   a) Array model
   b) "Times" model
   c) Repeated addition
   d) Two-step problem (one step required multiplication)
2. Wrote a problem involving multiplication as a computation
3. Wrote a problem involving addition
4. Wrote a problem involving subtraction
5. Wrote a problem involving division
6. Wrote a problem involving comparison
7. Wrote a problem which was nonsensical

For each student who wrote a multiplicative word problem, the problems were classified according to the model of multiplication that the student used. Problems which involved multiplication as a computation were not considered to be multiplication problems. For instance, one student asked, "What times what equal 36?" Finally, a few of the problems were not story problems in that they did not ask a question or that they did not make sense. These problems were classified as nonsensical. For example, Todd wrote: "If a boy has 3 blocks on his desk and his friend ask him can he use his 3 bloks [blocks] to multiple [multiply] then his friend sied [said] what is the anser [answer]? 9"

Preliminary Results and Conclusions

We found that only 39% of the students were able to write story problems which were multiplicative in context. Of the students who were able to write a multiplication story problem, 90% used an *array* model of multiplication. In addition, there were 6 addition problems, 4 subtraction problems, 2 division, 1 comparison, and 3 nonsensical. (But in general, students who wrote these problems used multiplication to solve them.) Even when students used manipulatives to model their problems, they did not realize that the context of their story problem was not multiplication.

We also found that in spite of the interviewers' attempts to put the students in disequilibrium, the students refused to adjust their thinking to fit the circumstances. The following transcript is an example of an interviewer's attempt to promote disequilibrium.

> Frank's Story Problem: "Their are 5 people playing basketball on one team and 5 other people playing on the other team. If you multiply 5x5= How many players will be in all?"
>
> Interviewer: How would you draw a picture of this?
>
> Frank: I would draw circles for the people -- 5 on one side and 5 on the other side and then make a multiplication [sign] [drew 5 circles, x 5 circles, then drew a 5x5 array of circles]
>
> Interviewer: [pointing to row 1 of the array] I see 5 people on this team and [pointing to row 2] 5 people on the other team, but where did these people [pointing to rows 3,4, and 5] come from?
>
> Frank: They came from...[long pause]... they came from when you times 5 times 5 and they came from that...from 5 times 5.
>
> Interviewer: So why did you multiply?

Frank: So there would be enough people on the team...Like, just in case if 3 people got hurt, there would only be 2 people left and then you can put in 3 more people.

Interviewer: Let me ask you this: if you were watching a basketball game and ... they're playing each other and you see 5 on say the Chicago Bulls and 5 on ... you know. How many would be out there playing?

Frank: 5...I mean, 10

Interviewer: How did you get that?

Frank: How did I get 25?

Interviewer: No, how did you get 10?

Frank: Added 5 plus 5

Interviewer: What's the difference between your problem and my problem?

Frank: This is a multiplication problem [pointing to his problem] and this is addition [pointing to interviewer].

Interviewer: OK, why is this one [Frank's problem] multiplication?

Frank: [Long pause] 5, maybe 5 people wouldn't be enough to ... [long pause] play on the team or ... [long pause] because ... I don't know ... because ...

In spite of our efforts to put them in disequilibrium, the children did not understand that the context of the problem determined the operation to use. As McIntosh (1979) put it, "A great deal of children's difficulty with numbers stems from their not being able to see what the problem is about, so they simply extract any number in sight and perform some computation." (p. 15) In fact, one of the students who wrote an addition problem was given chips to model her problem. She saw that when the problem was modeled she got 5 (3 + 2) as the answer (instead of 6, which was her answer). She even claimed to understand that her problem was actually an addition problem. However, when we asked her to write another problem, she wrote another addition problem, but concluded the problem with "Use multiplication to show your answer."

This research report will address the children's inability to recognize that context determines the operation, their refusal to be put into disequilibrium, as well as the implications for teaching multiplication.

THE CLINICAL INTERVIEW: CONDUCT AND INTERPRETATION

Tim Rowland

Institute of Education, University of London

The purpose of this paper is to illustrate the power and the process of the clinical interview as a tool for research into students' mathematical thinking. The case in point involves a 10-year-old solving a problem requiring division of an integer by a fraction. The interview unearths unexpected idiosyncratic methods and links with decimal fractions, leading the analyst to speculate about rational number constructs that might underpin such actions.

THE CLINICAL METHOD: PRINCIPLES AND PITFALLS

Piaget's post-doctoral studies in therapeutic psychoanalysis – he read Freud and attended Jung's lectures – inspired his approach to the study of children's thinking.

> This is the method of clinical examination, used by psychiatrists as a means of diagnosis ... [in which] the good practitioner lets himself be led, though always in control, and takes account of the whole of the mental context. (Piaget, 1929, pp. 7-8).

The clinical method, the basis of Piaget's work for half a century, has been adopted by researchers world wide. Ginsburg's work, for example, has drawn extensively on his own mathematical conversations with children.

> The primary method is the in-depth interview with children as they are in the process of grappling with various sorts of problems [...] Interviews like these ... are rare in mathematics education but essential to improving it. (Ginsburg, 1977, p. iv)

The clinical method is appropriate for the purposes of identifying (eliciting), describing and accounting for cognitive processes (Ginsburg *et al.*, 1983, pp. 11-13). The verbal clinical interview is characterised by the following features (*ibid.*, pp. 18-20): (a) the interviewer employs a *task or tasks* to channel the subject's activity (b) the interviewer's questions are *contingent* on the child's responses: the interviewer constantly makes instantaneous decisions about the direction of the interview (c) the procedure demands *reflection*: the interviewer asks the subject to reflect on what s/he has done and to articulate her/his thoughts (d) the contingent nature of the procedure enables the interviewer to *test hypotheses* that s/he has generated in this interview, or in earlier interviews.

The contingent interviewer is having continually to make rapid assessments of what 'witnesses' say, to probe without leading the witness, striving to create the conditions for the surface manifestation of the subject's thought.

Such mathematical conversations can provide teachers with effective assessment data, and the professional skills of teachers related to questioning ought to equip them particularly well to deploy the method for diagnostic purposes. The primary intent of the clinical interview as a research tool is not to teach the child but to enlighten the interviewer. The temptation for teachers to teach remains powerful, however. Piaget

himself remarked that "It is so hard not to talk too much when questioning a child, especially for a pedagogue!" (Piaget, 1929, pp. 8-9)

Doig and Hunting describe a programme for training teacher-clinicians to use interview methods of student assessment. They note that clinical approaches to assessment offer the advantage of interactive communication between the student ("data source") and the teacher ("data interpreter), but that teacher-clinicians have been observed to "fall back on ingrained methods such as telling students, or providing direct information rather than questioning" (Doig and Hunting, 1995, p. 285). At the previous PME, Markovitz and Even (1994) reported that junior high teachers are more prone to these teacher-habits than elementary teachers in clinical interview situations.

According to Hunting (1987, p. 145), it is as though the technique were "rediscovered" in the 1980s. The purpose of this paper is to make a contribution to the illumination of the process of the clinical interview – conduct and analysis. The bonus is speculative insight into the mind of a remarkable, young mathematical thinker.

CONSRUCTIVIST PERSPECTIVES ON THE CLINICAL METHOD

Continuing international interest in radical constructivism lends urgency to the need to make sense of the way individual learners have constructed their mathematical knowledge, and adds weight to the efficacy of the clinical interview as a means of achieving this objective. At the same time, radical constructivism forces a re-assessment of the analyst's interpretation of the clinical interview. An essential means of communication in the interview is language. From a constructivist point of view (von Glasersfeld, 1995), each individual associates words with past experiences. The 'meaning' of the word (for that individual) consists of a co-ordination of word and experience (or *re-presentation* of experience), so that each calls up the other. Von Glasersfeld calls this two-way (mental) use of language 'symbolic', arguing that symbolic communication is achieved by means of co-ordinations which are *compatible*: their being identical is neither necessary nor, for that matter, empirically verifiable. This compatibility is inherent in the notion of taken-to-be-shared meanings (Cobb, 1989).

From this perspective, the clinical analyst is not, in any direct sense, finding out 'what is going on in the head' of the subject, but fabricating a story, an account of the subject's inner world which is compatible with the analyst's own construction of the subject him/herself, of the subject-matter in hand, of the nature of knowledge and learning, and so on. Doig and Hunting (1995) and Hunting (1997) refer to the need for sound pedagogical content knowledge on the part of the clinical interviewer, as s/he constructs a theory of the student's understanding in the interview and tests the theory through contingent questioning. My 'reading' of a pupil's contribution in the account which follows is significantly informed by various investigations and reports on student's rational number constructs (much of it usefully summarised and integrated in Carpenter *et al.* 1993). Numerous related contributions to PME include Markovitz and Even (1994), Goldin and Passantino (1996) and Lamon (1996), each of which refer to clinical methodology.

A CLINICAL INTERVIEW: THE ANALYST'S ACCOUNT

The interview discussed in the remainder of this paper is one of a number which I conducted and transcribed over a period of some years (Rowland, 1999). My interest was in how pupils apply the framework of knowledge that they possess to the solution of non-routine problems which invite generalisation. The problem which inaugurates this interview can be represented as $100 \div \frac{3}{4}$. The problem is presented in terms of 'quotition', the separation into an unknown number of parts, each of a given size.

Susie was aged just 10. I had interviewed her a number of times, and judged that she would find a presentation such as "How many lots of three-quarters are there in a hundred" accessible but non-trivial.

The interview begins[1]:

1	TR	Right, I want you, to start with Susie, to explain to me what you mean by three-quarters.
2	SL:	Well, if you have one thing, whole thing, and you cut it in half, and then the two bits in half again, and take away three of them, and take away one of them, the three left are three-quarters
3	TR	What about five-sevenths?
4	SL:	Well once again, if you cut a cake like that, [she draws] cut it into seven equal pieces, it has to be equal ..
10	SL:	It has to be equal, so if you take away two of those pieces you've got five left.

At this stage, as analyst/researcher, I am probing[2] to discover what kind of constructs are bound up in Susie's 'knowing' of rational number? How might her rational number scheme determine particular practical actions on her part? (Kieren, 1993, p. 57). Her contributions [2] and [10] are significant in this respect, and will be considered later. Following the preamble, I quickly got to the point:

11	TR:	Right. Right. Now the next thing I want you to think about is, how many lots of three-quarters are there in a hundred?
12	SL	How many lots of three-quarters are there in a hundred.
13	TR	Yes
16	SL:	Em, [. .] . how many lots of three-quarters . . Yes ... I think ... have one hundred, add . . what was it? ... oohhh . . It's impossible to third it - a hundred, you need a third of a hundred. So that must be [writes] three ... thirty-three point three recurring. [Writes 33 3r, changes r to R] I'll put a capital R for that because that [r] means remainder. Ah, so if you add those two together, together, it should be one hundred and thirty-three point three recurring

---

[1] The transcript 'turns' are numbered 1, 2, 3 ... and referenced as [*n*] in the commentary/analysis. Some turns have been omitted in order to prioritise other material in this paper

[2] My commentary is mainly in the present tense, to convey the contemporaneous nature of interpretation and contingent response

1296

In effect [16], to find how many ¾ there are in 100, Susie adds to 100 a third of 100. I note in passing her preference for the infinite decimal representation of one-third. My attempt to find out why she believes (with good cause) that her procedure works does not meet with success.

17 TR: Right, [.] what I actually asked you, right, was how many lots of three quarters in a hundred. And what you've done is to take a hundred, and then a third of a hundred, and add it on. Now, can you explain to me how that tells you how many three-quarters there are in a hundred?

18 SL: I actually have worked that out quite a long time ago; worked that out, I did. It hasn't ... I did actually do some maths and worked it out that way [inaudible] I did try doing it that way, and then tried doing it another way. It worked, but the other way I had was too difficult, so I just stuck to this way.

19 TR: When did you work out this other way?

20 SL: I can't remember ... well ...

I am still unclear about much of what she is saying in [18]. What exactly did she work out "quite a long time ago"?. What was this other way? Invert and multiply? Her teachers informed me that she had not been taught that method at school.

My next question is designed to find out whether Susie can adapt her method to division by other fractions, choose one that will readily allow such a method to be demonstrated.

23 TR: OK. What about, how many four-fifths in a hundred?

24 SL: Four-fifths. It's correct, isn't it? [refers to 133.3R written]

25 TR: Oh yes, that's correct.

26 SL: Em, that was three ... what was that again? That was three-quarters

27 TR: That was three-quarters in a hundred, now we're talking about four-fifths.

28 SL: That must be a fourth, this must be a fourth of it ... mmm a fourth of a hundred [pause]

29 TR: A fourth of a hundred OK, so what have you got?

30 SL: One hundred and twenty-five.

31 TR: OK. Describe what you do again Just describe.

32 SL: I just had the hundred, and then I had one fourth of hundred, and added them together.

Much as I (the analyst) marvel at the ingenuity of her method, I also (the mathematics educator) realise its limitations. But does Susie? Indeed, she does. [34, 36]

33 TR: Right What sort of ... can you give me another example of how many lots of something in a hundred, that you could do that way

34 SL: Well, you could, there, it's a fact you can, could not do the same way with ... seven . ninths

35 TR: You couldn't do the same Why not?

36 SL: Because it has to be one different Like with this one [indicates ¾] it was one and that one [$^4/_5$]was one

39 TR: One difference between which numbers?

40 SL: The number of them and the quarter. And it has to be the smaller one to the number.

Susie seems to be expressing the required general relationship between numerator and denominator (it is not clear whether or not she knows these terms) with reference to the particular example ¾ . In fact, "The number of them" [40] precisely captures the etymology of 'numerator'. I hesitate (the cough, [41]) before asking my next question, because I predict that Susie's answer will require her to divide 100 by 6, and (knowing her) that she will do it mentally. I was quite unprepared for her response:

41 TR: Right, [cough] could you, um, work out how many lots of six-sevenths there are in a hundred? [...]

44 SL Now what's a sixth of a hundred? Mm [pause], yes, I know a third of a hundred is that [indicates 33.3R] [I a sixth will be half that. [ ] So what's half of three. Ah, one . .

49 TR: Can you work it out up here? [away from written 33.3 R]

50 SL: No, I'm working out this, so I can ... I will put it up there when I've worked it out. I need just to be close up there, which will help me work it out.

Susie wrote 15 beneath the 33, then over-wrote the 5 with a 6. Then she wrote 5 beneath the .3R; later she changed that 5 to 6 as well. She volunteers an explanation to me:

51 SL: So, do you know why I carried five into that? I had that one, and I had a half, so that I had that. Why I'm moving in this way, it's a bit different. In a normal adding sum you move the other way [i,e. right to left rather than the left to right here]

52 TR I'm not clear what you're doing Susie, you're working out a half of thirty-three point three recurring ...

57 SL I had five [from 15], and I have one of those [from 1.5], and then we carry the five .over to there And it will continue happening. Six and carry five, six and carry five, so it must be [pause] sixteen point six recurring.

58 TR: Sixteen point six recurring. OK.

59 SL: Which is one hundred and sixteen point six recurring.

In such rare moments, this interviewer struggles to suppress his excitement. My question about dividing by six-sevenths had opened an oyster, to reveal a pearl. In effect, Susie writes that half of 33.333... is 15+1.5+0.15+0.015+ ... (half of each 3); adding the units, tenths, hundredths and so on she gives 16.6666... *"And it will continue happening"*. [57] Six and carry five, six and carry five. The at home-ness of this 10-year-old with infinite recurring decimals is an accidental (but characteristic) by-product of the main thrust of the contingent interview, a theme that I opt not to pursue further at this point.

I choose, instead, to see whether Susie is able to expand her schema to deal with fractions not of the form $^{n}/_{(n+1)}$. I thought it unlikely that she would, but had to test that judgement.

62 TR OK Now, you said that it wouldn't work for seven-ninths didn't you, this method Right? Now, I'd just like you to write down five-sevenths, just here.

My contingent choice of $^{5}/_{7}$ in preference to $^{7}/_{9}$ is significant: I don't want any difficulty in dividing 100 by 7 to block Susie's method, if indeed she has one.

63 SL. I'm going to have to think though, very well. Um, I'll try .. [pause] Ahh, of course ... [interrupted]

64 TR: You have . nk while I push the door up.

65 SL . you can't .. I don't understand. It's definitely a hundred So that means two . . Ahh, ahhh, you've got two left, and you need five each time. So if you have two hundred ... um . divided by five. How many times does five go into two hundred? Well, it goes into one hundred twenty times ..

66 TR: Mm-hm

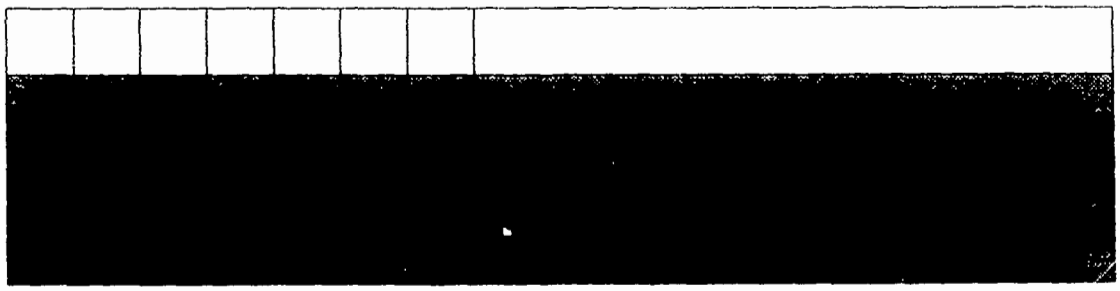
67 SL: Must go into forty times So that's ... a hundred and forty [. .]

69 SL: That's a two difference.

The exclamation 'ahhh' in [65] seems to announce a moment of special insight. Susie proceeds to extend and articulate this generalised process. From this point, she consistently deploys 'you' as vague generaliser (Rowland, 1999):

89 SL. The next one, when you have two difference, you have to do two hundred divided by that, the number, and add a hundred to the equals.

90 TR: Right, add a hundred to the equals.



91 SL: And with three you have to do three hundred divided by whatever is the top number.

Susie's computational algorithm can be formulated as follows:

for $p < q$, $100 \div {}^{p}/_{q} = 100 + [100(q-p)] \div p$

DISCUSSION: PART-WHOLE OR PART-COMPLEMENT?

How does Susie conjure up these algorithms, progressively adapted for increasingly general application? I develop a hypothesis during the interview, as follows. I surmise that Susie takes a global view of the division problem $100 \div \frac{3}{4}$, in which she first imagines one three-quarter part of each of the 100 'things'. I don't know what her things are. My corresponding image would be a long thin rectangular strip, standing on a 'base' 100 units long, with ¾ of the height blocked out, or shaded.

Thus, 100 "lots of" ¾ accounts for ¾ of the whole. The remaining ¼ is one third of the shaded part. *Addition of one third of the part already accounted for will complete the whole.* The essence of the imagery is the perception of the fraction (¾) in relation to the complement (¼) which is one-third its size.

Pirie, Martin and Kieran (1994) asked three categories of students (school and university) a set of six (written) questions about fractions, including: How would you explain ¾? Pirie *et al.* describe four "major images" which emerged from the

questionnaires. (1) Division: a quantity divided by a quantity (2) Part of a whole (3) A number of some sort (4) A way of writing: a number over another number.

I suggest that Susie's image relates to (2)., but is crucially a part-part or *part-complement* image embedded in a part-whole construct[3]. I failed to elicit any direct confirmation of such imagery from Susie by contingent questioning, but there is indirect evidence to support (compatible with) my interpretive hypothesis, as follows.

- Describing a tenth in a classroom episode some months earlier (Rowland, 1992, p. 44), she had said:

  SL: If you have ten, and you take away nine ones, you have just the one left . . it's because you take away a ninth ... no, nine-tenths. So there's one-tenth left.

For Susie, a tenth is the remnant when nine-tenths is taken from the whole.

- At the beginning of this interview, she described three quarters [2] and five-sevenths [10] in part-complement terms in her drawings and in her choice of words.

  2 SL Well, if you have one thing, whole thing, and you cut it [in four] and take away one of them, the three left are three-quarters.

  3 TR: What about five-sevenths?

  10 SL. it has to be equal, so if you take away two of those pieces you've got five left

Susie constructs each fraction beginning first with the part-whole construct for the fraction *and* its complement, then removing its complement from the whole.

FINALE

To conclude the interview, I challenged Susie to adapt her method to divide by improper fractions, such as five-thirds. Again, as with $^5/_7$ earlier, I chose $^5/_3$ contingently to minimise for Susie any complications with whole number arithmetic. The challenge was speculative: the hypothesised imagery schema does not seem to extend to dealing with such cases, because the 'parts' to be removed are greater than the initial unit. She rose to the challenge however, this time *subtracting* a fifth of 200 from 100.

177 SL: One hundred divided by five-thirds [sighs]. Right. See, this one [$^5/_7$] you added it. I can't understand that [$^5/_3$]. That one's harder Ahh, ahh, oh yes, you would have twice as much for the difference, won't you. So that's ... so suppose we had five-thirds Want five-thirds. You would have to take a hundred .

178 TR Yes

179 SL: Take away um, a fifth of two hundred

180 TR Right.

189 SL: And then you have two hun ... one hundred would be that's forty That equals forty So take away forty equals . sixty

Perhaps she perceives five-thirds as having a complement of negative-two thirds within the whole, and hence the need to 'trim away' the excess two-fifths (from 100 lots of five

[3] The mistaken tendency of some children to denote the part as a proportion of its complement rather the whole is well-documented (e g Hart, 1981)

thirds). Alternatively, her thinking at this stage may be predominantly algebraic, encapsulating and making the appropriate adjustment to the earlier procedure.

I was convinced that Susie brought intuitive knowledge of fractions (Kieran, 1993), drawing on unusual but powerful fraction imagery, to create a global, gestalt overview of the problem and a highly idiosyncratic solution. She demonstrates expansive generalisation and readily perceives the possibility of reconstructive generalisation (Harel and Tall, 1991) as she confidently and flexibly adapts her method to solve a comprehensive class of related problems.

DIVISION WITH REMAINDER

CHILDREN'S STRATEGIES IN REAL-WORLD CONTEXTS

Silke Ruwisch

Institute for Didactics of Mathematics

Justus-Liebig-Universität, Giessen, Germany

One-step division problems in the model of equal groups and equal measures can be partition or measurement problems. They can also be divided into problems without remainder, problems with a remainder which is not used for the solution, and problems with a remainder which raises the solution by one. Most studies concerning these aspects used word problems. This paper describes an empirical investigation about children working in the real-world context „juice punch". 12 second-graders – age 7 to 8 – and 28 third-graders – age 8 to 9 – were videotaped pairwise. The results of the qualitative analysis show, that it depends on the solving strategy, if the children had difficulties in dealing with the remainder.

Although division is not very difficult from a mathematical point of view, it is the most complex operation children have to learn at primary school (eg. Anghileri 1995, Burton 1992, Greer 1988; Harel & Confrey 1994; Schmidt & Weiser 1995):

- Multiplication and division are „second level operations", which are based on addition and subtraction.
- Division is taught as the inverse of multiplication, so the understanding of division requires the understanding of multiplication.
- There is a greater number of situational models with multiplicative structure than with additional structure.
- Within the models of equal groups and equal measures two aspects of division can be differentiated: measurement and partition.
- Division with remainder is an additional difficulty, because only integers are allowed as a result. No other operation requires this differentiation.

Division problems in the model of equal groups

Most division problems in contexts are founded in the model of equal groups and represent one of the following aspects: measurement or partition. In case of *measurement problems*, the divisor indicates the number of elements of each subunit, whereas the quotient gives the number of sets. From this point of view dividing means *grouping or repeated subtracting.* In *partitive problems*, the number of subsets is known, while the number of elements per set is to be found. The action „dividing" suggests a *sharing procedure* here.

Context-bounded division problems can also be divided into problems in which

- the remainder is zero,
- the remainder is non-zero but is not used for the solution, and
- the remainder is non-zero and raises the solution by one.

1302

Therefore, the following six situations can be differentiated within the model of equal grouping (see Brown 1992, Burton 1992):

Division Type / Re-mainder	Measurement Problems	Partition Problems
Zero	Susan wants to pack up 16 plates into boxes. One box can hold 4 plates. How many boxes does Susan need to pack all the plates?	Susan wants to pack up 16 plates evenly into 4 boxes. How many plates will be hold from each box?
Non-zero but neglectable	Susan wants to pack up 18 plates into boxes. One box can hold 4 plates. How many boxes may Susan fill with plates?	Susan wants to pack up 18 plates evenly into 4 boxes. How many plates will be hold from each box?
Non-zero and raises the solution by one	Susan wants to pack up 18 plates into boxes. One box can hold 4 plates. How many boxes does Susan need to pack all the plates?	Susan wants to pack up 18 plates into 4 boxes. How many plates must be put into one box?

Table 1: Measurement and Partition Division Problems

Solving division problems

Although division is such a complex operation, young children without any formal instruction to the operation are already capable of solving one-step division word problems. The findings of different investigations (e.g. Brown 1992, Burton 1992, Kouba 1989, Mulligan & Mitchelmore 1996, Murray et. al. 1991) show:

- About half the children solve division problems by using manipulatives or fingers.
- Children use much more often grouping strategies than sharing one by one, although the problem may be a partitive one.
- Problems with remainder are more difficult than those without remainder.
- Even if division problems with remainders are calculated correctly, the interpretation of the result causes difficulties.

The Study

All investigations dealing with division problems in context used one-step word problems, which were told verbally. Our question was, how children would solve problems in a realistic context, in which they had the possibility of using real materials. Especially we were interested in the following questions:

- Which strategies do children use to solve division problems in real contexts?
- How do children solve measurement problems with remainder in real contexts?
- How do children interprete remainders in real contexts?

To answer these questions we investigate the problem-solving strategies of German second- and third-graders (age 7-9) in real world situations. The main focus of this paper lays on the strategies of children dealing with the context „juice punch".

Design of the situational context

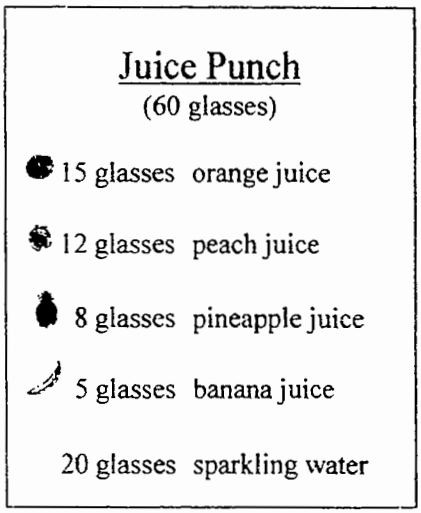

Figure 1: Recipe for a juice punch

For our investigations we constructed three real-world settings which are similar to each other in their arithmetical structure but differ in the situational contexts: classroom party, juice punch, and doll's house (for details see Ruwisch 1998). The second context, juice punch, will be described in more detail now, because the examples used later are taken from it.

In the situational context „*juice punch*", the children were asked to determine the number of bottles which are necessary to realize the recipe given in figure 1. To simulate an everyday situation, the children had the possibility of using real materials for their solution: a punch bowl, a 0.1 l-glass to measure, and bottles of different sizes. These bottles contained the same amount of liquid as original bottles in a super-market – 0.2 l, 0.5 l, or 0.7 l. In contrast to a real situation, they were filled with water and labled with the type of fruit and the amount of liquid given in glasses. As in supermarkets, the bottles were sorted according to their size and the type of fruit (see figure 2).

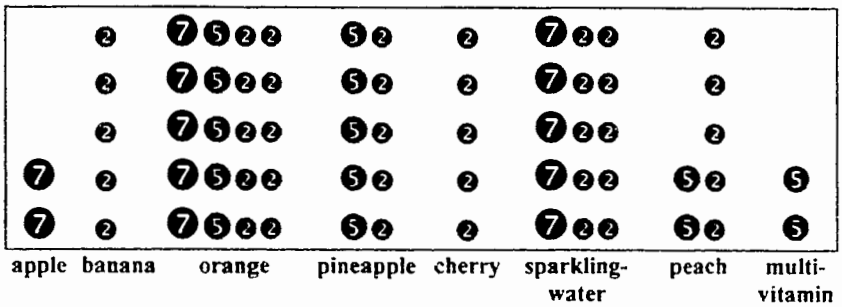

Figure 2: Tables with bottles of fruits and sparkling water

Data and Methodology

Subjects. The subjects of the whole study were 122 children from 7 different forms of German public primary schools, 40 of them have worked with the „juice punch". Thus, 12 second-graders – age 7 to 8 – and 28 third-graders – age 8 to 9 – participated in this part of the investigation. At the time of inquiry the second-graders had not been introduced to multiplication or division yet. The third-graders had already learnt the multiplication table and had been instructed to both types of division problems. They were also familiar with division with remainder, although the different situational interpretations are not taught explicitly in Germany.

Procedure. The children were withdrawn from the classroom and confronted pairwise with the materials in a separate room. They were given a short introduction into the situation (see figure 3). Then they had to work by themselves until they indicated to us that they had finished. On average the working-phase – which was videotaped – lasted 20 to 30 minutes.

„My niece asked me for a juice punch for her birthday party. Do you know, what that is?" ... (eventually explain) „10 children will come to the party. At home I looked for recipes for juice punches, and I found one which yields 60 of these glasses (show the glas). I have brought the recipe for you here (turn around the recipe). Can you read it out to me?" ...(let them read aloud by turns) „As you can see, the details of the recipe are given as glasses, and therefore I don't know, how many bottles I need. So that you can find this out for me, I have put juice-bottles here (point to the tables with the materials) which are filled with water. Can you fill in this shopping list (turn around the shopping list), how many bottles I have to buy for the juice punch in the supermarket?"... „If you are ready, please let me know."

Figure 3: Verbal instruction

Results

Analysis. The videotapes were transcribed in detail for each pair. We differentiated different forms of transcripts due to the degree of resolution (see Wollring 1994): a) coarse transcripts of sequences, b) verbal transcripts with middle resolution, and c) verbal and action transcripts with high resolution. The latter form of transcripts was used for the case-studies, this paper refers to. The transcripts were interpreted turn-by-turn in small groups of 1 or 2 researchers and 3 to 4 teacher students.

Children's strategies and action patterns. The children used three different solving processes to determine the number of bottles: 4 third-graders *estimated* the number, 4 second-graders and 10 third-graders *mixed the punch by measuring with the glass*, and 8 second-graders and 14 third-graders *calculated the numbers* (for details see Ruwisch 1999). Only the children of the last group came across the problem of division with remainder. Their difficulties, their searching and solving processes, and their discussions are described in detail now.

Children's strategies solving a measurement division problems with remainder. Treating the whole problem, the children had to solve 5 smaller problems. The number of bottles of every juice, except banana, could be solved without remainder. It was interesting to us, that most children tried to find out a solution without any juice left, although they were not asked to do so by the interviewers. So calculating children chose the corresponding size of the bottles and found the following solutions:

- 3 bottles of 5 glasses to get 15 glasses of orange juice,
- 2 bottles of 5 glasses and 1 bottle of 2 glasses to get 12 glasses of peach juice,
- 4 bottles of 2 glasses to get 8 glasses of pineapple juice, and
- 10 bottles of 2 glasses or 2 bottles of 7 glasses and 3 bottles of 2 glasses to get 20 glasses of sparkling water.

The 5 glasses of banana juice given in the recipe could not be realized with the given bottles of 2 glasses each without some amount of juice left at the end. So, here these children had to solve a measurement problem with remainder. We could observe three different reactions to this problem:

4 thirdgraders had no problems at all to find the solution. They did neither talk about banana juice as a special problem, nor had difficulties in finding the solution „3 bottles of 2 glasses", which all them wrote down at once on the shopping list. Although these children tended to calculate the minimal number of bottles necessary, it seems as if they did not even come across the problem of the remainder. Acting in a simulating real situation, it seemed to be clear to them, that they have to buy one more bottle.

8 second-graders and 10 third-graders did come across the problem. All of them were somewhat puzzled at the beginning, like the example of Max & Felix (3rd grade) shows:

F *(F. is still writing down the solution for the pineapple juice)*
M **Then?** *(looking at the recipe)* **Then banana.** *(turning around to the bottles)* **Banana, banana** *(finding bottles of banana juice, turning around to the recipe)* **Then we need, how much banana?** *(looking at the recipe)* **5 glasses.**
F **5?**
M *(turning around to the bottles, looking at a 7 glass bottle of apple juice)* **These are 7 glasses.** *(tapping the 7 glass bottle of apple juice)*
F *(turning around to the bottles)* **Yes, that's of course ... 5** *(looking at the bottles next to apple juice)*
M **2.**
F **Oh, damn, there are no bigs of this kind, that's mean.**
M **Oh yes, but they are 7ers** *(turning around to the recipe)*
F **Pardon, 5? How shall we manage that?**
(M. is looking into the recipe, F. is again turning around to the bottles.)
F **Are there also anywhere ones?** *(looking around the other given bottles)*
M **5, 5.**
F **Is** *(looking at the lables of the other bottles, looking at the bottles standing behind the others)* **there anywhere anything, dipdidipdidip**
M *(spreading out his arms)* **that's impossible.**
F **Ahm, what kind is this one** *(touching a bottle of multivitamin juice)*
M **Ahhh! ... Ha?**
F **Maybe of these?**
(Both are standing in front of the bottles of multivitamin juice)
M **There is all together. 5 glasses are in it. Well, it doesn't matter** *(shrugging his shoulders)*

All of these children knew that 5 glasses could not be reached by bottles of 2 glasses.

4 second- and 4 third-graders only stopped for a short moment, giving comments like „here are no 5s, how will that work? Okay, let's take 2 small ones and a half". These children also wrote down „2 and a half" as their result. Although they did not give

the solution „3", they nevertheless interpreted the remainder in a correct way: Being asked by the interviewer at the end, how many bottles he or she would have to buy, the children answered „three, but there will be one glass left."

The other 10 children had greater difficulties in finding a solution, which satisfied themselves. All of them showed a first puzzled reaction, looking for a quick solution, like Max & Felix did. Because they could not find one at once, they put this problem aside and started with another one. They only returned to the banana juice, when they had finished all the other parts of the recipe.

The process of searching for a solution was no linear approximation. The children tried several possibilities. But all processes can be characterized by expansion in some of the following different directions:

- spatial expansion: the children suggested, that bottles with 5 glasses of banana juice could be found between the other juices, under the tables, or at another place inside the room;
- offer expansion: The children looked for bottles with one glass of juice:

> F **I know! No, not really.** *(Turning to the bottles of banana juice)* **Are there anywhere ones, is here anywhere standing a 1** *(looking at the lables of all bottles of banana juice)* **please, let anywhere stand a 1, please, please,**
> M *(touching a bottle of 7 glasses of apple juice)* **we ought to choose a smaller bottle, that's not possible**
> F **Such a small picco** *(demonstrating with his thumb and fingers half the height of a 2-glass-bottle, turning around to the recipe)* **I don't get it** *(looking into the camera).*

- expansion of interpreting the problem posen: instead of buying bottles of one juice only, the children tried to use multivitamin juice:

> F **We don't need that. They want to pull our leg. That one** *(pointing to the bottles of multivitamin juice)* **we don't need as well. Or maybe, if we, how much do we need** *(looking into the recipe)* **5. or, if we from these, nooo, it's impossible, too, there we also have only big ones.**
> *(Both are standing in front of the bottles of multivitamin juice).*
> M **Aha, of every glas 1** *(pointing to the lable of the bottle of multivitamin, turning around to the shopping list)*, **then we should of these** *(pointing to the pineapple juice in the shopping list)* **1 less, and of these** *(pointing to the peach juice in the shopping list)* **1 less, and of these** *(pointing to the orange juice in the shopping list)* **1 less, and of these** *(pointing to the sprakling water in the shopping list)* **1 less,**
> F **Yes.**
> M **then it would come out even here** *(pointing to the banana juice in the shopping list).* **But, wait, does it work?**

- expansion of acceptable solutions: in the end all children found the solution „2 and a half" and wrote it down.

F **5. .. Of these, these two** *(touching 2 bottles of 2 glasses)*
M **Then we do, shall we cut one in two?** *(looking at F.)*
(Both are loughing.)
F **Or half of it, then something is left. But, who did say, that it matters if something is left** *(going along the bottles, looking)* **Well, what's this here** *(touching a bottle of 5 glasses with pineapple juice)***?**
(Both simultaneously) **Hm, hm** *(shaking their heads).*

and some minutes later:

F **Ah, there is nothing else, Max.**
M **Yes** *(lets go the recipe and the bottles of peach juice and turns around to F.)*
F **As this solution.**
M **Pardon?**
F **3 point 2 glasses** *(taking the pencil, going to the shopping list and writing „3.2".)*
M **Hm, write it down. 3,? ah, 3 point**
F **2**
M **glasses.**
F **Stop!** *(writing „R 1".)*
M **What is?** *(reading, what F. is writing)* **R 1?**
F **Remainder one glas.**
M *(touching groaning at his head)* **Well, does not matter.**
F **Ready.**
M **Yes.**

Interpretation and Conclusions

The results show, that specific strategies are predestined for specific difficulties. Estimating will not give exact results, especially if the children are not used to do it. Measuring is a very slow solution strategy which cannot be used without having the bottles in front of you. So, calculating with the numbers given on the lables is one of the most effective and efficient strategies for the given problem. But: Children who used this strategy, tended to think very precisely, although the situational context did not require such a precise thinking. So, these children had to solve self-made problems, when they tried to give an exact number of bottles with no amount of juice left. Nevertheless, all children were able to find the solution, even if they were not very satisfied by it. Although some children wrote down „2 bottles and a half" or „3 bottles of 2 glasses, remainder 1 glass", all said, that 3 bottles had to be bought.

If the interpretation of the remainder as raising the solution by one is easier in a real-world context than in solving word-problems, cannot be said, because it could be, that the difficulty in both environments is to decide what should be written down, the solution or the interpretation of that solution in the situational context.

It also must be said, that the data which could be interpreted for this paper, was very small. It consisted of one measurement problem with remainder and 4 measurement

problems without remainder. Division with remainder had not the priority for the design of this study. Therefore, more investigations in real-world contexts have to be made, also encluding measurement problems, in which the remainder is not used, as well as encluding all kinds of partition problems.

ARITHMETIC AND ALGEBRAIC PRACTISES: POSSIBLE BRIDGE BETWEEN THEM

Patricia Sadovsky
Universidad de Buenos Aires

Abstract
In this work we analyse strategies of students with no previous experience in algebraic work (11/12 years old) to tackle problems on Euclidean division where the notion of variable must be used. The results of the analysis let us make the hypothesis that solving problems which require, apropos of a particular concept, the use of the notion of variable, simultaneously contribute to a progress towards the conceptualisation of that content and also to enter the algebraic practises. These results are part of a broader diagnosis whose goal was to get data to characterise a possible articulation space between arithmetic and algebraic practises. Such a characterisation will orientate the design and implementation of didactic situations that will be tested in the next stage of our research.

The research questions

As we considered the many researches that deal with the passage from arithmetic to algebra (Bednarz,N and Janvier, B; 1996; Kieran,C; 1992; Mason,J; 1996; Panizza, Sadovsky, Sessa; 1996, 1997; Vergnaud,G et al; 1988), we made the hypothesis that it was possible to generate a didactic articulation space between the arithmetic and algebraic practises, so that the students could tackle much better the essential and inevitable rupture entailed by the entrance to the algebraic world.
(We are thinking of 11 to 12 years old scholars).

We talk about an articulation space naturally organised around a number of problems. But we also talk about rupture. Articulation and rupture are terms which seem to contradict one another. As it is well documented in the literature on this subject, there is an unavoidable rupture due to the fact that the entrance to algebraic world means to reject meanings and practises that have been build up throughout their scholastic education. Nevertheless, the possibility of a space of problems which the students can understand and for which the usual arithmetic procedures could work as base strategies that would not be enough, let us talk of articulation. Thus, there is articulation because the arithmetic knowledge they have is enough to tackle a set of problems though not to solve them, but there is rupture because there it exists the need to abandon certain practises.

Which algebraic capacities would this space include and which ones it would leave out? How could it be characterised? Under which didactic conditions could these articulation practises emerge in the classroom? How would this work modify the conditions to enter to the algebraic world? Since it would mostly be about the establishment of a practise: How would the unfolding of this articulation space impact

on the teaching of the different mathematics concepts involved in these problems? Up to what extent would the algebraic procedures unfolded with respect to a certain content be available when dealing with some other contents?

These questions were the ones that guided our research. Our methodological framework is the one of the engineering didactic (Artigue, M;1990). Our study has a stage which deals with the characterisation of an articulation space between the arithmetic and algebraic practises (at the moment we are working on this stage), a stage of designing and proving didactic situations and ultimately one of giving validity to the situations that have been designed.

While the mobilization of the notion of variable is a central element of the algebraic activity and represents and important rupture with regards of the arithmetic practises we have decided to structure this articulation space focusing on problems which from different mathematics contents and, apropos of different kind of tasks, demand implicitly or explicitly the mobilization of the notion of variable. On the other hand, we have considered that the distinction between sense and denotation (Drouhard, et al; 1995) in respect with the numerical algebraic expression could become a didactically valid starting point to elaborate problems that would urge the students to analyse the structure of the expressions and stablish relations among different expressions without appealing to the actual solution of the operations. Finally, taking into account the results offered by several researchers (Malara,N; 1998 Arcavi, A et al.; 1990) we have decided to include in this articulation space problems that would entail the students' inquiry, the pose of conjectures and the validation of arithmetic theorems.

Being our aim to better characterise the articulation space and to make hypothesis that nourish the elaboration of didactic sequences (1999 project), we devised a diagnosis test for students in grade 7(mean age11/12 years old) with no experience on algebraic work. The aim of the test was :

- to analyse the strategies unfolded by the students who lean on arithmetic practises when faced to problems which demand the mobilisation of some of the issues above mentioned.

- to study the fertility of the situations presented in order to propitiate an evolution towards algebraic practises and outline the possible evolutions .

The diagnosis was administered in three stages to Grade 7 students from three different schools. The children had to solve the problems alone, they were given pencil, paper and a calculator. After the problems had been solved we interviewed some of the students to inquire them about their productions. The interviews were audio-recorded.

The test consisted of two different kind of problems:

-problems for which the analysis of the structure of numerical algebraic expressions and the comparison among different expressions was a must.

-problems which could be modelized by means of a two variable equation (whether linear or not), some about rectangle areas and perimeters, others about realistic situations and a third group refered to the notion of Euclidean division.

We will only present here the results we obtained from the analysis of the third group of problems.

The problems

The problems on Euclidean division we presented to the students were:

1. Find a division operation whose dividend is 25, its quotient 8 and its remainder 12. How many are there? If you think there are less than three write them all down, and explain why there are no other ones. If you think there are more than three write down at least four of them and explain how other solutions could be found.
2. Find a division operation which dividend is 32 and its remainder 27.How many are there? If you think there are less than three write them all down, and explain why there are no other ones. If you think there are more than three write down at least four of them and explain how other solutions could be found.
3. If you divide 527 by 46 the quotient is 11 and the remainder 21.
a) Verify it.
b)Can you find any other number that when you divide it by 46 the remainder is 21? How many are there? If you think there are less than three write them all down, and explain why there no other ones. If you think there are more than three write down at least four possibilities and explain how other solutions could be found.
4. Find a division operation which quotient is 20 and its remainder 14.
How many are there? If you think there are less than three write them all down, and explain why there are no other ones. If you think there are more than three write down at least four of them and explain how other solutions could be found.

The relation dividend= divisor x quotient + remainder, divisor>remaninder≥0, which from now on we will call Euclidian relation, is the core of all four problems.

What is the status of this relation for different students? For one specific student, does this status modify in the different problems? Up to what extent do children conceive the Euclidean relation independently of the division operation? Is this independence necessary to give solutions?, and to explain how they are obtained? Which transformations take place in the strategies when the notion of variable is at stake? For those students who implicitly mobilise the Euclidean relation to give examples (problems 2,3 and4): Is the explicitation of the relation a means to explain how other solutions were obtained?

Analysing some of the cases, we will try to answer the above mentioned questions.

Results

Broadly speaking the students perceive the Euclidean relation as subjected to the division operation and they frequently cannot disentangle it from the actual solution of the operation. Now, this way of perceiving the Euclidean relation perfectly adapts to

the first problem; and its limits can only be seen when facing problems where the mobilisation of the notion of variable is necessary. So speaking, **we think that these problems are simultaneously a chance to find the limits of the arithmetic practises and enrich the conception of Euclidean division.**

How does this dependence on the Euclidean relation with regard to the division operation manifest? What are its consequences? We will analyse it following Daniela´s procedures.

Daniela finds the divisor to problem 1 using the Euclidean relation; she writes: 8 . 25 + 12 = 212. Then, to justify that there is only one possible division, she shifts the centration and says: " If they give you a result with a remainder and a divisor, there is only one possible solution. If we had divisor and quotient or divisor and remainder there would be more than three." Let us observe that to justify that there is only one possible division she mobilises one representation of the division as an operation in which given two numbers (dividend and divisor) we get another two (quotient and remainder). Having in mind this last representation, she anticipates aforehand in which cases she would get more than one possible solution. She mobilises once again the Euclidean relation when tackling problem 2. She gives several examples and explains that we could obtain more: "*multiplying 32 .X plus 27* ." When she tackles problem 4, she points out: *" There is only one solution because you have a `given´ quotient and remainder."* That is to say, before mobilising the Euclidean relation —as she had previously done in the case of problem 2— concentrated on the division operation, —and probably also on a certain representation of what the algorithms of the arithmetic operations broadly are— Daniela supposes that there is only one possible division operation, probably because she has been given the two numbers that are the results of an division. Taking into account the main importance of the rol of the focusing at its final stage to elaborate a proceeding (Inhelder,B y Caprona,D; 1992), we think that this first anticipation stops Daniela from refering to the Euclidean relation and stablish the analogous roles that unknowns and givens have in problems number 2 and number 4. (Let us realise that beyond the restrain on the divisor posed by problem 4, the formulas which model both problems are identical).

While Daniela was working, we could observe her commitment to problem number 4 and her hard attempts to get to a solution. There are traces in her sheet of paper that at a certain point, she proposes 945 as dividend and 46 as divisor and gets 20 as quotient and 25 as remainder. Nonetheless, she cannot get profit from this result. This would point out that she needs certain hypothesis with regards to the expected quantity of solutions, to make trials to move from an approximate solution to the desire one.

Let us analyse now the written representations she uses for problem number 4. After thinking hard she writes down:

X	X
14	20

and then she writes down: 20 .X + 14 = Y. After she has written this, she tries but cannot solve the equation as if the mere manipulation of it could make it emerge `the´

expected solution. That is to say, this representation has for her the statute of an equation in which X and Y are unknowns and not variables and , thus, she cannot conceive it as a formula which produces infinite solutions. (Should it be observed that the written equation has for Daniela an instrumental value —as it generally occurs with the production of a representation— though she is conceiving it wrongly.) Should it be noticed, that one of the aims of this didactic work, a propos of these issues, would be the possibility to make students conceive these expressions as formulas so that these formulas are a support that has both the functions of treating the information and of objectivation (Duval, R:1995). Quoting R. Duval, that they can make the conversion of register (in this case from operation register to formula register), conversion that as the author points out it is not cognitively neutral (Duval, R; op.cit.). The conversion of register should make it possible for the students to stablish the analogy between the quotient and the divisor in problems 2 and 4, analogy that cannot apparently be perceived when representing the division as an operation. In other words, the production of the formula would draw near two problems that when seen from the representation of the division as an operation they seem to be essentially different. We talk about analogy and not equivalence because these elements variation domains are not the same. So speaking, a didactic work with problems such as the ones we have proposed should think about the possibility of an interaction between the two registers we have been talking about. Why? We have found during our research some students who focus in the formula losing sight of the restrictions on the remainder. With respect to this issue let us compare Diego´s and Andrés´ works.

Andrés is one of the few students who`trusts´ in the Euclidean relation as well as in the operation. From the very beginning, he writes down the formula d= c.D+r and he uses it to provide solutions to problems 2,3 and 4. But he does not realise that in problem 4 he had to consider divisors greater than 14 and successively he gives the divisor the values 2,3,4,and 5. Having all his attention centred in the formula, he does not look for controls and does not notice his mistake. In other words, he trusts so much in the formula —thing most students do not do— that he does not validate his production.

Diego is a student that after working hard manages to solve problems 1,2 and 3. He uses the calculator and thanks to the many trials he makes with it he manages to put at stake the Euclidean relation in order to produce the demanded operations. Afterwards he makes the operations to validate them. This control is the one that allows him to realise he is doing something wrong when he gives divisors lower than 14 in the case of problem 4. These results make us think of the possibility of advancing in the conceptualisation of the Euclidean division, of giving the Euclidean relation both the statute of instrument and object, and, at the same time, of accepting the student´s entrance in algebraic procedures, asks for the jointed manipulation of the operation and the Eucledean relation controlling one another.

As we have already pointed out, a didactic work with problems such as the ones we proposed would let the students find the limits to the arithmetic practises, thus

generating the conditions for the entrance to the algebraic procedures. Since to face a problem like the second one, for example, it is necessary for the students to give any value whether to the dividend — if they use the trial and error strategy as to propose any operation with divisor 32 and then "move" towards the solution— or to the quotient to be multiplied by the divisor (32) and then added the remainder (27). The students resist a lot this practise of giving any value, they generally think that it is only possible to work with the numeric data given in the problem .

Hernán, for example, finds the correct dividend for the first problem and when we interview him he says that to obtain the dividend :" *I made 8 that is the quotient multiplied by 25 that is the divisor and added 12 to it that is the remainder."* Then, he says that this solution is the only possible one because: *"with the operations I have made, the only possible solution is 212".*

When he tries to solve problem 2 he proposes 347 as divisor getting 10 as quotient and 27 as remainder. See that 347 is 32 x 10 + 27. When we asked him how he had obtained that number (347), he answered:*" I invented a number and added 27 to it.. It could have been any number."* Though he says he has chosen any number, the number he has "invented" is 320 that is 10 times the divisor. It all happens as if Hernán somehow knew that number had to be "obtained" from the numeric data he had been given, but at the same time he would not be completely aware of the relation between the quotient 10 and the 320 that is ten times the divisor. He gives only this solution to this problem and does not says how many solutions it could have. On the other hand, as the number 320, which Hernán says he has invented, is an approximation to the dividend which apparently has for him no relation with the quotient, it could be said that he conceives the dividend as an "starting point" for the procedure he has to put at stake and not as the number he has to obtain to fulfil the requested conditions. We shall see here another trace of the arithmetic practise: "in relation with the division operation you start from the divisor and the dividend". On the third problem it is much clearer that the number that Hernán "invents" has somehow a relation with the data and that he takes as starting point the dividend. Let us see. This student carries out the verification proposed in part a). To do this he does the division operation —this is what most student did— and for part b0 he divides 5270 by 46 and as he obtains 26 as reamainder he proposes 5265 as divisor. When he finished the problems he says this to us :

I: How did you get the operation?
H: I added a zero to the 527 of the other operation (he refers to the divisor of part a)) and I got 26 as remainder so I started lowering the number until I got 5265.
I: Are there any other possible solutions?
H: Yes, if you invent other numbers. But I don't know which number to invent, I tried but I couldn't.

Throughout the procedures put at stake by Hernán we see that he mobilises the Euclidean relation for the first problem, but this same relation is not available when one of the elements of this relation must be determined by him. This does not allow

him the production of other solutions though he seems to intuitively perceive that they exist. To undergo the resistance to give values, what is necessary to face problems 2,3 and 4 would allow Hernán to advance in the conceptualisation of the Euclidean division.

At the very beginning, we wondered whether the explicitation of the Euclidean relation could be a means to explain how the solutions are achieved in each of the cases. On this issue, we would like to point out that a lot of students who immediately provided some results without showing the traces of how they had obtained them, they explicited the relation when they were asked to explain how the solutions were obtained. Taking into account that to make explicit the relations used it always means a conceptual advance a propos of the implicit put at stake, this result tells us about the potential didactic productivity of asking for an explanation about how they arrived to the solutions.

Conclusions

How do these results nourish the making up of didactic sequences that aim at the construction of an articulation space between the arithmetic and algebraic practises?

The results that arise from the analysis of these problems seems to confirm a general hypothesis that guides our project: tackling problems which require, a propos of a particular mathematics concept, the putting at stake of the notion of variable entails an opportunity to advance in the conceptualisation of such a content. The advance in these conceptualisations and the arise of algebraic practises would be completely imbricate processes. To this effect, the teacher's interventions in the didactic sequences should contemplate a twofold institutionalisation: regarding the mathematics concepts being worked and the practises being installed. The institutionalisation at algebraic practise level would run through different mathematics contents and it would be each time linked to the contexts in which such procedures were produced. Understanding these practises would have the characteristic of understanding "how it is to be done" , that is different to the mere conceptual understanding (Inhelder, B; Caprona,D; op.cit).Specially, in relation with the didactic implementation of the afore analysed problems it would be important to consider that there would be — on the side of the students — a variety of possible procedures all of which would enchain procedures that would allow them to evolve towards the conceptualisation of the Euclidean division in terms of the Euclidean relation. After the didactic work the students should stablish:

- The dependence of the dividend regarding the divisor, the quotient and the remainder
- The similarities and differences between the production of division operations when the divisor and the remainder are fixed and when the quotient and the remainder are fixed

- The identification of the quotient and the remainder from the Euclidean relation without making the operation.

At algebraic practise level the didactic work with these problems should let the students:

- To advance in the incorporation of the procedure by which a value is given to a variable to get the value the other one that depends on the first one .
- To stablish the instrumental value of the Euclidean formula as producer of special operations and representative of the many examples produced and the infinite solutions that the problems admit.

The fieldwork we are going to face from now on will most probably confirm some of these issues, will open up our spectrum to other possible ones that now we cannot loom and, as it always happens, will compel us to renounce to a lot of the elaborations that preceed the difficult, complex and challenging task of putting to test our work with the students.

ON SOME UNDER-ESTIMATED PRINCIPLES OF TEACHING UNDERGRADUATE MATHEMATICS

Ildar Safuanov, Pedagogical Institute of Naberezhnye Chelny

The classical and contemporary experience in university mathematics teaching revealed the importance of such things as the strong individuality of a lecturer and especially the style (in oral lectures and in textbooks as well). Thus, the teaching has much in common with the art, and it seems useful to research teaching by means of art studies. Note the importance of such under-estimated principles as: 1) genetic approach: developing didactics from the method of science itself; 2) concentrism (teaching in a concentric way); 3) the principle of multiple effect.

1. Introduction.

As indicated Pototsky (1975), the undergraduate mathematics teaching is almost not investigated, the pedagogy of higher mathematics essentially is not present, and few monographs on problems of university mathematics education exist.

Though since 1975, when the Pototsky's book was written, the situation has changed in some extent (the researches of L.D.Kudryavtsev (1985), A.G. Mordkovich (1986), H. -C. Reichel (1992), D.Tall et al. (1991) devoted to various aspects of teaching of mathematical disciplines at universities and pedagogical institutes have appeared), the methods of teaching of undergraduate mathematics are investigated insufficiently (at least in the former U.S.S.R). Perhaps the Western situation is more prosperous so we will restrict our following considerations to the undergraduate mathematics teaching in Soviet and post-Soviet universities.

Kudryavtsev (1985, chapter 2.5) has put forward a problem of developing methodical principles of teaching of undergraduate mathematics. He complained of difficulty of the formulation of exact methodical principles.

The training of the university students essentially differs from the training of the school pupils. In universities such mechanisms of influence on students, as direct compulsion, authority of seniority by age are less significant; on the other hand, the university students are better prepared for the perception of a material through various channels. In the training of the university students there is less "didacticality" in a school sense and more art. Probably, partly for this reason the university teaching was less studied: the opinion existed, that the art cannot be learned, the art is not a subject of a scientific investigation, it can only be acquired on the basis of personal experience.

However, as L.D.Kudryavtsev (1985) and N.L.Gage (1964) indicated, any art has its rules, which can be explored scientifically, and any art can and should be learned (and taught): artists, and musicians, and writers study hard.

1319

On the other hand, it might be more fruitful to investigate some aspects of mathematics education by methods developed in art studies. Indeed, mathematics teaching, unlike mathematics itself or, say, philosophy, is a completely applied field unable to develop independently of practice. It makes mathematics teaching really close to such artistic fields as theatre or literature. Investigating these applied fields must result in some practical recommendations. One can regard these fields not only as art but also as craftsmanship and their investigations even as "design science" [Wittmann (1995)]. Of course it is impossible to quickly develop the universal system of all required recommendations (similar, say, to the theatrical system of Stanislavsky). We attempt here only to indicate some (not ALL) UNDER-ESTIMATED (exactly as indicated in the title) principles that, in our view, could in some extent stimulate or refresh the efforts of the mathematics-educational community in elaborating the recommendations. We will touch only two aspects of mathematics teaching: 1) general subject-related directions in developing methods of teaching; 2) effect on students.

These two aspects do not cover the whole realm of the undergraduate mathematics education. We are not aiming at constructing a complete system of didactical principles for teaching university mathematics which would allow to increase all the results of teaching (students' knowledge, creativity, motivation, interest, future professional skills etc.). Moreover, we can not guarantee that the use of the principles we are discussing would improve students' knowledge of mathematics in traditional sense (say, amount of mathematical facts, proofs, problem-solving patterns understood by the individual and/or stored in her/his memory), and we do not invent non-traditional meanings of mathematical knowledge. Our aims are rather closer to those of (physics educator) R.Feynman (1963) who tried to construct his course in such way that most able students could keep and strengthen their enthusiasm. We also agree with his statement that "there is no benefit of teaching for somebody except those for whom there is almost no need of teaching". It is especially true in our Soviet and post-Soviet conditions. Lastly, we are fond of his intention, designing the course for the most active listener, to take into consideration also interests of less able fellows, so that they could "seize the essence".

In this paper, the first aspect is represented by *the principle of genetic approach to the methods of teaching*. This is a rather general principle, extracted from experiences and thoughts of generations of undergraduate mathematics educators. Of course, deep development of this principle requires the study of students' (higher mathematics) learning processes. We did not yet accomplished such deep studies, so we only survey various manifestations of this principle implied by several authors, and also present some examples inspired by this principle. In particular, we do not discuss in this paper such important and fashionable problem as understanding and constructing proofs by students.

We hope that scientific community, e.g., members of PME's Advanced Mathematical Thinking group can deeply and fruitfully contribute to the further

development of this principle from the point of view and in terms of the process of (higher mathematics) learning.

We draw more attention to the second aspect (effect on students) that, in our opinion, is greatly under-estimated. Here it is represented by two principles: of concentrism and of multiple effect.

We do not declare that these principles are quite new, or that *we* have discovered them. Many authors have expressed the ideas similar to these principles.

Thus, we will try to briefly describe three insufficiently investigated, but, in our view, rather important and global for mathematics education principles: the principle of the genetic approach to the methods of teaching mathematical disciplines, the principle of the concentrism and the principle of the multiple effect.

Last but not least, we would like to draw attention of mathematics educators to the importance of such also greatly under-estimated aspect as the *style* of teaching and writing textbooks. Shortage of space does not allow us to discuss this problem in details here, so we will do that elsewhere.

2. The principle of the genetic approach to the didactics.

The essence of the genetic approach is that the didactics of a scientific discipline should correspond to the method of the science itself. Many prominent mathematics educators stated the ideas, connected with this principle, e.g. F.A.W. Diesterweg (1962) and H. Poincare (1990). It is especially important for mathematics teacher preparation. As shows E.Ch. Wittman (1992), "a genuine integration of mathematics and education (during the preparation of the teachers) can be achieved only if educational and psychological relationships and processes *inherent* in good mathematics are elaborated and developed". Diesterweg wrote: " the method of teaching of each subject should correspond to its source or principle... Otherwise the method will be arbitrary, borrowed from the outside, not following from the nature of a subject, and rather being contradicting prescription ... Here alongside with the statement: " the Man represents a method " - a rule: " the Subject represents a method " is true. Diesterweg warns against the understanding genetic approach as historical. A student should be raised to the height of modern science. He should not learn all out-of-date, already rejected points of view and errors of the past. Rubinshtein (1989) wrote that there coexist dialectical *unity* and *distinction* between the ways of pupil's learning and the cognition processes of mankind. He argued that the subject's *logic* extracted during the process of the historical development of the cognition represents that unity.

Of course, it does not mean that there is no role for the history of mathematics in mathematical education. It is quite allowable to make students acquainted with the history of mathematics by giving special historical courses. Moreover, sometimes it

1320

is useful to insert (not importunately and obtrusively) some historical facts in regular or advanced mathematical courses as it was done, say, by H.S.M.Coxeter (1966).

More precisely interprets the genetic approach to the didactics V.V.Davydov: " the substantial contents of a concept can be revealed only by finding out the conditions of its origination " (1972).

The most talented scientists - educators of the past skillfully used the genetic approach in teaching. The physicist M.Planck gave the best description of that: " I have never chosen shortest and most elegant proofs and reasoning, but always searched for those best corresponding, on my opinion, to the physical essence of a subject, because I did not want to show, how the known rules were open, nor how it is possible to prove them briefly today, but mainly the way, by which it was possible to open that theorem ... "

Much earlier G.W. Leibnitz (1880) expressed a similar idea: "I tried to write in such way that a learner could always see the inner foundation of things he is learning, that he could find the source of the discovery and, consequently, understand everything as if he invented that by himself".

Genetic approach can be used at various levels of teaching process: in designing syllabuses, in learning a topic or theme, in solving a problem. Accordingly, this approach may be used in various ways. One may find numerous examples of the genetic approach in classical and modern textbooks and in lectures of successful educators. For example, probably the worst way to teach number theory is a traditional for Soviet pedagogical universities approach: number theory is taught as application of the divisibility theory in rings of principal ideals. In our view, the genetic approach requires that most elements of number theory should be taught *before* abstract algebra because number-theoretical problems are interesting as they are for those at least minimally inclined to mathematics, and these elements can serve as good examples motivating many concepts of abstract algebra.

The next is an example of using genetic approach in studying a separate theme. Before studying linear congruences modulo m, we consider several problems where students have to check divisibility of numeric values of expressions into natural numbers. Together with students, we discover that remainders play the main role in solving these problems. Thus, the idea of introducing special relation between numbers with the same remainders arises etc.

A good example of using genetic approach in proving is provided by Davis, Hersh and Marchisotto (1995, pp. 307-313). G.Polya (1965) noted that in problem solving, the genetic approach implies the principle of *successive phases.*

However, one should not use the genetic approach as the absolutely strict rule but rather as the source of further interesting ideas [see Polya (1965, Ch. 14)]. For example, "pure" genetic approach would require that one should study not only the elements of number theory, but also theories of polynomials with one and several

variables before passing to theories of rings. It would be excessive waste of time and efforts. Motivated by number theory, students can learn divisibility theory in integer domains and then study polynomial theories as easy special cases.

Nor means the genetic approach that didactics of a discipline should be closed in boundaries of subject's contents. On the contrary, as noticed J.Dewey and Heintel [see Wittmann (1992)], taking subject matter's method fundamentally into account in building didactical models means using the method of highest order, scientific method and, therefore, breaking out the narrow boundaries of special disciplines. This means that one should also take into account all manifestations of human spirit's activities that are related to the scientific method and may help students to master the scientific method. In particular, genetic approach does not deny the importance of investigating the *effect on students* and the *artistic side of teaching.*

3. The principles of the concentrism and of the multiple effect

Many authors expressed the idea that teaching (not only of undergraduate mathematics) should be conducted in a concentric way. L.S. Vygotsky (1996, p. 87) wrote: " The rule is to completely avoid a repetition and to make teaching concentric, i.e. to arrange a subject in such way that it should be studied in maximally brief and simplified form at once in full volume. Then the teacher returns to the subject, but not for a simple repeating the past, but for studying the material once again in the deepened and extended form, with a variety of new facts, generalizations and conclusions, so that all things learnt by pupils earlier repeat again, but uncover their new sides, and new elements bound themselves with already familiar ones in such way that the interest arises by itself. In this respect both in a science and in life only new about the old can rouse our interest ".

Earlier Diesterweg (1962) suggested three rules close to the concentric way of teaching in the sense of Vygotsky: «1. Distribute a material in such a manner that at each stage a pupil would be in a position to guess or definitely expect the next stage. 2. Indicate at each stage some elements or parts of the following material and, not making essential breaks, cite certain elements from the future themes in order to excite inquisitiveness of pupils, not satisfying it, however, fully. 3. Distribute and arrange a material in such way that (where possible) at the following stage during studying new things the previous elements were repeated". He noticed that mathematics teaching could benefit from the concentric way.

We will try to specify here the traits of the concentric way of teaching mathematical disciplines at the undergraduate level. In our opinion, the main features are:

1) the *preparation* and, in particular, the *anticipation*;
2) the *repetition* at the higher or deeper level and the *increase*;
3) the *fundamentality* (the requirement of deep and strong study of the carefully selected foundations of a discipline);

The *preparation* is the extremely important element both in teaching and in various kinds of art. This element is well known by professional writers and theatrical directors. For example, A.P.Chekhov wrote: " If in the first act a gun hangs on the wall, in the last it must shoot ". A little bit modifying the classification of A.Zholkovsky and Yu. Scheglov (1977), one can consider three types of the preparation: a) the presentation; b) the anticipation;) the refusal.

Various ways of the presentation of the teaching material are investigated in detail in didactics of school mathematics (for example, before the study of a new material it is possible to activate the necessary knowledge from the previous themes or from related disciplines, to consider familiar examples etc.). Such ways can be studied also for teaching at the undergraduate level.

As an example of the element of the type "refusal" a problem way of studying a theme can serve (students are put before the fact of absence of the theory for the solution of the problem, and then the required is constructed in some way).

The most interesting and fruitful of these elements is, in our view, - the "anticipation". The indications to this element can be found at many classics of mathematics education. The above-cited rules of Diesterweg directly state this requirement. The demand to teach pupils to guess is put forward by G.Polya (1965) and Pototsky (1975). A guess and foreseeing by the students should be intensively used in teaching. Mordkovich (1986) also has described the elements of such method, comparing it with a spiral.

Concerning the repetition, note that one can speak not only about the repetition of those or other elements of a material, but also about repetitions of the relations between objects at various levels of a mathematical discourse. For example, the relations between objects in the theory of finite-dimensional vector spaces in many respects are repeated in the general theory of linear spaces, the relations between objects in analytical geometry on a plane in many respects are repeated in analytical geometry in a space; the relations between objects in the elementary number theory in many respects are repeated in the theory of polynomials. Even more interesting repetitions of the relations between objects one can find at the higher levels of abstraction, say, in abstract algebra. For example, categories and functors are in the relation similar to the relation between algebraic systems and homomorphisms; the composition of morphisms in a category is similar to the partial algebraic operation.

The *increase* means that elements repeated at later stages of study should be deepened and extended, equipped with interesting, impressing details.

For the efficiency of the concentric study, the anticipation should be based on very deep study of the fundamentals of a subject. The deep and slow study of the foundations requires the economical and thorough selection of the most necessary material. It is possible to name the requirement of deep and strong study of the carefully selected foundations of a discipline the principle of *fundamentality*.

We will name the approach to the teaching of a mathematical discipline combining the requirements of fundamentality, preparation and anticipation, repetition and increase the *principle of concentrism.*

The principle of concentrism, developed and used by many educators, is, in our view, closely connected to the *artistic side* of teaching. Indeed, elements of preparation, anticipation, repetition, increase are important for the composition of artistic works [musical pieces, theatrical plays, stories, paintings etc.] As we remarked in the ending of Section 2, it does not contradict to the genetic approach to methods of teaching. For example, G.Polya (1965) who supported the genetic approach, at the same time compared teaching to the theatrical art and even to music. Unfortunately, although it is widely admitted that teaching has much in common with art, the artistic side of teaching is under-estimated and almost not studied [cf., Koehler (1997)].

Another principle connected with the artistic side of teaching is the *principle of multiple effect* (on students and on the readers of textbooks). The essence of this principle is that the essential educational result can be achieved (in a lecture course or in a textbook, or even at a microlevel - in a separately taken lecture) not with the help of one means, but many, directed to one and the same purpose. For example, the following *means of expressiveness* may be used in teaching undergraduate mathematics:

1) The variation (passing through the various) – e.g., the explanation of a theoretical rule on a series of various examples, or, even more important, the consideration of a subject from all basic sides.
2) Splitting (material into smaller pieces);
3) The contrast - for example, the use of rather fruitful questions of a kind "How differs the concept (figure etc.) A from the concept (figure...) B. H.Poincare (1990) emphasized the importance of this element, speaking about mathematical definitions.

One may note that elements related to the principle of concentrism are connected with *metaphorical* relations (relations of *similarity*) and elements related to the principle of multiple effect are connected with *metonymical* relations (relations of *contiguity*). It would be interesting to deeply investigate the possibilities of combining metaphorical and metonymical relations in producing an educational effect [cf., R. Jacobson (1973), R.Barthes (1967), M. James et al. (1997)].

4. The conclusion.

Thus, for teaching mathematics at universities one can formulate the important principles indicated by classics of mathematics education, but poorly investigated and insufficiently used in practice: the principle of the genetic approach to teaching, the principle of concentrism and the principle of multiple effect. The *style of teaching* is extremely important, too. It is necessary to deeply study the role of above-discussed principles not only for classroom teaching, but also for the creation of the textbooks.

FACTORS INFLUENCING STUDENT'S GENERALISATION THINKING PROCESSES

Marlene C. Sasman: *Mathematics Learning and Teaching Initiative (Malati), South Africa*
Alwyn Olivier: *Malati & University of Stellenbosch, South Africa*
Liora Linchevski: *Malati & Hebrew University of Jerusalem, Israel*

In this study we presented students with generalisation activities in which we varied the representation along several dimensions, namely the type of function, the nature of the numbers, the format of tables, and the structure of pictures. Our results show that varying these dimensions has little effect on children's thinking – as in our previous study, few children tried to find a functional relationship between the variables, but persisted with using the recursive relationship between function values, making many logical errors in the process.

INTRODUCTION

Number patterns, the relationship between variables and generalisation are considered important components of algebra curricula reform in many countries. These curricula often use generalised number patterns as an introduction to algebra. However, there is insufficient research that deals with the cognitive difficulties students encounter and the feasibility of such an approach. Much of the available research on students' thinking processes in generalisation reports on students' strategies in abstracting number patterns and formulating general relationships between the variables in the situation (e.g. Garcia-Cruz and Martinon, 1997; MacGregor and Stacey, 1993; Orton and Orton, 1994; Taplin, 1995).

In a previous study (Linchevski, Olivier, Sasman & Liebenberg, 1998) we presented grade 7 students with problems like the following:

(C3): Matches are used to build pictures like this:

Picture 1 Picture 2 Picture 3 Picture 4

The table shows how many matches are used for the different pictures. Complete the table.

Picture number	1	2	3	4	5		20		100		*n*
Number of matches	3	5	7	9							

Few students managed to construct a function rule to find function values. Rather, they focussed on recursion (e.g. $f(n + 1) = f(n) + 2$ in problem C_3 above), which led to many mistakes as they tried to find a manageable method to calculate larger function values. The most common, nearly universal mistake was to use the proportionality property that if $n_2 = k \times n_1$, then $f(n_2) = k \times f(n_1)$. For example, in problem C_3 above, from $f(5)$[1] = 11 they deduced that $f(20) = 4 \times 11 = 44$. Although this property applies only to functions of the type $f(n) = an$, students erroneously applied it to any function. It is possible that our use of "seductive numbers" in a sequence like n = 5, 20 and 100 *stimulated* the error (we regarded these numbers as seductive from a multiplicative point of view).

[1] Formal functional notation was not used in the interviews with students. It is used here for ease of communication

We found that most students' generalisations and justification methods were invalid, because they are not aware of the role of the database in the process of generalisation and validation.. For example, in problem C3 above, they did not, and seemed unable, to verify their generalisations against the given data pairs (1 ; 3), (2 ; 5), (3 ; 7), (4 ; 9).

We also found that students worked nearly exclusively in the number context and did not use the structure of the pictures at all.

Based on the above we viewed the following as questions for further research:

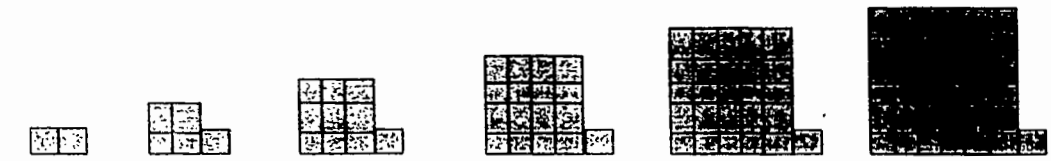
- whether the use of non-seductive numbers will *prevent* students from making the multiplication error, also when they encounter seductive numbers in other problems
- whether the visual impact of the table, as for example shown in problem C_3 above, also contributed to the persistence of the proportional multiplication error
- whether pictorial representations in which the function rule is "transparent" will help students to use the structure of the pictures to more easily find function rules.

In this paper we report on some first findings on these three questions.

RESEARCH SETTING

The activities

We designed a series of eight generalisation activities in which we varied the representation of the activities. Four activities were formulated in terms of numbers only (in the form of a table of values), and four were formulated in terms of pictures only (in the form of a drawing of the situation). Each numerical representation had a corresponding pictorial representation. Two of the functions were linear functions of the form $f(n) = an + b$, and two functions were simple quadratic functions

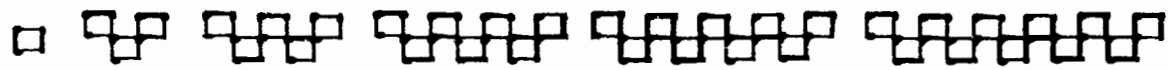


The numerical tables of values were presented in different formats: "continuous" (e.g. I_T below, in which input values for which the corresponding function values had to be calculated were included) and "non-continuous" (e.g. II_T, where the input values were not given, but were presented verbally by the interviewer). The tables were presented in both vertical and horizontal format.

The pictorial representations of the activities were chosen to be either "transparent", i.e. the function rule is embodied in the structure of the pictures (e.g. in I_P below), or "non-transparent", i.e. the function rule is not easily seen in the structure of the pictures (e.g. in III_P). As with tables, pictures were presented in both "continuous" and "non-continuous" format. All the drawings were presented to students in vertical format, but is here given horizontally due to space considerations.

The questions in each activity were basically the same, namely given the values of f(1), f(2), f(3), f(4), f(5) and f(6), we asked students to first find f(7) and f(8), and then the function values of certain further input values and to explain and justify their answers and strategies. These input values were both "seductive" (e.g. 20, 60) and "non-seductive" (e.g. 19, 59).

We supply below a selection of the activities. The subscript P indicates that the activity was presented in a pictorial representation and the subscript T indicates the problem was presented in the form of a table of values.



I_P: *Blocks are packed to form pictures that form a pattern as shown below:*

I_T: *Tiles are used to build pictures to form a pattern. The table below shows the number of tiles in a particular picture.*

Methodology

We interviewed ten grade 8 students at one of our project schools in a historically disadvantaged area of Cape Town before they had received any instruction on patterns, sequences or algebra. The students were selected by the teacher so that they were representative of the grade 8 class. Each student was interviewed three times in 45-minute

BEST COPY AVAILABLE

sessions. All interviews were videotaped and the tapes transcribed. The analysis will be used to design a teaching intervention to address the cognitive difficulties students have in the processes of generalisation.

RESULTS AND ANALYSIS

Most students had no difficulty finding f (7) and f (8) in any of the activities – they either found and used the function rule correctly, or used recursion correctly for these nearby values. However, in trying to find a manageable strategy for finding further-lying function values, students invented a variety of different strategies, both correct and incorrect. These strategies and their frequency are summarised in Table 1.

Table 1: Number of students using each strategy per activity

Activity number and representation format	Recursion	Proportional multiplication	Additive decomposition	Difference method	Extended recursion:	Function rule	Other
I_P Transparent picture, continuous Seductive values: 20, 60, n Quadratic function: $f(n) = n^2 - 1$	2		1		2 wrong variations	5	
I_T Horizontal continuous table Seductive values: 20, 60, n Quadratic function: $f(n) = n^2 + 1$		4		1	1 wrong variation	3	1
II_P Transparent picture, continuous Non-seductive values: 19, 59, n Linear function: $f(n) = 8n - 4$	1		1	3	1 2 wrong variations	2	
II_T Vertical non-continuous table Seductive values: 20, 60, n Linear function: $f(n) = 8n - 4$		4		3	1 2 wrong variations		
III_P Non-transparent picture, non-continuous Non-seductive values: 23, 79, n Quadratic function: $f(n) = n^2$	3		1	1	2 wrong variations	2	1
III_T Vertical non-continuous table Seductive values (29, 87, n) Quadratic function: $f(n) = n^2$	1	1			1 wrong variation	6	1
IV_P Transparent picture, non-continuous Seductive values: 20, 60, n Linear function: $f(n) = 4n + 1$	1	2		2	2 2 wrong variations	1	
IV_T Horizontal continuous table Non-seductive values: 23, 117, n Linear function: $f(n) = 4n + 1$	1		3	1	2 2 wrong variations	1	

The nature of the function

Finding function rules It is interesting to note from the data in Table 1 that more than half of the students found and used the function rules in activities I_P and II_T. These both represent simple quadratic functions. One could be tempted to conclude that students easily recognise such simple quadratic function rules. However, one immediately also notices the marked differences in students' responses for the same functions in the picture and the table contexts. In activity I_P the picture is transparent, but students find it much more difficult to recognise the same function rule from the equivalent table in activity I_T. In activity III on the other hand, students easily find the rule in the table, but not in the non-transparent picture.

It is clear that students found it much more difficult to formulate function rules for linear functions. From our interviews it seems that students try to construct simple multiplication (proportional) structures, but when it does not fit the database, they quickly give up and then invent all kinds of error-prone recursion strategies.

Recursion When students focus on recursion patterns, however, they find the constant difference between consecutive terms in linear functions much easier to handle than the changing difference in quadratic functions, leading to many errors. We describe these strategies and errors in the following sections.

Seductive vs. non-seductive numbers

The proportional multiplication error In our earlier work with grade 7 students we found a persistence with the erroneous proportional multiplication error. Also in this study six of the ten students interviewed used it at least once in the series of activities. For example:

Interviewer:	How many tiles in Picure 20? (*in IV_P*)
Peter:	OK. I am using 5 (*meaning $n = 5$; $f(5) = 21$ in the picture)* to get to 20. So 21 times 4 is 84, because 5 times 4 is 20.

This erroneous strategy was used only with what we call "seductive numbers". When students could easily find the function rule the nature of the input values was immaterial, i.e. they did not make the multiplication error, even for seductive numbers.

Extended recursion A few students managed to adapt their focus on recursion to a manageable strategy for finding further-lying function values. This extended recursion method is symbolised by $f(n) = (n - k)d + f(k)$, where d is the common difference between consecutive terms. Here is an example:

Interviewer:	OK. Shape 59? (*How many matches in Shape 59 in II_P?*)
Hamid:	So first I subtract 19 (*he had previously calculated $f(19) = 148$*) by 59 and then you get your answer of 40 and then I times it by 8 (*the common difference between terms*) and then I get my answer and then I add it by 148, that is Shape 19's answer.

Some students used this method also in the case of seductive numbers.

Students using this method often seemed to lose track of all the details. This was mostly because they worked verbally, and did not write down information or their strategy. For example, several students correctly calculated $(n - k) \times d$, but then did not add $f(k)$.

While the extended recursion method is correct for linear functions, many students also erroneously applied it to or adapted it for the quadratic functions. For example:

Interviewer:	Ok, and then Picture 20? (*How many matches in Picture 20 in I_T?*)
Harold:	I subtract 20 by 8 (*he had previously calculated $f(8) = 65$*) . . . I subtract 8 by 20, then I get 12 ... with that 12 I times by 2 is equal to 24 ... then I add 24 by 15, is equal to 39 then I add 39 to 65, is equal to 104.
Interviewer:	Just explain the 15 please
Harold:	That's the 15 I added by 50 (*f(7)*) to get 65 (*f(8)*).

Additive decomposition of input value The introduction of "non-seductive numbers" gave rise to other inappropriate strategies when students could not find a multiplicative relationship between the non-seductive numbers such as 19, 23, 59 and 117. Some

students used additive decomposition of the input value, symbolized by $f(n) = f(a) + f(b)$, where $n = a + b$. For example:

Interviewer:	OK, in Picture 117, how many tiles? *(How many tiles in Picture 117 in activity IV_p)*
Errol:	*(Writes 30 = 121, 40 = 161, 50 = 201 . . . 100 = 401, 117 = 470)* Picture 117 is 470.
Interviewer:	Can you explain to me how you got that?
Errol:	Uhm, as I followed on Picture 100, I had to end up at 401 and I added Picture 17 to Picture 100 which gives Picture 117 *(He had previously calculated Picture 17 as 69)*

The difference method The erroneous difference method, symbolised by $f(n) = n \times d$ was invoked with both "seductive" and "non-seductive" numbers. For example:

Interviewer:	Ok, how many in Picture 23? (*How many tiles in Picture 23 in IV_T?*)
Linda:	(*works on calculator*) . . . 92
Interviewer:	Just explain please?
Linda:	It will take too long to add 4 every time (*she previously found a constant difference of 4 between the terms of the sequence*). So I just said 23 times 4.

The visual impact of tables

From Table 1 it is clear that the visual presentation of the numbers in a table format for the function did not impact on the errors students made. The table in activity I_T was horizontal and "continuous" whereas the table in II_T was vertical and "non-continuous". Four students made the proportional multiplication error in both these examples. One student committed the difference method error in I_T whilst 3 students committed the error in II_T. The way we presented the questions as "continuous" or "non-continuous" in the picture activities also did not effect students' strategies. This can probably be explained by the fact that when the input numbers were not presented in writing, students made their own "continuous" "tables", so the visual distraction remained.

"Transparent" vs. "non-transparent" pictures

In I_P five of the ten students successfully recognised the function rule from the structure of the transparent picture. In II_P most students recognised that 2 squares (8 matches) were being added but then converted to numerical mode, constructing their own "table" of values, e.g. " ... 1 = 4, 2 = 12, 3 = 20, etc.". Only two students described the function rule from the structure of the pictures, namely as $(n + n - 1) \times 4$ and $n \times 4 + (n - 1) \times 4$ respectively. Only one student used the structure of the picture in IV_P to identify the function rule. No child could recognise the function rule of using the non-transparent picture as the database in III_P. Two students found the function rule once they reverted to the number context.

It seems that these students do not have the necessary know-how of *how* to use the structure of a picture to find a functional relationship. If one wants to find a function rule in a table, one necessarily takes some specific value of the independent variable (input number) and tries to construct a relationship between this input-output pair. In the case of pictures, few students seem to intentionally take a specific input number and try to see this number in the structure of the picture, as illustrated in the following diagram:

Of course, it further requires a rich number sense, e.g. in II to see a further relationship in the numbers (2 is one less than 3, and 3 is one less than 4) before one can formulate the function rule $[n + (n - 1)] \times 4$. In IV one must see the multiplication or equal addition structure before one can formulate the rule $4 \times n + 1$. A weak number sense will therefore also contribute to students' difficulties in using the structure of pictures to see the general in the particular required to formulate function rules.

Most students could see and use the structure of the pictures in a *recursive* way, e.g. in II students used the structure that 2 squares (8 matches) are added each time, and in IV they used the structure that 4 tiles are added to each successive picture. However, this did not help them to find the function rule, and students mostly then constructed a table of these values and then used the numbers in the table inductively. Of course, one could use the extended recursion method to use this recursive structure to formulate the function rules as $4 + 8(n - 1)$ and $5 + 4(n - 1)$ respectively.

Verification of strategies

Consider the following protocol:

Interviewer: Ok, Shape 19? (*How many matches in Shape 19 in II_p?*)

Peter: *(Peter successfully found f(7) and f(8) by counting the number of squares and then multiplying by 4 to get the number of matches. Now he starts making a systematic table of the number of squares in each Shape, using a recursive pattern:*

7	8	9	10	11	12	13	14	15	16
13	15	17	19	21	23	25	27	29	31

He then stops and goes back to looking at the pictures again.)

OK, I realised if I do this it is a bit of a hassle, so I looked at the pattern (*in his database*) and I figured the difference (*between f(n) and n*)

I took here (*pointing at f(5)*) . . . the difference between 9 (*f(5)*) and 5 (*n*) is 4 and by number 6 it is 5 . . . yes (*he checks again*) . . . 5. And by number 7 it is 6 and by number 8 it is 7. So I just tried it out. So I said to myself OK it is right and it will take too long to do it like this (*referring to his table of values*). So Shape 19 is 19 + 18, is 37, so 37 blocks times 4 gives you . . . 148 (*using the calculator*).

Clearly, Peter has constructed an efficient rule, which we can symbolise as $[n + (n - 1)] \times 4$, based on a sound analysis of patterns in the given and his extended database, and he verified that his pattern holds against the database several times. He was convinced and he could use the method with assurance. However, this style of working stands in stark contrast to most students' approach to such generalisations. While the students who used a function rule necessarily deduced the rule from the database, the other strategies reported in this paper are mostly not based on the database – students did not find the methods in the database, nor did they check it against the database. This applies to correct as well as to incorrect strategies. Students seem not to realise the need to validate their generalisations, and seem not to have the know-how of how to validate a generalisation against the database.

DISCUSSION

As in our previous study, students worked nearly exclusively in the number context and not with the pictures, favoured recursion methods, had difficulty in finding function rules and made many errors, including the proportional multiplication error. There is,

however, one marked difference, namely the variety of strategies used by the students in the present study in comparison to the previous study. Of course this could be attributable to the differences in the subjects, who are at a different grade level, and from a different socio-economic background. We would argue, however, that the difference is mainly attributable to the introduction of non-seductive numbers in our activities.

It is for this reason (the greater variety of strategies), that we plan to extensively use non-seductive numbers in our planned intervention. However, as is evident from the examples in this paper, the use of non-seductive numbers will probably not prevent the ubiquitous proportional multiplication error when students encounter seductive numbers, nor will it prevent the other erroneous strategies reported here. For that we believe we should address two more fundamental issues, viz.

First: The development of an awareness of the need to view any strategy as an hypothesis that should be validated against the database, and a focus on skills of how to do it. When one looks at the variety of strategies used by students, one can probably safely say that they have the ability and flexibility to find many patterns and relationships between numbers. The problem, however, is that most students are finding *random* relationships between the numbers without reference to the given database. We are struck not so much by the frequency and persistence of students' errors, but by their lack of an essential aspect of "mathematical culture", namely to view any strategy as an hypotheses that should be justified or verified against the given database. It seems that students lack simple *strategic knowledge*, e.g. to test an hypothesis against special cases.

Second: A more explicit study of the properties of different function types, and a comparison of such properties to become aware and make explicit which properties apply to which function types. All the erroneous strategies used by students are correct properties for some function, which students wrongly apply or overgeneralise to other functions.

This research presents and analyzes difficulties experienced by teachers who were attempting to find meaningful ways to help their students learn about addition and subtraction of integers. Results indicate that teachers can generate meaningful contexts to help their students understand addition, but have great difficulty doing the same for subtraction. The contexts that they generated appeared to be based on an understanding of subtraction that involved "taking away" one amount from another. No example of subtraction as the comparison of two quantities was given. As a result of their difficulties in finding meaningful contexts, they tended to prefer a more procedural approach to teaching subtraction, claiming that using an algorithm "is more meaningful than making up a story".

Introduction

The purpose of this paper is to present research findings related to our work with teachers in a long-term teacher development intervention. An underlying premise of this intervention is that teachers need appropriate experiences and materials from which to build new models of instruction. In addition, teachers must also be provided with opportunities to develop a deeper understanding of the mathematical concepts they are expected to teach and an increased awareness of the ways in which children learn (Schorr, Maher, & Davis, 1997; Lesh and Kelly, 1997; Janvier, 1996; Alston, Davis, Maher, and Schorr, 1995; Simon, 1995; Cobb, P., Wood. T., Yackel, E. and McNeal, B. 1993; 1986; Davis, 1984). To this end, in each workshop session, led jointly by the authors, teachers are presented with challenging problem tasks and asked to work together to produce solutions that represent important mathematical ideas. After sharing their own ideas and representations, they are encouraged to use these or similar tasks in their own classrooms. During classroom implementation, teachers are encouraged to recognize and analyze their students evolving ways of thinking about these mathematical ideas. Teachers are also encouraged to carefully study and assess student work, and to select particularly interesting products to share in subsequent workshop sessions. Studying these samples of student work together provides the opportunity to consider the development of these ideas in students and discuss the pedagogical implications of using this approach. As one might expect, this approach to thinking and doing mathematics is unfamiliar for many experienced teachers, and is not easy.

Experience and research have shown that all teachers possess beliefs about the way mathematics is learned (Thompson, 1985). These beliefs are generally acquired

prior to actual classroom experience, and held through years of teaching (Tabacknick and Zeichner, 1984). In addition to long held beliefs about mathematics instruction, many teachers may not possess adequate subject matter knowledge. Cohen and Ball (1990) point out "how can teachers teach a mathematics they never learned, in ways they never experienced?" (p. 233). The old models that teachers have for providing mathematics instruction are generally quite robust, and even teachers involved in long term interventions will fall back upon those old models, especially when under pressure to have students perform well on tests whose goals may be inconsistent with those of the teacher development intervention.

The purpose of this paper is to provide documentation, in a specific content domain, relating to some of the difficulties that teachers experience as they attempt to make the transition from teaching mathematics as a set of rules, procedures, and algorithms toward thinking about and teaching mathematics as a "collection of ideas and methods which a student builds up in his or her own head" (Davis, 1984, p. 92).

Background[1]

This research is one component of a multi-year teacher development intervention. that began with the purpose of supporting the effective classroom use of exemplary mathematics curriculum and meaningful assessments as an integral part of instruction. To this end, university researchers work directly with groups of teachers from four economically disadvantaged high schools in an inner city in New Jersey. The particular high schools were chosen because they have student achievement levels in mathematics that are amongst the lowest in the city. The school district is currently under the supervision and control of the state due to overall poor student performance.

Methods and Procedures

This paper is based on an analysis of the problem-solving activity that occurred during one full-day workshop session in the third year of the intervention. Ten teachers were present. Three of the teachers had been part of the project since year one (tier I) and three of the teachers had joined the project in its second year (tier II). The remaining four teachers had joined the project during the third year (tier III). The workshop under discussion was the second workshop of the academic year.

The format of this particular workshop, typical of each of the project sessions, began with discussion initiated by the teachers about issues that they consider relevant to the project. As a general practice, the researchers' role during these discussions is that of facilitator and observer, providing opportunities for them to learn about the knowledge, beliefs, and concerns of the participants. Based upon this, the

[1] This work was supported in its first year by a teacher enhancement grant from the National Science Foundation which was directed by Richard Lesh and Thomas Post. Beginning in the second year, support has come from the school district itself. The opinions expressed are not necessarily those of either sponsoring agency and no endorsement should be inferred

researchers are able to make decisions about the direction of future workshop sessions.

The specific mathematical content of this paper, addition and subtraction of signed numbers, was introduced in the beginning discussion by one of the teachers. These particular ideas had not been considered in previous sessions, and, in fact, were not the topic selected by the researchers as the main mathematical idea to be explored during the session.

The data for this research includes the researchers' observation notes, problems and illustrations printed by the teachers on large pieces of chart paper as they were explaining their ideas to the group, and their individual written work completed during the session.

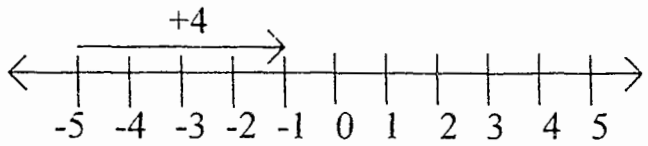
Results

On the occasion reported in this research, a spontaneous general discussion about operations with signed numbers occurred, following from a concern expressed by one of the teachers.

The following dialogue represents excerpts from that discussion as recorded in the field notes of the researchers with further documentation from the chart papers used in group discussion.

Kate[2] (tier III): *One of my students, Richard, is generally a very good student. I'm concerned because when he does examples like positive thirteen minus eight, he ends up with fifteen. I think that using calculators is the cause of his problem.*

Mark (tier I): *I think that signed numbers are a problem for many of my students as well.*



When other teachers also added that their students had difficulties with signed numbers, Mark wrote on a large piece of chart paper in front of the group:

$$-1-(-5) = -1+5 = 4$$

Mark: *See, the question is what do you add to negative five to get to negative one. There are lots of ways to do it. You can also think how many units must you move to the right on a number line.*

He illustrated his point by drawing a number line with an arrow directed from -5 to -1 and labeled it +4 (as below). Two additional examples were given and illustrated on a second number line, 1 + 3 and -3 + 2.

[2] Names have been changed to preserve the anonymity of the teachers and students.

Mark:.... *or you can always consider the negative number as money you owe, like you owe someone ten dollars and you pay six so you still owe someone four.*

Jack (tier II): *I like it when the teacher becomes a number and actually walks!*

Mike (tier III): *I like to think that the plus sign means "have" and the minus sign means "owe". So, if you have positive five minus three equals positive two, the positive sign in front of the five means have, the minus sign means owe, and the positive sign in front of the two means still have.*

He wrote the following on the large chart paper in front of the room:

"+" means "have"

"-" means "owe"

⊕5 ⊖3 = +2

have owe

Joan (tier I): *When you have to subtract a negative, you should use three words--keep, change, and change. So if you have negative three minus negative four, you keep the first sign, and change the other two.*

She wrote the following on the large chart paper in front of the room):

- 3 - (- 4) =

Keep Change Change

Jack: *I like that, because the more you try to give them a reality example, the more confused they get.*

Researcher: *Can you make up a story to go with Joan's problem if you wanted to?*

Jack: *Its hard, but you can.*

Researcher: *Go ahead, why don't you all try.*

Mark: *You can always do it with money, like I said before.*

After a general discussion, the researchers redirected the teachers' attention to the problem that Joan had written on the chart paper. They again challenged them to work individually or together to create meaningful situations or stories that would make sense out of each of four numerical expressions involving operations with signed numbers.

Researcher: *Well, make one up. While you are at it, try to make up problems for these as well. You can work together if you like.*

She added the following three problems to the piece of chart paper:

$$-3 - (+4) = \qquad +3 - 4 = \qquad -3 + 4 =$$

The teachers worked individually, occasionally conferring with neighbors. During that time, several teachers noted to the group how difficult it was to make up a real story to coincide with any of the problems listed above.

Susan (tier III) began the discussion. She said that she liked to use algebra tiles to help, and her example was based upon that. Her written example follows:

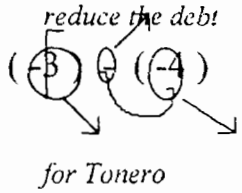
> *Sandy got squares for positive and negative numbers. -1 = ☐ in red color. 1 = ☐ in blue color. -(-1) = ☐ in blue color. She took 3 red squares, and then subtracted four in blue. How many squares in what color did she have?*
>
> $$-3 - (-4) = -3 + 4 = 1$$

When the other teachers responded that they did not understand the example and asked how this could be considered a "real situation", Susan explained that she was referring to the use of actual blue and red tiles, concretely, to solve the problem. She used the chart paper in an attempt to illustrate this, but immediately became confused herself, unable to remember how she had produced the blue (negative) and red (positive) squares necessary to concretely remove 4 red squares and end up with 1 positive blue square.

Harriet (tier 1) then suggested the following problem instead:

> *Sharifa had $3 negative (out of pocket) and she gave Maria negative one times minus $4. How much did they have together?*

Several other teachers responded that they thought this would be confusing for students as well. In the ensuing discussion, one of the researchers asked whether the teachers had been writing their stories for this problem to match the answer (positive one) that they already knew. All the teachers agreed that this was indeed the case and stated that, for subtraction of negative numbers, using a rule was preferable. Jack repeated his earlier remark, emphasizing the following:



> *The more you try to give them a reality example, the more confused it gets! "Keep, change, change" is more meaningful than making up a story.*

The written examples for the problems were collected from all of the teachers at the end of the session. Analyzing that data confirmed the difficulty that teachers had encountered in finding sensible situations for subtraction.

Ellen (tier 2) tried an example that documents how difficult developing a meaningful story had been for her. She wrote:

> *Sam has been borrowing money from some of his friends. He owes Tonero $3. He owes Habebah $4. He started to repay his debts.*

She first wrote the following annotated expression to show how the symbols connected to the words of her story:

On reflection, Ellen apparently changed her mind, and wrote this numerical expression on her paper to go with her story:

$$-3 \oplus (-4)$$

Both Susan and Harriet also wrote sensible stories that were based on addition. It appears that Susan changed a subtraction problem to an addition one, as indicated by her symbolic representation.

Susan's work follows:

> *Pete was on the 3rd floor, then he took an elevator 4 floors down. On what floor is he now?*
>
> $$+3 - 4 = +3 + (-4) = -1$$

Harriet wrote the following story for the same problem:

> *Ericson owed $4 to Alice. However he received $3 from Mahmoud. How much money will he actually have out of his pocket?*

In analyzing the written work of the teachers, all but one of the papers included at least one example that was a sensible addition story using signed numbers. No teacher provided an example for subtraction of a negative number from another quantity that was realistic. Mark's example indicates that he may have been considering subtraction of a negative number as a "forgiven debt". He wrote:

> *A couple of weeks ago, James borrowed $3 from Mary with the understanding of paying back the very next day. But James forgot to meet up with his obligation. Mary then got upset and demanded James to pay her money. James then replied. In fact you owe me one dollar. Do you remember when you borrowed $4 from me 10 years ago?*

However, along with his story, he wrote the following equations as the appropriate numerical representation for what he had written:

$$-3 - (-4) = -3 + 4 = 1$$

Discussion and Conclusions

A number of examples generated throughout the session appeared to be based on an understanding of subtraction of whole numbers that involved "taking away" one

amount from another. In each case, the appropriate numerical expression involved addition, with the negative sign indicating either direction or a debt. No example of subtraction as the comparison of two quantities was given after Mark's reference to the number line, and even in this case his comment "what do you add to negative five to get to negative one" appears to indicate that he was thinking of addition.

The examples reported document the value of having teachers write meaningful stories both as a means of deepening their own understanding, and uncovering areas of difficulty. However, the results reported indicate that more attention should be given to developing meaning for subtraction as comparing a first quantity with a second, first with whole numbers, and then with integers.

In addition, the results indicate that the teachers still felt that it was helpful to offer students "real world" problems, especially those involving money, to help them understand addition of signed numbers, but that was not the case for subtraction. Jack's comment sums it up: *The more you try to give them a reality example, the more confused it gets! "Keep, change, change" is more meaningful than making up a story.* In fact, the teachers unanimously agreed that Joan's suggestion to use the procedure involving "keep, change, change" was the best way to approach subtraction of integers.

As indicated in the results, when the researcher asked the teachers whether or not they were generating their problems for subtraction with the answer already in mind, they all indicated that they indeed were. Further, their written work indicates that they consistently converted subtraction problems into addition problems, and their problem situations more closely reflected addition situations.

Another point worth noting has to do with the use of concrete materials in the teaching of mathematics. As indicated by the results, Susan had great difficulty in recreating a situation in which addition and subtraction of integers could be modeled with tiles. This occurred despite the fact that she had mentioned on more than one occasion during the discussion that using what she referred to as algebra tiles had been very helpful to her students. She not only had difficulty in representing how the tiles could be used, but also in generating the statement of a problem that could be used to precipitate a discussion involving them. In fact, her initial word problem using the squares (tiles) reveals some basic misconceptions about the difference between using concrete materials and generating a real situation. In this case, Susan thought that using the concrete materials was the real situation.

The results of this research indicate how difficult it is for teachers to provide meaningful problem-solving situations for their students in this particular content domain. Further, they indicate that at least in this circumstance, when teachers experience difficulty in providing a meaningful context for their students, they often resort back to a procedural approach.

A final point needs to be made. The teachers involved in this research are caring, committed teachers who have all successfully completed degrees in college mathematics. Each of them works hard to create meaningful instruction for students, and is eager to learn more about how to meet their needs. An important implication of this study is the need to encourage mathematics education researchers to constantly focus attention on the mathematical thinking of teachers, and to create contexts and environments in which teachers and researchers can openly work on these ideas together.

WAYS OF TALKING IN A MULTILINGUAL MATHEMATICS CLASSROOM[1]

Mamokgethi Setati
University of the Witwatersrand, South Africa

In this paper I investigate the nature of talk in a multilingual mathematics classroom in South Africa. In particular, this paper explores how the teacher uses code-switching to facilitate communication of mathematical ideas. The paper draws from a wider study on language practices in multilingual mathematics classrooms in South Africa where multilingual teaching and learning is now encouraged. Current national policy defines eleven official languages and flexibility for schools in determining their language policy.

INTRODUCTION

It is well known that language (reading, writing and speaking) is important for thinking and learning, and that language is not only an issue in mathematics classrooms but in all classrooms. This issue, however, takes on a specific significance in multilingual mathematics classrooms. Learning and teaching mathematics in a multilingual classroom in which the language of learning is not the learners' main language is, undoubtedly, a complicated matter. Learning mathematics is similar to learning a language since mathematics, with its conceptual and abstracted form, has a very specific register. School mathematics also involves a range of discourses, ways of using and valuing language. These places additional demands on mathematics teachers and learners.

> *Mathematics teachers ... face different kinds of challenges in their multilingual classrooms from English language teachers. The latter have as their goal, fluency and accuracy in the new language - English. Mathematics teachers, in contrast, have a dual task. They face the major demand of continuously needing to teach both mathematics and English at the same time (Adler, Slonimnsky and Lelliot et. al., 1997).*

Learners on the other hand have to cope with the new language of mathematics (its specific register and discourses) as well as the new language in which mathematics is taught (English).It is therefore important to understand the different language practices that teachers in multilingual mathematics classrooms use to enable learners' meaningful communication of mathematical ideas, concepts, generalisations and thought processes. In this paper I will present the initial stages of an analysis of data collected for a wider study on language practices in intermediate multilingual mathematics classrooms (Grades 4 - 6) in South Africa. I will focus on one case and will explore the following questions:

- how does the teacher use the learners' main language to help learner access to mathematics?
- what languages do the learners use in mathematical discussion?
- how do learners use the language of the teacher, the language of mathematics and their own everyday language in the process of learning?

THEORETICAL FRAMEWORK

Two major areas of enquiry inform this study. The first relates to Vygotsky's theory of socio-cultural development. Development occurs in and through socially mediated activity and language plays a key role in mediation (Vygotsky, 1986). The presence of a more experienced other who embodies and models the intended outcome for the learner is crucial within this framework. In a mathematics class, the more experienced other can be the teacher and the intended outcome for

1342

the learner is mathematical excellence which includes the ability to talk "within and about mathematics" (Adler, 1998).

Pupils learning mathematics in school, in part, are attempting to acquire communicative competence in mathematical language. Learning to be able to articulate the meaning of certain concepts involves the development of a language that can best describe the concepts involved. This is especially pertinent to mathematics because mathematical talk is known for involving both specialised terms and different meanings attached to everyday words. Mathematical language comprises both informal and formal components. Informal language is the kind that learners use in everyday life to express their mathematical understanding. Formal mathematical language refers to the standard use of terminology (mathematics register) which is usually developed within formal settings like schools. In most mathematics classrooms both forms of language are used and these can be either in written or spoken form. "One difficulty facing all teachers, however, is how to encourage movement in their learners from the predominantly informal spoken language with which they are all pretty fluent, to the formal language that is frequently perceived to be the landmark of mathematical activity" (Pimm, 1991: 21).

Another useful way of categorising discourses in mathematical classrooms is to use Sfard's (1998) distinction between calculational and conceptual discourses. She defines calculational discourse as discussions in which the primary topic of conversation is any type of calculational process, and conceptual discourse as discussions in which reasons for calculating in particular ways also become explicit topics of conversations (Sfard, 1998: 46).

The second area of enquiry relates to the work that has been done concerning teaching and learning in multilingual classrooms. One of the significant findings in this area relates to the benefits that result from using code-switching[2] in teaching and learning mathematics (Setati, 1996; 1998, Adler, 1996). Other studies have shown that use of the learners' first language in teaching and learning provides the support needed while the learners continue to develop proficiency in the second language (Khisty, 1995; Adler, Slonimnsky and Lelliott et al., 1997)

In this paper I look at ways in which the teacher models and uses different mathematical discourses and code-switching and how these enable the development of learners' mathematical linguistic abilities. I will argue that this case suggests a complex correlation between code-switching, using a range of mathematical discourses and pupils' ability to communicate mathematics.

METHODOLOGY AND RESEARCH DESIGN

This is a qualitative study (Cohen & Manion, 1994) that focuses on one carefully selected grade 4 teacher together with her class during their mathematics lessons. The study is both descriptive and exploratory (Bailey, 1978:38). It is descriptive in the sense that it describes in detail the way in which the teacher and learners use languages during the mathematics lessons. The study is also exploratory because it explains how the teacher uses languages to facilitate learners' access to mathematics

Data was collected by means of teacher interviews, lesson observations and learner interviews. The teacher pre-observation interview was done before the lessons were observed and focussed on the

[2]Code-switching is when an individual (more or less deliberately) alternates between two or more languages (Baker, 1994: 77).

preferred language practices of the teacher. Lessons were observed for a week and the last two lessons observed were video recorded. A reflective interview with the teacher after observation of lessons focussed on the critical incidents in the lessons observed and the teacher's understanding and rationale for the language practices used during the lessons. The pupil interview focussed on learners engaging in mathematical talk related to mathematics lessons observed.

To analyse the lesson transcripts and learner interview, four categories were used to understand ways of talking mathematics in this classroom: informal and formal calculational discourse and informal and formal conceptual discourse.

In the section that follows I first give a description of the context in which data was collected and then continue with the analysis.

THE CONTEXT

Ntombi, the teacher, teaches in a primary school (grades 1 - 8), west of Johannesburg in South Africa. She has been teaching for ten years and has a Senior Primary Teaching Diploma plus a three year university degree. Like her learners, she is a first language Tswana[3] speaker. However, in addition to Tswana she can speak three other languages (English, Afrikaans, S. Sotho).Her grade 4 class that was observed had 60 learners in total, 26 girls and 34 boys. They were all multilingual and could speak from two to four languages and this included English which is a second language for all the learners in the school. Compared to other learners in the wider study, these pupils were relatively fluent in English. While their level of fluency could not be compared to a first language speaker, they were able to communicate in English. The main language in the area and the school is Tswana and all the learners are fluent in it. The language of learning in the school is English[4] and its use is encouraged in the school.

A GENERAL DESCRIPTION OF LESSONS OBSERVED

Five consecutive lessons were observed in the same grade 4 class and they all focussed on multiplication. To introduce the first lesson Ntombi started by writing the word "multiplication" on the board and talking with the learners about what it means both in Tswana and in English. She proceeded to give them an example on the board:

14	*This was elaborated procedurally: 6 times 4 is 24,*
x16	*write 4 carry 2. 6 times 1 is 6 plus 2 is 8. 1 times 4*
84	*is 4, 1 times 1 is 1. 4 plus zero is 4, 8 plus 4 is 12,*
+14	*write 2 carry 1 and 1 plus 1 is 2. Therefore the*
224	*answer is 224.*

This was followed by group exercises and then class-work which were both similar to the example. During group work there was a lot of interaction mainly in Tswana between learners. During teaching, Ntombi communicated with learners in both English and Tswana and engaged them in mainly formal calculational discourses. These kinds of discourses were also observed among learners during group work.

---

[3]Tswana is one of the eleven official languages in South Africa.

[4]According to the new language policy in South Africa schools have a right to choose their language of learning

Lesson 2 started with checking and marking of home-work. Volunteers from different groups were called to the board to write their solutions. If the answer on the board was incorrect another volunteer was requested. The teacher identified those who had problems with the home work and did more examples with them, emphasising the procedures to follow, while the rest of the class continued with more multiplication problems. After working with the selected group she gave them an exercise to do as home work. Both the teacher and learners used English and Tswana interchangeably (code-switching) and formal calculational discourse was dominant during this lesson. The lesson ended with the whole class singing a song while they put away their mathematics books.

Similar to lesson 2, lesson 3 started with checking and marking of home work. She then worked with one group ('good group') on multiplication of three digit numbers by two digit numbers while the rest of the class was busy with corrections. Code-switching and formal calculational discourses were also dominant during this lesson.

After checking and marking homework in different groups during lesson 4, the teacher worked with the same group ('good') on a word sum while the rest of the class was very noisy and not involved. The word sum she did with the group was: "In Thusong primary school, there are 10 classes and in each class there are 19 learners. How many learners are there in Thusong?" After doing this example she started a song to get the learners' attention back. At the end of the song she wrote two different exercises on the board· one for the 'good group' and the other for everyone else. For the 'good group': "In KTS there are 15 classes. In every class there are 13 learners. How many learners are there in KTS school?", for the rest of the class: 301 x 15, 408 x 19, 485 x 15. During this lesson discourses became more informal and conceptual and code-switching continued to be a dominant practice.

In lesson 5, after checking and marking the home work, the teacher continued to work with the 'good group' on another word sum example: "In the SPCA[5] are 12 cages. In each cage are 12 dogs. How many dogs are there altogether?" The rest of the class was working on lesson 4's word sum. In handling the word sum with the 'good group', the teacher started by asking learners to read and then focused on the new words like "SPCA", "cage" asking them what they mean. Most of the learners' explanation of these words were in Tswana. This was followed by a discussion on what they were required to find in the word sum and how the solution can be found. After finding the solution she wrote two different exercises on the board for the learners to do as a class test. During this lesson the teacher engaged learners in both formal and informal calculational and conceptual discourses.

DESCRIPTION OF TALK IN AND ACROSS LESSONS[6]

During teaching, Ntombi focused mainly on formal mathematics language. Her classroom mathematical discourse moved across calculational and conceptual discourses. She taught procedures explicitly. Throughout lessons 1, 2, 3 she lead the learners in calculational processes used to solve problems. Her focus seemed to be on getting the learners to master the procedure and not on the reasons for using the procedure or on why the procedure works. Her talk was in terms of procedures where numbers are manipulated as objects that can be 'carried' For instance,

[5]SPCA is an abbreviation which stands for Society for the Prevention of Cruelty to Animals.

[6]Due to limitations of space it was not possible to display transcript extracts in sufficient detail, examples have been selected.

"We carry down 1 and say 9 plus 3 is 12".What is interesting is that the teacher is not the only one who 'owns' this kind of talk. She models the talk and then gives learners an opportunity to practice it. This was evident during lessons and learners' interview where learners used the language of the teacher in most of their discussions. In the extract below the learner is working out the solution for 444 x 19.

> *P: Let us say 9 x 4 is 36.We write 6 and carry 3 then again we say 9 x 4 36 + 3 is 39 we write 9 and carry 3.We say 9 x 4 again is 36 plus 3, 39 and cover the units.We say 1 x 4 is 4. And again 1 x 4 is 4.We say again 1 x 4 is 4 and then we underline and then 6 + 0 is 6. 9 + 4 is 13 carry 1. 9 + 4 is 13 plus 1 is 14 carry 1. 3 − 1 plus 4 is 8.* (Lesson 4)

In the above extract, the learner is imitating the 'teacher's language' of mathematics where numbers are referred to as objects that can be 'covered' and 'carried'.

While it can be argued that this kind of talk can and does occur in many mathematics classes, what actually makes a difference is the fact that in Ntombi's multilingual class this kind of talk is supported by the learners' main language. For instance if the teacher discovered that there was an error in the procedure she handled this in the learners' main language. For instance, in the extract below the teacher had asked one of the learners to work out 59 x 19 and according to the procedure she taught them they firstly needed to write this problem vertically. In trying to write it vertically the learner wrote the multiplication sign incorrectly between the 1 and 9 in 19. The extract shows how the teacher used Tswana to deal with this error in a non-threatening manner.

> *T: Alright, I must put it down, okay. And then we say 1 + 0. 3 -... Go na le phoso fa?[Is there a mistake here?]*
> *P: No.*
> *T: Nix, nix? Lebella sentle. [Really? Look carefully.] (The learner corrects the multiplication sign writes it at the correct place.)* (Lesson 4)

This is not the only way in which the learners' main language plays a role. In fact to move across the discourses Ntombi used the learners' main language. The following episode which occurred during lesson 5 is a typical example of how Ntombi used the learners' main language to engage learners in informal conceptual discourse.

> *T: Eh, can you all read here?*
> *P: In the SPCA are 12 cages, in each cage are 12 dogs. How many dogs are there altogether?*
> *T: Now, first of all, what is this SPCA?*
> *P: When your dog is ill..... (unclear)*
> *T: Yes, sure.*
> *P: Fa ntja ya gago e lwala go na le batho ba tlang ba tla go tsaya ntja ya gago a ba a isa ko spetlele fa ba bona e le botoka ba e busa.[If your dog is ill, there are people who will come and take it to the hospital and they bring it back when it is well.]*
> *T: Ee, spetlele sa dintja akere?Ke ko diphologolo, di pets tsa mo ntlung di nnang teng akere?[Yes, it is a hospital for dogs, right? It is where pets are kept]*
> *P: Ba kile ba tsaya ntja ya ko gae.[They once took my dog.]*
> *T: Ba kile ba tsaya ya kwa lona? [They once took your dog?]*
> *P: Le ya ko gae.[And mine too]*
> *T: Ao! Ba e tlhatlhoba ka eng? La patela? [How do they examine it? Do you pay?]*
> *P: No. Mahala. [Free.]*

T: Ooh, ke mahala? [Oh it is free?] Go raa gore e a thusa ka gore seo se se tona ke gore re tshwanetse go tlhokomela diphologolo tsa rona akere?[This is helpful because the greatest thing is that we should take care of our pets] O tla bolella baba sa itseng, baagisani gore bathong ga ntjanyana ya gago e kare e a tlhotsa o tla e isa ko SPCA [You must tell your neighbours and all those who do not know that if their dogs are ill they can take them to the SPCA] (Lesson 5)

While it may seem as if the discussion that the teacher is having with the learners above is not important in a mathematics class, in this case it is. The problem that is being dealt with here talks about the SPCA and therefore the teacher uses this as an opportunity to educate the learners about the SPCA. The use of the learners' main language here enables active interaction with the teacher, for instance, learners are free to share their stories about the SPCA

T: Right. Jaanong ga re bala fa yare[when we read here it says] in the SPCA are 12 cages. Ke mang a ka re bolellang gore [who can tell us] what is a cage? E kare re bolela ka dilo tse re sa itseng gore di ko kae.[It seems that we are talking about things we do not know].
P: Ke ko ntja e dulang. [where dogs stay].
T: Ooh, a re ko ntja e dulang, gore ga o batla gore e ske ya latlhega o e tswalela mo caginyaneng.[She says that's where dogs stay, if you don't want your dog to get lost].
P: Ee.[Yes]
T: Jaanong di cages tse di di kae?[How many cages are there?]
P: 12.
T: 12?
P: Yes.
T: Ke rata go di kwala ga gore o mongwe o utlwa re re 12 mme ga re di bone akere? O bala le nna gone.[I want to draw them so that we can see them, right? Count with me.] (Draws 12 boxes on chart representing cages. Pupils count together with her)
T: Go raa gore re ko SPCA jaanong akere? [We are now at the SPCA]
P: Yes. (Lesson 5)

In the above extract the teacher is dealing with the word cage, which could be new to most second language learners. It is important to note that while the teacher engages learners in an informal talk about the new words in the problem, these words are explained in the learners' main language and not in English. The learners talk about what a cage is in Tswana. The teacher continued in the same manner to get the learners to interpret each of the sentences in the word sum.

In interpreting the sentence "In each cage are 12 dogs' the teacher made drawings of the cages and dogs inside and then moved on to what the question requires them to do.

T: Ee ke raa gore tla re baleng potso e.[Let's read the question.]
Ps: How many dogs are there altogether?
T: Go raa goreng? [What does it mean?] Ke batla go tlhaloganya seo pele.[I want to understand that first] Morero ke eo potso e re botsa gore dintja tso tsotlhe tse di mo dicaging di di kae. [Morero, there's a question, it says, how many dogs are there altogether in the cages.]Dintja tso tsotlhe di di kae?[How many dogs are there altogether?]Jaanong ke batla go itse gore karabo re a go e bona jang.[I would like to know how are we going to find the answer.]
P: We are going to write tens, hundreds, thousands and units. (Puts chart on the

board.) ... and we must underline, when we are through we say 12 times 12, we underline again when we are through we put the button here and we say 2 x 2... (Learner goes on with the procedure in English until he gets the answer)
P: The answer is 144.
T: Go raa gore re na le dintja tse kae?[It means how many dogs do we have?]
P: 144. (Lesson 5)

It is interesting that in the above extract the teacher rephrases the question for the learners, a practice that she has not been doing since the beginning of the problem. On the other hand to deal with the teacher's question: "how are we going to find the answer" the learners move out of the informal talk, that they have been interacting with the teacher in, into the formal calculational discourse which they have learned.

What the above extracts show is that these learners are aware of the dominant culture of mathematics classrooms in which formal written mathematical language is valued and therefore when required to give an answer they draw on their knowledge of formal procedures. Another interesting factor is the fact that the formal calculational discourse happens in English and this is perhaps due to the fact that this discourse is acquired in English.

In the next extract the teacher tries to engage them more in conceptual discourse.

T: 144. Mara jaanong go tlile jang gore re tshwanetse gore re di timese ko gonne nna nka nne ka nagana gore mare why re sa re 12 plus 12?[But now, how did you know that you are supposed to multiply, why are we not saying 12 plus 12?]
Kenosi: Because re batla di answer tsa rona di be right. [Because we want our answers to be correct]
T: Oh, Kenosi o arabile are o batla go bona a tshwara dipalo tsa gage right ke moo a reng 12 x 12. [Kenosi has responded, he wants his answers to be correct.]
O mongwe a ka reng? [What do the others say?]A ka re tlhalosetsa jang?[How else can you explain this?](A few pupils raise their hands and she point at one.)
T: O batla go leka?[Do you want to try?]Emella re uthwe, Ntsiki?[Stand up and try, Ntsiki]
Ntsiki: Bare ko SPCA go na le di 12 cages ene gape go na le dintja tse 12 bjanong ge re di bala dintja tse di di kae?[They say at the SPCA there are 12 cages and 12 dogs in each cage, so when you count the dogs in each cage what will you get?] (Lesson 5)

It is interesting that when the teacher asks them why they multiplied, the first reason she gets is that they want their answers to be correct. This is also very typical of most mathematics classrooms where it is important to know what the correct answer is and not why the answer is correct. On asking for alternative answers, Ntsiki used the teacher's drawing to explain how she would get the answer. Her response is also in Tswana.

It seems that in engaging learners mainly in formal calculational discourse the teacher communicated to learners what is valuable mathematics language. It is therefore not surprising that when the learners were engaged in conceptual discourse they quickly shifted back to the formal procedural discourse. Nevertheless, Ntombi's learners were exposed to and engaged in all four kinds of discourses. During the learners' interview learners could draw on all kinds of discourses. Mathematically, Ntombi's learners were able to engage in both calculational and conceptual discourses. They could carry out their procedures with ease and whenever they were required to

give reasons for some of the steps in their procedures they managed well. It is feasible to argue here that Ntombi's ways of talking enabled learners both mathematically and linguistically.

DISCUSSION

My analysis suggests an important correlation between code-switching, the kinds of mathematical discourses used and whether these enable or constrain learner access to communicating mathematics. As the analysis above shows, Ntombi uses a range of discourses in her teaching and these were reflected in the learners' communication of mathematics. What is very important to note, however, is that the movement between one discourse to another was facilitated by the use of the learners main language (Tswana). This is particularly important because while Ntombi's learners' are relatively fluent in English, it is not their first language and as the data shows some of the learners could not engage in calculational and conceptual discourses without using their main language, Tswana. It is therefore possible that if Ntombi did not allow them to use Tswana, the discourses could have remained formal and procedural. Obviously one cannot claim that use of code-switching enabled learners' communication of mathematics, however, the correlation between code-switching, mathematical discourses and whether and how they enable learners to communicate mathematics is a fruitful area to explore further.

STUDENTS' USE OF DIAGRAMS IN STATISTICS

Pamela F. Shaw and Lynne Outhred,

Macquarie University, Australia

This paper summarises the preliminary findings of a study into why students in an introductory statistics course do or do not use diagrams in questions which could be done with or without the use of a diagram. It was found that students were reluctant to use diagrams but those who used diagrams were more successful. Very little relation was found between use of diagrams and previous maths studied.

INTRODUCTION

In mathematical problem solving two factors have been found to be important - a verbal or logical component and a visual component (Krutetski, 1976). The logical component includes translation of words into algebraic symbols while the visual component comprises diagrams, pictures and graphs. Moreover, students have been found to emphasise these components differently when solving problems. Presmeg (1986) used the term "visualisers" for students who prefer to use visual approaches for solving a problem which may be solved by either a visual or non-visual method.

In statistics it is important that students can utilise both visual and non-visual methods; visual (e.g., graphical methods) are necessary for an initial inspection of the data to determine distribution characteristics, such as normality, dispersion, and outliers, while non-visual methods are predominantly employed in hypothesis testing and calculating confidence intervals. However, students may be reluctant to use visual methods, such as graphing or drawing a diagram, because of an emphasis on algebraic methods in mathematics teaching. For example, Vinner(1989) found that tertiary students tended to prefer an algebraic proof rather than a diagrammatic proof, even when the latter, as stated by students was easier to follow. He felt that this preference was affected by the method of teaching where students gained the impression that symbolic solutions were more prestigious than diagrammatic solutions.

Visual representations may be included as part of a problem information or students may produce their own representations as part of the solution process. In research on primary and secondary students' interpretations of graphs that accompanied statistical problems, Curcio (1987, 1996) identified three levels of graph comprehension:

- literal reading from the graph;
- comparisons using the graph - reading between the data;
- reading beyond the data.

If students are at the literal and comparative levels in their knowledge of graphs, they may have difficulty solving statistical problems when they are only given the raw data. Reading and Pegg (1998) analysed the responses of Australian students in Years 7 to 12 to two data reduction questions, one of which presented the raw data

and the other a graphical representation. They found that students responded at a higher level when the data was presented in raw form rather than in graphical form. However, Roth and McGinn (1997) have questioned whether graphical ability is related to cognitive ability rather than to practice in using graphical methods in practical and social situations.

Students who represent problem information visually when they solve mathematical problems may be more likely to make a visual representation of statistical data (e.g., a stem and leaf plot or a graph). Shaw (1998) investigated whether the use of statistical displays was associated with the use of diagrams in non-mathematical and mathematical problems. The results of the study indicated a relationship between the use of statistical displays and the use of diagrams in mathematical, but not non-mathematical situations. Moreover, students who spontaneously drew diagrams for the statistical problems were more likely to gain higher marks in the final examination than students who did not.

In this paper we report some preliminary findings concerning the spontaneous use of diagrams by tertiary students as they solve statistical problems. The aims of the study were to:

- investigate the relationship between ability and the use of visual solution methods;
- determine if students who drew diagrams were more successful than those who did not.

METHODOLOGY

Students in introductory statistics courses at two Australian universities were given an assessment task comprising a number of statistical problems and one mathematical problem whose solutions would be facilitated by the use of an appropriate diagram. At both universities the course was a large (>500) service course for first year students. Both courses covered displaying and summarising data, distributions and sampling distributions, hypothesis testing of means for one and two samples, regression and categorical data. The problems required responses at Curcio's third level - extrapolation from and interpretation of the data. There were four versions of the task, the versions differing only in the order in which the problems were given. Students were asked to provide their University entrance score as an indicator of ability.

In addition, nine students from one of the universities were subsequently interviewed at the end of their course and the interviews audio-taped. These students completed the same problems but were asked to verbalise their solution. At the end of the interview they were asked about their use of diagrams.

The 88 students reported here were given the assessment task in a lecture midway through the course when they had studied hypothesis testing with one and two samples but had not yet received any instruction on regression.

Each student's response was given a diagram score of 0, 1 or 2 (0 = no diagram, 1 = partial diagram and 2 = correct diagram) and a score for the solution from 0 to 3

where 3 = correct solution. In addition, The students were asked to give the level of mathematics they had studied at secondary school and this was coded from 0 to 3 where 0 = no mathematics at Year 12 and 3 = 3 unit mathematics. (Students with the highest level of mathematics (4-unit) enrol in a different statistics unit.)

The assessment task

The four questions used in the assessment task are given below. The fourth question was a modification of a question used by Campbell et al (1995).

Problem 1 **Area under the normal curve**: The age of academic staff at Newport University are normally distributed with a mean of 38 years and a standard deviation of 5 years. What proportion of staff would be expected to be aged between 45 and 50 years?

Problem 2 **Linear relationship between two variables**: It has been claimed that as academic staff get older their tolerance of students decreases. A test of staff tolerance of students has been developed. Ages of a random sample of six staff at Newport University and their tolerance scores are listed below. Are the data likely to support this claim?

Name	Grey beard	Long legs	Mac	Boffin	Blondie	Shortie
Age	52	39	33	25	22	45
Tolerance	28	35	35	50	39	23

Problem 3 **Distribution of a single variable**: The employment history of a random sample of 30 academic staff at Newport University was obtained. Listed below are the number of years that they have worked at Newport University. As a person with statistical knowledge you have been asked to comment on this data.

1	7	5	2	5	6	4	5	5	6	2	2	2	6	6
3	5	6	9	5	5	1	3	4	7	5	2	2	7	6

Problem 4 **Linear algebra**: The blood alcohol readings of two lecturers from Newport University were recorded the morning after an accident. The readings were:

Alison	6 hours after accident: 5 units 8 hours after accident: 2 units	Brett	5 hours after accident: 7.5 units 9 hours after accident: 5.5 units

Assuming a linear relationship, when were their readings the same?

RESULTS

It is clear from Table 1 that for each problem (with the exception of Problem 1) the largest group of students are those who do not draw a diagram and who cannot solve the problem. Problem 1 would have been the most familiar to the students and in lectures and tutorials students would been told to draw diagrams for problems of this type. For Problems 1 and 3 those students who drew a diagram were far more likely to obtain a successful solution than those who did not. However, for Problems 2 and 4 successful students were approximately equally divided between those who drew

and those who did not, but very few students who drew a correct diagram could not solve the problem.

Problem 2 was given to these students before they had been given any instruction in regression and their responses reflect ideas developed at secondary school. The majority of the students (81%) did not draw a diagram and less than a quarter of these students obtained the correct answer whereas of the 19% of students who drew a diagram, most were successful.

Table 1 Students categorised by diagram usage and solution (%) for each problem (n=88)

	No solution or an inadequate solution (Score = 0 or 1)	Reasonable or correct solution (Score = 2 or 3)
Problem 1 Areas under the normal curve		
No diagram*	34	19
Correct diagram	13	34
Problem 2	***Linear relationship between two variables***	
No diagram*	63	18
Correct diagram	3	16
Problem 3	***Distribution of a single variable***	
No diagram*	60	6
Correct diagram	16	18
Problem 4	***Linear algebra***	
No diagram*	52	19
Correct diagram	8	21

* A partial diagram was included in the "No diagram" category.

In Problem 3 most students simply calculated measures of centre and spread without checking the form of the distribution. In fact, the data was bimodal with peaks at 2 and between 5 and 6.

Problem 4 was a mathematical question, rather than a statistical one. It could be answered graphically, algebraically or using ratios. Slightly less than half (45%) of the students satisfactorily answered this problem. Again there was a relationship between the use of a diagram and successful completion of the question.

Since students are in general more successful when they draw a diagram why do more students not apply this strategy to solve problems? Below we report on the information gained from the nine interviews as to why students draw diagrams. Four

of the students drew diagrams for three or four problems, the other five drew diagrams for at most two of the problems.

Why students drew diagrams

When students talked about why they drew diagrams their comments seemed to fall into two categories: those that appeared to be motivated by a conceptual approach to problem solution and those who appeared to be following procedures.

i. Conceptual basis

- Some students find that visualisation helps their concept formation. They think in pictures and get a general idea. Student 5 even considers statistical formulae as a form of picture.

I *Now, you've drawn a lot of diagrams. Why did you do that?*

S5 *Well, I think in pictures. I've always found it easier to do things like maths and science than English, because I have a lot of trouble with words, I often don't understand them, or I've felt I've understood what's been said, but I haven't. Whereas pictures, it's pretty easy to get the general idea, um, yeah, I've always found it easy with pictures. ... I just find it easy to work with pictures, but words, they just go straight out of my head. Like I say, I've always done badly in English and things like that because I don't do very well with words.*

I *So you prefer pictures to formulae, for instance.*

S5 *Much, yeah, but even formulae, they're like little tiny pictures,*

I *Right*

S5 *Um you know, like I can remember that the μ is the same as the biggest bit on the picture of the normal distribution, like I remember it as a picture, so that's how I, I just guess percentages by how much do you reckon that is compared to the rest of it. That sort of thing, that's why I'm not very good at remembering formulas and stuff, because they are sort of words, but I prefer them to the actual words, that's why the first thing I do is write down the μ and σ because they are better than reading them back in the paragraph we're been given.*

Another student uses diagrams as a way of reducing the information processing load during problem solving:

S7 *Why did I do that? So I can see what I am doing. Because in my head I can't have too many things at once, so I have to do everything on paper.*

ii. Procedural basis

- Some students drew diagrams because they had been told to do so in class. This was particularly evident in the question on areas under the normal curve. However, Student 6 had not noticed this emphasis until she came to revise for the examination and she was concerned because she did not feel confident in her ability to draw diagrams.

I *Well, in most of the examples that you've done, well you have drawn a lot of diagrams, why did you do that?*

S6 *Oh, they say to in class, basically, and like I just noticed going through some revisio:., it's often called for.*

I *What, drawing a diagram, in the revision?*

S6 *Um, yeah, they seem to refer to ... like with these it seems to make sense anyway, and with this stem and leaf plot, ... but like I didn't notice it throughout the year, throughout the semester, that we were being asked to do it much, except for here.*

I *Right*

S6 *And then I was going through the revision all the time, and I noticed that "oh, yeah, graph this " and I thought "Oh God" because my visual spatial is like really poor.*

Why students did not draw diagrams

i. Conceptual basis

Students gave several reasons for not drawing diagrams: they were not sure what to draw; they did not feel that they needed a diagram; diagrams had not been emphasised in teaching; or a previous diagram had not helped obtain a solution.

For the single variable question, Student 4 said that he had not drawn a diagram because "*I was only asked to comment on the data ... on a bunch of numbers*". However, when prompted on Problem 4 he had a sudden insight and went on to correctly solve the problem.

I *So you could see no relevance in drawing a diagram?*

S4 *No, what's the use of it. On question 4 th[illegible] wasn't enough information to draw any linear relationship because like with Brett, I could of ... actually, actually ... I might be able to get something out of this ... you do, okay, blood alcohol units on the y axis, ...*

ii. Procedural basis

I *So why don't you draw diagrams?*

S8 *I do when I'm asked to do it for statistics.*

There were a number of concerns that the students raised that indicated they did not realise the value of diagrams in helping them solve the problems. For example, that diagrams were too time consuming to draw or that graph paper was not provided "*I guess if I had actual graph paper, I would have plotted those two points, draw a line and worked it out that way, put those lines on graph paper, but my freehand drawing isn't that good*". The other reason given was the emphasis on using formulae in the computer assessed tasks in the course.

Problems in drawing diagrams

Very few of the interviewees had any difficulty with Problem 1 (area under the normal curve). This was probably because the interview took place at the end of the term when students were studying for their final examination.

Although diagrams can be helpful, if students draw an incorrect diagram or cannot interpret the diagram they have drawn, then diagrams may be counter-productive. The main problems with diagrams that were apparent from the interviews were:

- Despite drawing a stem and leaf plot for Problem 3 some students identified the distribution as normal rather than bimodal;
- In the linear algebra problem (Problem 4) several students felt that they could not extrapolate beyond the range of the given data

S6: Um, when were their readings the same? Well if their readings were the same, I would imagine they would have crossed over at some point.

I Okay. It seems a reasonable idea.

S6: So I'm just thinking I've chosen the wrong way to do it, or I've or whether I've plotted it incorrectly

Relationship between visual solution methods and mathematical level

The mean diagram score for each level of mathematics studied is given in Table 2.

Table 2 Mean diagram score for each level of secondary school mathematics.

Mathematics level	N	Mean diagram score	Standard deviation
0	7	2.1	2.3
1	6	3.8	2.2
2	32	3.3	2.2
3	31	3.1	2.3

The results shown in Table 2 do not indicate that students with higher mathematics levels were more likely to draw diagrams. The students with no mathematics in Years 11 and 12 were less likely to draw diagrams than those who had studied some mathematics. However, students who had studied 2-unit or 3-unit mathematics had slightly lower scores than those who had studied the most basic mathematics. These results have to be treated with caution because of the small number of students whose results have been analysed at this stage. Nevertheless, the results shown in Table 2 may indicate that students who have studied more algebra may attempt algebraic solutions rather than graphical ones.

CONCLUSIONS

The preliminary results from this study show that for these four problems the majority of students did not draw diagrams, despite being encouraged to draw diagrams throughout the course. The problem for which drawing was most common

involved finding an area under the normal curve, a standard problem for which students had been taught in their course to draw a diagram as an integral step in the solution process. Despite this, only 47% of the group drew diagrams and for the other three questions less than a third of the students drew a visual solution. For all four problems it is clear that the students who draw a diagram as part of the solution process are far more successful than students who do not.

Why then do students not see that diagrams are a useful problem solving strategy? The main reason that came out of the interviews was that students were not sure that a diagram was worth the effort it took to draw it, rather than not knowing what to draw. Although when questioned, one student did not seem sure which diagram to draw, she went on to suggest drawing a histogram and the underlying reason seemed a lack of confidence in her drawing ability. Students seemed to want to calculate statistics, such as means and standard deviations without first obtaining a feel for the data. No student suggested a diagram might be an easier method of solving some types of problems.

We thought that students who had studied more mathematics at secondary school would be more likely to draw a diagram as these students were more successful on the assessment task. However, the preliminary analysis of the data did not seem to support this hypothesis. The results for the full sample may clarify this issue further.

Since students who draw diagrams are more successful than those who do not, a greater emphasis needs to be given to integrating the use of diagrams in the teaching of introductory statistics. Students were more likely to draw a diagram when they are clearly incorporated in the teaching. This result suggests that the construction and use of diagrams needs to be specifically integrated into course materials and assessment.

CONCEPTUAL UNDERSTANDING OF CONVENTIONAL SIGNS: A STUDY WITHOUT MANIPULATIVES

Corina Silveira

The University of Southampton, United Kingdom

This paper focuses on the beginnings of the learning of the system of natural numbers seen as a sign system and as an object of social use. It presents data of one case study conducted as part of an on-going longitudinal teaching experiment. The broader investigation studies a group of 5-year-old children in a primary school in the South of England. The appropriation of the conventional system of numbers is seen as a gradual approximation mediated by the use of spoken and written numbers in a diversity of situations. An established model of children's conceptual organisation of the number sequence is used to analyse children's thinking. Work with the conventional system of spoken and written numbers without restriction of the series is reported and preliminary reflections on how children appropriate these systems are outlined.

Introduction

Understanding the system of natural numbers entails understanding of two cultural systems of external or physical signs: the system of number words and the system of written numbers[1]. Although there is a vast body of research focusing on the learning of the former (e.g. Steffe et al., 1983; Steffe and Cobb, 1988; Steffe, 1992; Fuson et al, 1982; Fuson 1988), much less is known about how young children appropriate the system of number scripts and further, how the use of the system might mediate this appropriation in the beginnings of cognitive development. Recently, it has been acknowledged that there is a paucity of investigations into how children acquire knowledge of written numbers (Wright, 1998) despite some exceptions (e.g. Lerner and Sadovsky, 1995; Sinclair and Scheuer 1993; Sinclair and Sinclair 1984). Related to the learning of written numeration is, of course, the understanding of place value. Investigations have shown that despite considerable pedagogical effort, English speaking children show "inadequate understanding" (see Fuson, 1990 for a review). Extensive research in this area seems not to focus on the fact that both written and spoken numeration are complex systems of signs available to young children's inspection and use without the graduations normally imposed by schools.

Theoretical framework and research literature

The study holds the view that children construct their own mathematical knowledge and there is no other way to access this knowledge except by building models of it (Steffe, 1991; Steffe and Cobb, 1983). With Cobb et al. (1992) we concur that this

[1] These two systems will be to often termed written and spoken numeration to highlight the relational nature of the ideas they embed.

construction takes place irrespective of the pedagogy used. However, the quality of this construction seems to be very much dependent on the situations an individual is called to participate in with more competent peers. Hence, these researchers establish the dual nature of mathematics learning, both an individual cognitive activity and a communal, social practice. These two aspects of mathematics learning seem to be intricately linked when young children are initiated in the learning of the first system of signs they might associate with "mathematics": number words and written numbers. On the one hand, this learning can be seen as a process of conceptual reorganisation (Steffe et al. 1983, Steffe and Cobb, 1988). On the other hand, following a Vygotskyan tradition, it can be seen as a process of appropriation of cultural inheritance. In this sense, the conventional system of natural numbers and its particular spoken and written signifying forms, are seen as "cultural tools" which serve as "mediators that relate the developing child to his or her cultural inheritance" (Cobb, 1995, p. 364). For example, children's construction of more abstract arithmetic units (Steffe et al, 1983) can be seen as taking place as they engage "in culturally organised practices in which cultural tools play a role" (Cobb, ibid.) "with the guidance of more skilled partners" (Vygotsky, cited in Cobb, ibid.).

The idea that cultural tools mediate cognitive development is held by cross-cultural investigations which argue that differences in the word number sequence of different languages promote differences in conceptualisation of the numeration system (see for example Miura et al., 1988; Fuson and Kwon, 1992; Bell, 1990).

It is in this sense that written and spoken numbers mediate children's conceptual organisation, in so far as these marks and spoken words *play a role* in situations which recreate cultural practices. We have developed the idea that children might be restricted from using and talking about number words and written numbers because curriculum designs present "in doses" the work on the series of spoken and written numbers[2]. For example, by working with spoken and written numbers up to 10, successively up to 100 and then extending the work beyond 1000 in the consecutive years of school[3]. This progression is a pedagogical choice fully endorsed by educational practitioners.

When the work with written numbers is extended beyond 10, instructional devices or manipulatives (e.g. Dienes blocks, Multilink) are usually employed in order to "bridge" the learning of numeration. Research has also put the rationale of the use of these devices under criticism (see for example Perry et al., 1994; Thompson, 1992 for reviews; also Baroody, 1989; Kammii, 1985; Holt 1982 for a critical view). For example, Perry et al. have argued that the "notion of manipulatives in mathematics education has focused on the use of concrete materials to 'produce' the ideas assuming that the learners themselves do not bring with them the ideas that can be

[2] This assertion is based on national curriculum designs both in the United Kingdom and Argentina

[3] For example, in the UK numbers from 1to 10 are presented in Reception Year, up to 20 in Year 1

manipulated" (Perry et al., ibid., p. 488). Baroody has stated that "it does not follow from Piagetian theory that children must actively manipulate something *concrete* and reflect on *physical* actions to construct meaning. It does suggest that they should actively manipulate *something familiar* and reflect on these physical *or mental* actions" (Baroody, ibid., p. 5, italics in the original). The use of concrete materials has been said to hold a representational view of the mind with the assumption that students "will inevitably construct the correct internal representation from the materials presented" (Cobb et al., 1992, p. 5) because the concept to be learned is inherent or materialised in the physical device. Contrary to this view Cobb et al. (ibid.) have termed these instructional materials as "pedagogical symbol systems" to emphasise their "symbolising role in individual and collective mathematical activity". Meira (1998) has argued that the "transparency view" should be replaced by the idea that transparency is not a property of the physical embodiments rather it is "created" (Meira, ibid.) or "experienced" (Cobb, ibid.) through specific forms of using the device in socio-cultural practices. He suggests that physical embodiments should be conceived as "conversational pieces" or the motive for engagement in conversation and argumentation. Even in the beginnings of learning, the "conversational pieces" can be the very object of learning: the written and spoken system of numbers. That is, instead of working with artificial "pedagogical symbol systems", children can use, frequent, talk, and reflect upon the written and spoken systems in all their complexity. In this sense, three main assumptions underlie the research reported here: 1. Children elaborate early ideas on written and spoken numerical signs (Lerner and Sadovsky, 1995; Sinclair and Scheuer 1993; Sinclair and Sinclair 1984), 2. If the standard series of spoken and written numbers is not presented in chunks, children can have opportunities to appropriate and master the system of numeration; and 3. Children use external representations and conventional signs to express their thinking (Cobb et al., 1992) and physical properties of symbols can be resources of reasoning (Greeno, 1991). These three assumptions have been the working hypotheses of the research

Background orientation and methodology

The aim of the research is to develop a model of children's appropriation of written and spoken numeration which is compatible with an established model of children's construction of units (Steffe et al., 1983; Steffe and Cobb, 1988). A longitudinal constructivist teaching experiment (Steffe, 1991; Steffe and Cobb, 1983) with selected case studies has been undertaken. Data presented in this paper corresponds to one of the on-going case studies which have been conducted with 6 children of an English Reception class (age 5). A fieldwork diary has been produced to record relevant information (for example what activities in relation to numeration children have been presented with). All 6 children were interviewed outside the classroom on a one-to-one basis and in pairs during the Summer Term -March/July 1998-. Task

based interviews were of two types: 1. Counting type assessment to ascertain children's stage of learning according to the model of construction of units set forth by Steffe and his colleagues (Steffe et al., ibid.). Tasks presented in these interviews resemble those used by these researchers and children were interviewed on a one-to one basis. 2. Semi-structured exploratory interviews to ascertain ways of knowing or appropriating written and spoken numbers. These latter interviews typically present a scenario as an "excuse" to talk about and write numbers, and reflect upon the numbers produced. These interviews were with pairs of children who were thought to be in the same stage of construction of arithmetic units. Interviews varied according to children's responses and engagement but always had the aim of prompting discussion on the written or spoken numbers. Of paramount importance is how these discussions may allow two kinds of inferences. First, if children "notice" any regularities in either or both spoken or written numbers and secondly, if children have started to reason about these regularities. Data presented below mainly stem from the latter type of interview. A brief description of the interview from which they have been extracted follows.

Cinemas scenario: A picture of a cinema auditorium was prepared on a piece of cardboard with 9 sections for the audience (64 cm x 45 cm). The sections were divided with black strips of cardboard. The screen was represented with a piece of black cardboard and it had a small picture of the film "101 Dalmatians". Children were told that this was a big cinema and that the owner wanted to know how many people could come and see the film. All children were asked to figure out how many people there would be in the cinema if there were 100 people in each of the sections and they were asked to write these numbers for the owner of the cinema (e.g. 100, 300, 900).

Findings and reflections: the case of Eamon

The episodes presented here belong to one case study. We present this case because we think it shows one form of appropriation of the conventional number signs which is discussed in the next section. It should be noted that Eamon is a counter of the initial number sequence stage[4]. Eamon gives every indication that he is remarkably interested in numerical signs. He told us he knows how to write infinity, *"the biggest number of all: an 8 turned sideways"*. He also volunteered some of his ideas on the written and spoken system of numbers when he said that *"the more zeros it is, the bigger the number"* and that a million is *"a one and six zeros"* . After counting in tens beyond 100, he said *"I know I can make it bigger with tens"*. In the following episode Eamon and Sam, are presented with the cinema scenario.[5]

[4] This means that his construction of the number sequence has undergone a significant change: a particular number word stands for the possible counting activity and refers to the individual number words of the segment from 1 up to that particular number word.

[5] In the transcripts "S" is Sam, "E" is Eamon and "C" is the interviewer

C: "A hundred people can sit in this section and a hundred people *more* here, and a hundred people *more* here (pointing at the 3 middle sections). So how many people in total?" [E and S seem to be eager to answer, S stands up and sits down again]
S: "A hundred and thirty"
E: (looks at C) "Three hundred"
C: "Oh! Three hundred or a hundred and thirty? You have to decide now"
S: "It's a hundred and thirty" [E looks at C]
C: "What do you think Eamon?"
E: "Three hundred"

Eamon seems to use the hundred words as if they were entities to count. This is more clear in the following episode, where the children have agreed that only one hundred people are now in the cinema.

C: "What if only fifty people come back? Only fifty people, not a hundred, fifty people come back"
S: "It would be fifty hundred."
C: "Fifty hundred, do you think?"
S: "Yeah!"
E: (gestures as if he doesn't agree) "Fifty hundred?"
C: "Fifty hundred? What do you think Eamon...a hundred plus fifty..."
E: [about S's response] "That would it be more far than about thousands"
C: "So what if fifty more people come, how many would there be in total?"
E: "A hundred and fifty"

Eamon seems to suspect that *fifty hundred* means a lot more than a hundred plus fifty. This suggests that he is taking a *hundred* as a "thing" he can repeat. An entity that seems to mean one hundred individuals. After Sam is "convinced" that it is a hundred and fifty people, the following conversation takes place.

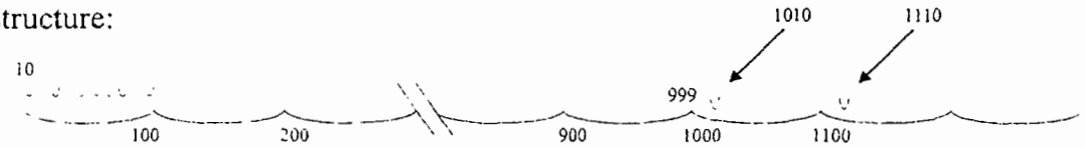
C: "That's good, and what if twenty more people come?"
E: "A hundred and twenty"
S: "Yeah"
C: "And what if...eighty more people come?"
S and E: "A hundred and eighty!"
C: "And what if eighty eight people come?"
E and S: "A hundred and eighty eight!"
C: "Very good! And what if a hundred more people come"
E: "Ugh...that must be...two hundred"

Eamon's particular use of number words transpires in another segment of the conversation.

C: "Now this is going to be a tough one for you. What if one million people come and see the film and tomorrow one million more come...how many all together?"

S: "..one..."
E and S: "Two million"
C: "How did you work that out so quickly?"
E: (smiling) "Because..."
S: (smiling) "We just know"
E: (subvocally) "We just know..."
C: "What if one million more come?"
E: "One million more is...three million"
C: "Three million?"
S: "Yeah..."
C: "And what if a thousand more come?"
E: "One thousand more...er...(shakes the pen in his hand), well...It's three million one thousand"

The above excerpt is not an isolated one. Unfortunately, Sam's contribution to the dialogue prevents Eamon to keep trying to justify his answer. Nevertheless, other segments of the discussion indicate Eamon's awareness of the organisation of the system of spoken numbers. The following episode occurs after the children have written 5000 and 9000.



C: "Which one is bigger...five thousand here or five hundred here?"
S and E: "Five thousand!"
C: "How do you know that?"
S: "Because it comes after a hundred!"
E: "Because first is one hundred, and then nine hundred and *then* one thousand, and then one thousand, and then two thousand, and then three thousand, and then four thousand, and then five thousand"
C: "Right...Oh, I see. And which one is bigger...three hundred...or two thousand?
E and S: "Two thousand!"
C: "How do you know?" [...]
E: "Because the same, three hundred and then...the last hundred is nine hundred and ninety nine...and then it's..."
S: "...a hundred..."
E: "...[it's] one thousand"

Eamon's explicit explanations on the organisation of the number words are present in other segments of the transcripts. In the transcript that follows, Eamon volunteers to count in tens *"up to two thousand and something"*. He counts in tens conventionally with no hesitation and he is interrupted at 500. Unfortunately for his companion, he wants to continue so it is proposed that he count from eight hundred.
E: "...800, 810, 820, 830, 840, 850, 860, 870, 880, eight hundred and ninety, one thousand, one thousand and ten, 1020 (clearly and conventionally), 1030, 1040,

1050, 1060, 1070, 1080, 1090,...(breaths in), t...one thousand one hundred, (looks at C), one thousand one hundred and ten, one thousand one..."
Eamon seems so eager to show what he *knows* that he misses out a whole interval (900-1000). This performance, it is believed, can no longer be thought of as a purely linguistic skill, that is, as another sequence in ones.

Discussion

Eamon has a remarkable command of the syntax of the conventional number words. He uses a multiplicative or an additive syntax in accordance with the appropriate semantics. For example, "two hundred and ten" for 200 plus 10 and "three million" for 2 million plus 1 million. His inferred organisation of the spoken sequence in tens suggests that he has reflected on these spoken signs and that "ten" has become intuitively important. Eamon's explanations seem to reflect the following piece of structure:

Based on the preliminary findings, we hypothesise that Eamon is forming a complex field of reference for signs such as ten and hundred. For example, he seems to understand that counting in tens *creates* bigger numbers *faster* and he knows somehow (implicitly or explicitly) that he has to count ten times an interval of a hundred to reach a thousand. This latter observation indicates that Eamon has developed an informal or tacit understanding of the role of ten in the organisation of our system of numeration. This, together with Eamon's intuitive understanding of the syntax of spoken numeration seems to suggest that his form of appropriation of the system entails a "relational understanding" (in the sense of Skemp, 1986) and because of this a "symbolic form of reference" (in the sense of Deacon, 1997).[6] This form of appropriation seems to contrast with others which are more "indicative" in nature (in the sense of Deacon).

This paper has attempted to focus on the intriguing role conventional signs play in the conceptual understanding of numeration. What seems to be evident is that Eamon is taking these conventional signs as material to think and to converse about. Because he is able to engage in discussion about written and spoken numbers, problematic situations can be posed upon these signs without the need to employ artificial devices. As Lerner and Sadovsky (1995) have pointed out: why do we have to create a new device in order to teach the real one? Further steps in the investigation will intend to take Eamon towards reasoning about these patterns or regularities of the physical signs.

[6] Deacon's argument is beyond the scope of this paper. However, this quote should clarify the point: "The symbolic use of tokens [physical signs] is constrained both by each token's use and by the use of other tokens with respect to which it is defined" (p. 100)

ON FORMULATING THE TEACHER'S ROLE IN PROMOTING MATHEMATICS LEARNING

Martin A. Simon, Ron Tzur, Karen Heinz, Margaret Schwan Smith, and Margaret Kinzel, Penn State University

Abstract. *This work represents our efforts to articulate and explicate a conceptual framework for mathematics teaching in which we specify mechanisms of student learning and the role of teachers in promoting that learning. We discuss two mechanisms of learning and how they provide possible sites for teaching, the learner's experience of disequilibrium and reflection on activity-result relationships. Conceptualizing learning in terms of reflection on activity-result relationships is considered as a way of addressing the learning paradox.*

In this paper, we report theoretical work in progress. We choose to present this work at the PME Conference to promote discourse on the ideas presented. Further development of the ideas will be greatly enhanced through discourse among researchers with different cultural, theoretical, and experiential backgrounds.

The focus of this paper is development of a conceptual framework regarding mathematics teaching that builds on significant work on the learning of mathematics. We approach the need for conceptualizing mathematics teaching not only from our role as mathematics educators (teachers), but also from our role as mathematics teacher educators and researchers of mathematics teacher development. It is only through clearly articulating conceptions of mathematics teaching, that the goals of mathematics teacher development can be defined and the approaches to and results of mathematics teacher education analyzed and evaluated.

The ideas that we present are not a description of a "new" form of teaching. Rather, they are our attempt to make explicit (articulate) some principles of mathematics teaching by importing, synthesizing, and further elaborating ideas that exist in the literature. Although examples of teaching which embody these principles can be observed with increasing frequency, it is our experience, particularly in conversations among US mathematics educators, that these principles are often not accessible subjects of discourse.

The fundamental commitment that mathematics educators seem to share is to promote students' development of powerful mathematical ideas and ways of thinking (and participating in mathematical activities). Teaching is evaluated by its effectiveness in doing so. Currently, in a number of countries, mathematics educators are promoting and participating in alternatives to direct instruction (c.f., Brousseau, 1997; NCTM, 1991; Streefland, 1991). Teaching that is predominantly teacher telling and showing has been challenged because of the perceived ineffectiveness of its results. This need for alternative approaches to teaching in conjunction with recent research and theory development on mathematics knowing and learning have tilled the soil for the development of new conceptual frameworks with respect to mathematics teaching.

Getting off the Continuum: Articulating the Problem

Many teachers in the United States are engaging in teaching practices that seem to fall on a continuum bounded on one end by telling students the mathematics that they are to learn and at the other end asking students for the mathematics that they are to learn. Participating in the current reform effort has tended to encourage teachers to move away from telling, and they have gravitated towards asking the students for the mathematics. In some situations, asking students for the mathematics that they are to learn seems to work. It works when the students have the understandings necessary to take the next step on their own in response to the teacher's question. However, there is often a problem with asking students for mathematics that they have not yet conceptualized. At times, the problematic nature of this teaching strategy is masked by the presence in the classroom of students who are advanced and can take on the telling role formerly occupied by the teacher. In other cases, however, none of the students can answer the teacher's question and the teacher must adapt her approach. In such cases, we often see the teacher move back towards the middle of the continuum, asking leading questions and supplying hints. This becomes the compromise position, not telling, yet accomplishing the results of telling. Neither the use of leading questions and hints, nor telling by a student seems to accomplish the goals of the reform. From the observers' perspective, we would argue that there is a need for formulated (explicitly articulated) approaches to mathematics teaching that can allow teachers to get off of this continuum.

Reconceptualizing Teaching

Prior Work

Many researchers have contributed to the conceptualization of aspects of mathematics teaching (c.f., Ball, 1993; Cobb, Wood, & Yackel, 1993). However, few have tried to articulate theories of mathematics teaching. It is perhaps significant that in the PME classification of research reports and members' research interests, there is no category entitled "theories of mathematics teaching" (or "integrated theories of teaching and learning"). However, over the last 25 years, two significant programs of research have made important contributions to theories of mathematics teaching, the French Theory of Situations (c.f., Brousseau, 1997; Douady & Mercier, 1992) and the Dutch Realistic Mathematics Education (RME) (c.f., Streefland, 1990; Treffers & Goffree, (1985).[1]

Our work builds on these two programs. The ideas that we develop elaborate Brousseau's idea of "teaching as the devolution of a learning situation from the teacher to the student." Brousseau (1997) asserted:

> Teaching consists of inducing students to assimilate the projected learning by placing them in appropriate situations to which they will respond "spontaneously" by adaptations. ... The main objective of teaching is the functioning of knowledge as a free production of the student within her relationship with an adidactical *milieu*. (p. 229)

We will explore the adidactical *milieu* in relation to constructivist learning theory and how learner's free productions can contribute to conceptual

development. In RME, students' free productions are also emphasized and considered a starting point for "progressive schematization," a process through which students' spontaneous solutions are developed towards the goal of formal mathematics.

Working from Constructivist Theory

There is likely to be consensus that theories of teaching should be integrated with theories of learning, that is, they should reflect and build on relevant learning theory.[2] However, using a theory such as constructivism to think about teaching involves a non-trivial adaptation, from describing learning when it occurs to promoting learning when it might not occur without an appropriate pedagogical intervention. As Cobb (1994) wrote:

> Versions of constructivism do not constitute axiomatic foundations from which to deduce pedagogical principles. They can instead be thought of as general orienting frameworks within which to address pedagogical issues and develop instructional approaches. (p. 4)

We use constructivism in service of developing approaches to teaching that offer an alternative to the unsatisfactory continuum of teaching described above. Although, following Cobb and Yackel (1996), we coordinate social and cognitive analyses of learning, the focus in this paper is on the cognitive. The reader is referred to Simon (1997) for a discussion of teaching from a social perspective.

Disequilibrium. We begin our discussion of alternative teaching approaches by considering "disequilibrium," a key mechanism in describing learning from a constructivist perspective. Disequilibrium refers to a result of either a learner's experience of an event not fitting with her expectations or a perceived lack of fit among the conceptions she holds. Disequilibrium is thought of as a trigger for conceptual reorganization leading to learning. To what extent does this aspect of constructivist theory provide a possibility for the teacher to make an impact?

We can think about the teacher's role as including intentional actions aimed at provoking disequilibrium with respect to particular student conceptions. The teacher can attempt to provoke disequilibrium, but disequilibrium only results if the issue is significant to the students and they perceive a conflict. Provoking disequilibrium, when successful, would seem to constitute an alternative to telling or asking for the mathematics. In some cases, it does seem to promote learning. However, it is important to ask whether disequilibrium dependably leads to learning and to look more closely at situations in which the intended disequilibrium cannot be induced. In explicating these two issues, we focus on the relationship between assimilation and accommodation.

Piaget (Bringuier, 1980) asserted that "adaptation is a whole whose two poles can't be dissociated. Assimilation and Accommodation" (p. 44). We interpret this to mean that every assimilation of new experience requires some level of accommodation, modification of current schemes, and every accommodation requires an assimilation into a (modifiable and modifying) set of schemes. The latter is particularly important because the intention of a teacher who tries to provoke disequilibrium is to trigger an accommodation in the students' schemes. Based on this relationship between assimilation and

accommodation, we would argue that the necessary (but not sufficient) conditions for provoking disequilibrium, an intended conflict experienced by the learner, are that the learner has schemes that allow for a compatible interpretation of the situation (conflict) to that of the teacher and schemes which can be accommodated to construct an understanding compatible with that of the teacher. This is a complex way of saying that disequilibrium only takes place when the learner can understand the conflict and conceive of the possibility of a solution. Here we are not saying that she has a solution in mind, rather that she conceives of it as solvable. We will use a problem-solving situation analogically to illustrate this last point. Consider the well-known Prisoner and the Hats problem:

> Three prisoners, two sighted and one blind are put in the following situation:
>
> They are told that the warden has 3 red hats and 2 black hats. He places one hat on each of their heads. Two of them see the hats of the others, but not the hat on his own head. The warden says that whoever knows the color of his own hat shall be freed.
>
> The first sighted man looks at the others' hats and says that he cannot determine the color of his hat. The second sighted man does the same, whereupon the blind man says he knows the color of his hat.
>
> What color hat did he have and how did he know?

For the problem solver who anticipates that the second prisoner has an informational advantage and that the third must have a still greater advantage, the problem may provoke disequilibrium and that disequilibrium may lead to a solution. (We are using this to concretize certain points not to claim that a conceptual reorganization necessarily takes place.) For the problem solver who only considers what each prisoner sees, the problem has insufficient information, and he is likely to assume that it cannot be solved. This problem solver has no disequilibrium related to the mathematics, although he may experience a conflict from having received an "unsolvable" problem from the teacher.

We provided an example in which the learner experienced no disequilibrium with respect to the mathematics. Another possibility that can occur, if the necessary schemes are not in place, is that the learner experiences disequilibrium that does not fit with the conflict intended by the teacher. This situation can be difficult to perceive by the teacher or observer. In such cases it is not likely that the disequilibrium will lead to the advances intended by the teacher. Note, that the students will always find a way to lessen their disequilibrium, however, that process may not result in the intended mathematics learning or any mathematics learning at all.

Where does this discussion of disequilibrium leave us? We can think about learning as the coming to know regularities among comparable mathematical entities. When disequilibrium can orient reflection upon comparable entities, provoking disequilibrium can be an effective way of promoting learning. However, it provides only a partial alternative to the continuum that we discussed earlier. What is needed is a way to think about a teacher's role in fostering conceptual development when disequilibrium does not seem to be a viable option, i.e., when necessary schemes are not in place. In grounding this exploration in

constructivism, we continue to eschew the notion that more powerful concepts can be infused into learners and embrace the idea of promoting an internal process of construction. This quest however, puts us face-to-face with what has been called "the learning paradox" (Pascual-Leone, 1976), the need to explain how learners "get from a conceptually impoverished to a conceptually richer system by anything like a process of learning" (Fodor, 1980, p. 149 cited in Bereiter, 1985). Bereiter (1985) pointed out that based on the learning paradox,

> The distinction is between kinds of learning that can be accounted for on the basis of knowledge schemas that the learner already possesses and learning that involves new cognitive structure to which already existing schemas are subordinated. (p. 217)

Reflection on activity-result relationships. To begin to explain the construction of new cognitive structures, we refer to the child's development of a concept of manyness. Consider a child who has one-to-one correspondence and has learned number names from one to ten. The child learns to imitate his parents' behavior with a set of objects, touching one object at a time while simultaneously saying a (the next) number name. Through repeated experience carrying out this activity with different sets of objects, the child comes to know that the last number he says represents the manyness of the set of objects. This can be explained in the following way. The child reflects on the relationship between the activity and the results of that activity. (Note, we are not claiming reflection at a conscious level.) For example, early on, he may come to realize that when there is a large collection of objects, he gets to show off most of his sequence of number names, but when there are few objects, he only gets to say a few number names.

What is it that might be generalized from this example that can contribute to our search for alternative teaching approaches?[3] First, the child is constituting a "new cognitive structure." Second, the activity that leads to the development of that new structure is one that the child can carry out without and before the cognitive advance. Third, the activity, carried out by the child who holds certain conceptions, has specific affordances that can lead to a specific cognitive advance. Fourth, key to the cognitive change is the child's reflection on the activity-result relationship which leads him to identify regularities in that relationship. This is a process that takes place over the course of repeated experience which is not motivated by the desire to make a cognitive shift, but rather by the original goal of the child's activity (in this case to imitate and play with Mom or Dad).

Thinking about teaching. Based on the above discussion, we suggest that to promote the development of a new cognitive structure, a teacher's role is to engage students in an activity that they are capable of carrying out, independent of the teacher (*situation adidactique*), that can lead to identification of regularities contributing to the cognitive advance intended. To do so, the teacher needs to understand the conceptions of the students in order to anticipate activities in which they can engage and possible ways that they may reflect on activity-result relationships. As Hoyles (1991) suggested, "activities must connect with pupils conceptions at the outset."

Although our formulation of this approach to teaching is different, we believe that it is consistent with what in RME is called "progressive schematization" (Streefland, 1991) and with Brousseau's (1997) notion of adidactical situations. It is also consistent with what we would consider to be effective use of manipulatives, observable in the United States. For example, engaging first graders in solving realistic word problems using counters affords them the opportunity to identify regularities in their solution activities as the basis for developing arithmetic operations. (Of course this description of the process is incomplete.) Note, the children are capable of solving what we would consider addition, subtraction, multiplication, and division problems using their counting schemes, their knowledge of operations carried out outside of mathematics class (e.g. combining quantities, sharing cookies) and their ability to represent the items in the problem with counters. Also, the children engage in the problems to find the answer to the problems, not to construct more advanced cognitive structures.

This approach to teaching is what Bereiter (1985) calls "indirect" in that the cognitive advance cannot be directly brought about, rather specific experiences for the development of the cognitive structure are fostered by the teacher. Thus, based on understanding the students' mathematics, the teacher anticipates a developmental process in the context of particular learning activities, what Simon (1995) called a "hypothetical learning trajectory."

Tzur (in press) contributed an important distinction between a reflective level of knowing which takes place in the context of the activity (e.g., understanding that the last number pronounced in a count indicates the manyness of the group) and an anticipatory level of knowing which exists independent of the activity (e.g., understanding that when the number "4" is spoken it indicates the manyness of a countable collection). Tzur described how teachers can foster first the development of reflective knowing and subsequently the development of anticipatory knowing by selecting tasks and questions that invite different levels of ref' 'ion on activity-result relationships, an additional consideration in the generation of hypothetical learning trajectories.

Discussion

The theoretical work that we describe in this paper is part of an ongoing effort to articulate aspects of mathematics teaching that can be useful in a variety of related domains: mathematics teaching, curriculum design, teacher education, and research on mathematics teaching and teacher development. In particular, we are attempting to articulate and explicate conceptual frameworks on teaching that specify the mechanisms of student learning and the role of teachers in promoting that learning. An assumption of this work is that teaching can be more scientific in responding to mechanisms of student learning than merely telling students the mathematics that they are expected to learn. Our claim is not that there are no examples of teaching that meet these specifications. Indeed, there are many rich examples of teaching that seem to be well-coordinated with the learning mechanisms that we have described. Rather, we are attempting to further the articulation and explication of and discourse on mathematics teaching.

Towards this end, we have described our growing understanding of the role of provoking disequilibrium and organizing instruction to foster reflection on particular activity-result relationships. Although the former seems to be useful, our current work emphasizes the latter, for as Bereiter (1985) pointed out, "certain kinds of learning really are problematic and . . . the learning paradox helps us see into the heart of the problem" (p. 221). That problem is how learners develop new and more complex cognitive structures. We have pointed to reflection on particular activity-result relationships as a mechanism for such learning, one that can be fostered by a knowledgeable teacher. For us, one of the indications that this mechanism may prove to be robust is that it seems to provide an explanation for much of the learning that we can observe in non-school settings. For example, the game, Checkers, can be played by any youngster who knows the rules for moving pieces and the goal of the game (to eliminate the opponent's pieces). However, it is predictable that youngsters who play the game over a considerable period of time, even without any coaching, will develop considerable insight into strategy for the game. We argue that this can be explained as a result of reflection on activity-result relationships.

In our current work, these ideas about teaching are proving generative at two related levels. First, as part of a conceptual framework on mathematics teaching, the ideas contribute to a conception of teaching that serves as a goal of our teacher development efforts. Second, we are exploring the use of these mechanisms of learning and teaching to inform our teacher education practice to contribute to our ability to promote more complex pedagogical structures. (See Simon, et al, 1998, for discussion of some of these pedagogical structures.)

Footnotes

[1] We acknowledge that there are other important bodies of work in this area to which we do not have access. We hope to use the international meeting to learn about these.

[2] An integrated theory would also suggest that ideas of teaching affect ideas of learning in the context of classrooms.

[3] We use positivistic language here in describing what we consider to be our experience and not an independent reality.

THE MULTIPLE MOTIVES OF TEACHER ACTIVITY AND THE ROLES OF THE TEACHER'S SCHOOL MATHEMATICAL IMAGES

Jeppe Skott, the Royal Danish School of Educational Studies

A lot of the research has been done relating teachers' beliefs to their classroom practices. This paper proposes an alternative understanding of that relationship. It introduces certain moments of the teacher's decision making, Critical Incidents of Practice (CIPs)*, that are characterised by the simultaneous existence of multiple motives of his/her activity. These motives may be experienced as incompatible and lead the teacher into situations with apparent conflict between beliefs and practice. Rather than as examples of inconsistencies these may be conceived as situations in which the teacher's school mathematical priorities are dominated by other motives of his/her educational activity, motives that may not be immediately related to school mathematics. I suggest to use CIPs as focal points in pre-service teacher training.*

Over the last decade many studies have been made on teachers' beliefs and of their roles in mathematics classrooms. The results of those studies are by no means unanimous. Some claim that very direct relationships exist between the teachers' beliefs, their classroom practices, and the students' learning (Schoenfeld, 1992). Others argue that there is no such relationship and that none should be expected as beliefs are situated, and any attempt to look for priorities that are stable across different contexts is bound to be in vain (Hoyles, 1992; Lerman, 1994; 1996). Between these two extremes Ernest have used the espoused-enacted distinction and pointed to possible mediating factors and social constraints regulating the extent to which the teacher's priorities may manifest themselves in the classroom (Ernest, 1989; 1991). Bauersfeld has pointed to classrooms as jointly emerging realities (Bauersfeld, 1988) and Paul Cobb and his colleagues to the dialectic between beliefs and practice (Cobb, Wood & Yackel, 1990; Yackel & Cobb, 1996; McClain & Cobb, 1997), indicating that though the teacher is important, his or her beliefs are not the sole producers of the classroom environment, let alone the learning opportunities.

This paper aims to contribute to a further understanding of the relationships between on the one hand the teacher's images of mathematics and of its teaching and learning in schools (the *School Mathematical Images* or *SMIs*) and on the other on his or her classroom practices. It discusses the case of John, a 42 year old second career teacher, and two other novice teachers who were selected for the study because of the SMIs they presented partly in their responses to a questionnaire[i], partly because of how they elaborated on these responses in later interviews. Both in the questionnaire and in the interview John showed a strong sense of commitment to the current reform efforts in mathematics education[ii]. He consistently emphasised the importance of investigations and communication on the part of the students and argued that less emphasis should be given to the performance of routine tasks. Further he described the roles of the teacher as a facilitator of learning rather than an explicator of mathematical concepts and skills. Characterising a good teacher of mathematics John said in the questionnaire that he or she knows how to

"-inspire the children to discover connections in mathematics
-understand an l accept the different solutions proposed by the students
-free himself from the textbook and introduce mathematics in many different ways".

John, the school, and the classroom

Already before he finished his pre-service training John took up teaching at a village school, where he was offered a permanent position upon graduation. It is a small school of 11 teachers and 130 students from pre-school to grade 7. Some years ago the school got a new headmistress who has influenced the atmosphere to the extent that some of the more conservative staff have left, while the rest are involved in different types of collaborative efforts in order to initiate changes compatible with the latest Danish educational law. In mathematics these changes are strongly inspired by the international reform efforts. John is pleased with these developments.

I attended John's grade 4 for in 2½ weeks in his third term after graduation, following his teaching of a chapter in the textbook on angles, parallel lines, and plane, geometrical figures. If possible we had a brief, general discussion about each lesson immediately afterwards, during which I also asked more specific questions based on my field notes. After the 2½ weeks I made a more comprehensive interview with John, asking him to comment on a number of clips from the video recordings made in his classroom.

The class consists of 14 girls and 6 boys, and though at times there are disciplinary and collaborative problems, John and the students have created an atmosphere in which the students' contribution to the interaction is clearly valued and in which they participate actively and make suggestions of their own. John uses a range of different approaches in order to maintain this atmosphere and to support the students' learning. Some of these have become conscious elements of his routine, while others seem to have developed less consciously. These approaches include

- making joint decisions during whole class instruction as to whether a student's suggestion is acceptable under the specified conditions (e.g. when the students are classifying quadrilaterals according to the number of sides of equal length: *How do you know that they are the same length? Does everybody agree?*).
- not accepting a question like 'I don't understand this', but encouraging or urging students to be more specific before he responds;
- insisting that students ask a peer before they ask him;
- encouraging students to modify or make up tasks of their own (e.g. when the students had made quadrilaterals on the geoboard each fulfilling certain criteria, he asked the them to modify the tasks to be relevant for triangles or pentagons);
- communication in everyday language prior to the introduction of standard mathematical terminology (e.g. when he asked the students to describe quadrilaterals some of which had parallel lines without introducing the term of parallel beforehand. Instead he mentions the term briefly afterwards and in a later lesson discusses it more thoroughly).

In all of this there is a fairly strong correspondence between John's SMIs and his interaction with the students. That seems to be the case both when he orchestrates a whole class discussion, and when he works with individuals or small groups of students. The latter may be exemplified with an interaction between John and one of the boys, Johannes. Johannes finds it difficult to solve a task of how to make a quadrilateral with four equal sides and no right angles on a geoboard. At first Johannes aggressively denies that he knows how to solve the task, but John is insistent and manages to make him come up with a first suggestion. Over the next 18 minutes John joins Johannes 6 times in order to push him, challenge him, and encourage him to make improved conjectures, and Johannes develops from claiming not to know what to do, over stating that the task is impossible to solve and claiming that he has solved it when in fact he has not, to coming up with a correct solution that he is able to justify. Throughout the entire period John avoids giving any direct instructions except the ones aimed at ensuring Johannes' initial involvement in the task ("Make a quadrilateral. You can always make a quadrilateral"). Instead he encourages and urges Johannes to move on when he first thinks he has solved the task: "Are they the same length, the four sides [pretends to be thinking aloud]? I think you are on to something here, but are they the same length? [Johannes shakes his head]. No, but you are on to something. You are on the right track. [John leaves him]." When Johannes finally succeeds, John – who has struggled almost as hard as Johannes – exclaims: "Yes! That's it. Bingo! Exactly." He waits at Johannes' table for eight long seconds building and sharing Johannes' triumph with him.

There are moments when John plays roles very different from the ones just described. An example of that occurs the next day, when one of the girls, Emily, claims to know how to solve the task that Johannes has struggled with in the previous lesson, and John invites her to show her solution to the class. He asks her to make her drawing on the chequered part of the blackboard, pretending it is geoboard. Emily, however, finds it difficult to present her results. She is initially incapable of using the blackboard as a geoboard, and having overcome that obstacle she gets stuck when trying to make the sides of the quadrilateral the same length. After she has made a few vain attempts, John asks her to move to the other side of the board to make a draft of her figure. She easily makes a free-hand drawing of a rhombus standing on a vertex. However, she gets stuck in her subsequent attempt to transfer the draft to the chequered board, and from that instant John takes over more and more, pointing, counting the squares, instructing her what to do, and finally making the drawing himself.

In John's interaction with a boy, Frederick, his comments also become very explicit. Frederick is working on a task of categorising ten different quadrilaterals according to whether they have two pairs, one pair or no pairs of parallel lines. The quadrilaterals, labelled from A to J, are to be written in a table that the students copy from the textbook. Frederick calls John and the following exchange takes place[iii]:

John: You have to find all the figures with parallel sides. Where the sides are parallel two and two [...] Those two, these two [points at two sides of a quadrilateral], they are parallel, they don't meet. ... If we extend them indefinitely, will they ever meet [places two rulers along the sides to emphasise the point]?
Frederick: No.
John: No. So at least it has two that are parallel. What if we look at the other two. Will they meet?
Frederick: No.
John: No. So it has two and two parallels, this one, doesn't it. So it belongs to the column you have made here [points at a column in Frederick's table].
Frederick: What am I to write, then?
John: You write this one into that column [points at the quadrilateral in the textbook and at the column in the workbook]. Above here you have to write that it is page 32 and task number 2 ... Then you write J in that column here ... right.
Frederick: [Short inaudible question].
John: Yes. Then let us look at the next one. [Frederick points at one]. This one. They don't meet either, any of them, so there are two here that are parallel and two here that are parallel [points]. So that belongs in the same column.
[Brief interaction between John and Andreas, the other boy at the same table]
Frederick: But what about the others? [Interrupts the interaction between John and Andreas. John does not respond. Johannes tries again] These two are parallel as well [John reacts. Frederick points at two sides of another quadrilateral].
John: Yes these two, but what about these? [points at the other two sides]
Frederick: No.
John: They aren't. So that one doesn't belong here, where they have to be parallel two and two. It only has two parallels, so that goes in the other column.

Multiple motives of teacher activity and *Critical Incidents of Practice*

John obviously provides very different types of support for the students' learning in the episodes referred to. He consistently avoids giving explicit instructions in the episode with Johannes; he initially tries to be unobtrusively supportive in the interaction with Emily, but when unsuccessful he takes over her attempt to initiate the others in her findings and becomes very direct in his explanations to her and the rest of the class; finally he is very didactic all the way through the episode with Frederick.

One interpretation of this is that John is inconsistent and only momentarily teaches in ways compatible with his SMIs. However, there are other interpretations, and in order to present one of them I shall briefly describe how two other teachers in the study reveal similar apparent contradictions between different elements of their practice. Christopher, a teacher from a Copenhagen suburb, sometimes deliberately refrains from providing direct instructions to the students and seeks to support their independent work, while in others he plays a much more direct role (Skott, 1999). Larry, another teacher with reformist intentions but working at a traditional private school, struggles to strike a balance between his own SMIs and what he considers to be the priorities of the school. It turns out that a key to understanding these classroom

interactions is the *Critical Incidents of Practice* or CIPs. These are defined as moments of the teacher's decision making (i) in which multiple and possibly conflicting motives of his activity evolve; (ii) that are (potentially) critical to his SMIs; and (iii) that are essential to the further development of the classroom interaction and to the learning opportunities.

In Christopher's case the motive of teaching mathematics is sometimes supplemented or replaced by other motives, for instance developing their self-confidence or solving organisational problems in the classroom. In these cases the main energising element of his activity may not be the facilitation of mathematical learning, but the fulfilment of more general educational aims or the management of problematic classroom situations. Larry often finds himself caught between the conflicting demands of the school culture and of the reform. These demands establish two dominant, but mutually competing motives of his activity: One of facilitating mathematical learning and one of complying with the perceived pressures of the school. Focusing on one or the other of these motives in turn, Larry gets involved in series of oscillating practices some which incorporate specific aspects of his reformist intentions, while others have virtually no resemblance with his SMIs. Both of these teachers, then, experience CIPs in which the existence of multiple motives of the their activity challenge the enactment of their SMIs. In these incidents their main focus may not be on facilitating mathematical learning. They may, so to speak, primarily be playing another game than that of teaching mathematics.

It is not surprising that the SMIs become less significant, when the object and motive of the teacher's activity is not one of teaching mathematics. In John's case the main challenge to the motive of facilitating mathematical learning – and therefore to the enactment of his SMIs - is his knowledge and understanding of the individual child. For example John commented on the episode with Johannes by saying:

> "It's difficult, but I try to make him get started on his own, because I know he can do it. The problem is that he doesn't think so himself, or he is afraid//in reality he is afraid//he is lost at that moment, because he feels good only when he is number one. You know, to him nothing is good enough, all that matters is being the best, that means finishing first. The moment Ian [the other boy at the table] puts the rubber bands on the geoboard he is ahead and Johannes gives up. It is very difficult for him to fight that. But that is his whole situation and the expectations of his parents and things. They are very ambitious. And they are very competitive. That's OK, but the problem for the kid is that he only thinks he is doing well, if he is number one. Nothing else matters."

The point here is that John is deeply involved in facilitating Johannes' mathematical learning in ways compatible with his school mathematical priorities, but also that he bases his interaction on the conviction that Johannes' self-esteem is vulnerable and strongly connected to criteria of success not immediately compatible with John's SMIs. It is just as important to John to convince Johannes that he is doing a good job and making worth-while efforts, even if he does not produce the first or only solution

to the task, as it is to provide him with the opportunity to construct concepts of parallel lines or rhombuses. In this episode, then, John tries and largely succeeds in striking a balance between two competing motives of his activity.

John's explanation of the interaction with Emily also includes much broader aspects than those related to her mathematical learning. John conceives her as both unrealistic with regard to her own competence and fragile when confronted with problems that challenge her self-perception. That is important

> "[...] when I react like this. I can feel that she is on thin ice, so I try to make her draw the draft. That is how I try to give//help her [...] Then at least she can make the draft. And then we can make the figure from her drawing between us. But I take over completely, I can see that."

In this episode John tries to be cautiously supportive, but Emily does not succeed. He then sees no alternative but to take over and make sure that they finish the task together using her example, if he is to avoid a blow to her self-confidence.

John's interaction with Frederick took place at the very end of the lesson, which partially explains why he becomes very explicit: He wants Frederick to finish the task before the bell rings. Also he commented that Frederick is normally good in maths, and that John expected him to be able to follow the explanations given. However, there are other situations with weaker students in which John plays a similar role of instructing them what to do. He says:

> "There are some children in here, some of the weak ones, with whom I've had to choose [...] especially with Louise, I've had to say to myself 'If only she acquires a system [of how to solve the tasks], then it doesn't matter if I've provided her with it, because at least she can follow what goes on'. I've chosen that. And she does [follow]. So up to now she is part of the team. She largely makes the same tasks as the rest, although she finds mathematics very difficult."

John, then, becomes explicit in a variety of different situations. With Frederick he finds the dual motives of supporting his learning and managing the classroom compatible. With Louise he has previously struggled to strike a balance between facilitating her mathematical learning and assuring that she remained part of the classroom community. Finding it impossible to reconcile the two he has settled for the latter and accepted that he needs to provide her with very direct support.

Conclusions

In the situations described above John's SMIs play very different roles. That clearly questions Schoenfeld's claim of a causal relationship between beliefs and practice. However, the interpretations made also challenge Hoyles' contention that beliefs are situated in the sense that each new context produces or encompasses a different set of beliefs. It is rather the motives of the teacher's activity that are contextually framed, and these motives in turn determine or influence the enactment of his mathematical or general educational priorities, sometimes urging him to enter another game than that of teaching mathematics.

This interpretation also questions previous studies relating beliefs to practice in another way. Sometimes rather condemning descriptions of teachers are made, when they are found not to be in accord with their professed reformist views. My argument is that what appear to be inconsistencies may rather be understood as situations in which the teacher's motive of facilitating mathematical learning is dominated by other and equally legitimate motives of for instance ensuring the student a place in the classroom community or developing his or her self-confidence. I am not saying that these different motives are necessarily incompatible. For instance in the episode with Emily, John may have accepted her draft as a solution to the task and asked the students in groups to develop ways of assuring that the side lengths were the same. Or in the case of Louise it may be important to define the *classroom community* differently from just having the students working on the same task. The point is not that there is no alternative to abandoning the SMIs in situations of multiple motives. The point is rather that in the critical incidents of practice the teacher often struggles to find such an alternative, although sometimes in vain.

This leads to a proposal for teacher education. There has been a growing tendency to focus more on the student teachers' practice in order to ease the transition from pre-service training to full time teaching and to ensure a high degree of consistency between the theoretical understandings and practical competence of the novice teacher. For the teachers in this study such a consistency has to a great extent been achieved. However, when they are challenged by the multiple motives of their activity during the critical incidents of their practice, they sometimes find it difficult to integrate their SMIs with broader educational aims or with managing the classroom. That may be because such an integration is sometimes impossible to obtain. But it may also be because they have not been confronted with situations that challenge the enactment of their SMIs in their pre-service training. The proposal, then, is to use CIPs – preferably from their own teaching experience – as focal points in discussions of the realisation of their SMIs.

---

[i] The questionnaire contained open and closed items on mathematics and its teaching and learning and was sent to all student teachers doing mathematics at a Danish college immediately before their graduation in 1997. Among the respondents 11 were selected for interviews upon graduation, while John was interviewed one year later. Among the interviewees 4 were selected to be part of the continued study.

[ii] The notion of *a reform* is obviously problematic, but I refer to the trends envisaged for primary and lower secondary school, including a view of learning informed by constructivism, a view of teaching as facilitating learning, and a view of mathematics inspired by fallibilism and social constructivism. The Danish curriculum for primary/lower secondary school also reflects these trends.

[iii] In the transcripts I use the following notations: ...: a pause; //: the speaker interrupts her/himself or is interrupted; [...] : an omission on my part; [text] an explanation on my part.

"This is crazy. Differences of differences!" On the flow of ideas in a mathematical conversation.

Cambridge, USA

This paper describes the flow of a mathematical conversation in a high school mathematics classroom. The analysis attempts to elucidate how the discussion of a particular mathematical problem is inherently open-ended and to describe the complexity in managing the wide range of ideas and choices emerging from the interactions among students and the teacher. A major implication of our analysis is that whether an idea turns out to be mathematically correct is only one piece of what contributes to making it valuable and inspiring. Another implication is that the teacher's mathematical expertise plays out throughout multiple ongoing dilemmas that go much beyond the classic dichotomy between "telling vs. letting them discover it."

The nature of conversations in the mathematics classroom has become a prominent theme of mathematics reform. Some of the most central questions raised by the many initiatives to reform mathematics education focus on what counts as a productive conversation for mathematics learning and what are the roles of the teacher in fostering and enriching them. Chazan and Ball (1995) argued that the opposition between "telling or not telling" is an oversimplification. Often the interpretation of videotaped data ends up taking the form of a superficial judgment on whether the teacher made the correct move, whether the students "get it," or in general, whether what is seen is an example of good teaching. In jumping to these types of judgments we close our own understanding of what the participants are experiencing and what the documented utterances and activities meant for them.

Calvert (1998) argued against another common image that what counts in a mathematical conversation is exclusively the truth of the propositions that are being argued. Explanations, according to Calvert, are often attempts at understanding and they may affect the participants of a mathematical conversation in ways that have little to do with proving, convincing, and competing.

Other researchers (Cobb et al., 1993; Bordieu, 1983) have postulated that classroom conversations are regulated by social and mathematical norms, mostly implicit, which are developed over time through extended and ongoing interactive negotiations between the teacher and the students. Simon (1995) suggests that while the teacher plans lessons and designs tasks aiming at realizing a hypothetical learning trajectory in the students, in the actual interaction with the students his plans are constantly revised and subject to redefinition.

In this paper we build on Chazan and Ball's idea (1995) that "any discussion holds the potential for discrepant viewpoints" and that it is the teacher's role to "manage" these views. We argue that the discussion of any

mathematical problem can be by its nature open-ended. Instead of seeing the teacher's role as deciding whether to make a problem open-ended, we see a teacher's role as making a set of decisions about how to manage the open-endedness that exists in the interactions around a mathematical issue. In addition, we see the teacher managing the open-endedness by working on a sense of direction for him and for the class. This work is at times expressed through efforts to preserve certain voices which otherwise may vanish, to foster mutual listening, and to comment on the fruitfulness of the different contributions. The sense of direction is co-developed by the teacher and students; some students adopt a leadership role in this regard by commenting on the quality of the conversation itself or by suggesting changes in how the group talks to each other or what it talks about.

This episode took place in a classroom of tenth and eleventh graders in a second year integrated mathematics course at City On A Hill Charter School, a public high school in Boston, MA. City On A Hill admits students from across the city of Boston by lottery; approximately 75% of the student body are students-of-color and over half the students qualify for free or reduced lunch. The teacher is Jesse Solomon. The fifteen-minute discussion that followed was not part of the day's lesson plan. The episode began when a student raised a question about one of the previous night's homework problems. The problem gave the sequence 1, 8, 27, 64... and asked students to find and graph the next three terms of the sequence. Maria (all of the students' names are pseudonyms) asked the initial question:

Maria: And on [problem #] 18, I couldn't figure out the pattern, and I tried and I asked my mom and my brother, and no one could... (...) And, um, I just, I- this is the only one, I left, I had to leave the graph blank, cause I couldn't figure out what the next two would be. I figured- I did the differences. I did multiplication, I tried times 2 plus 4, times 2 plus 3. I tried that. I couldn't get it. My mom couldn't get it, and she told me just clean my room.

When Maria read the problem, I thought that it was trivial, that the 'answer' would quickly be evident for the class. However, the students immediately showed that for them the problem was far from obvious; that struggle made it interesting to pursue. [Bold type expresses first person commentaries by Solomon.]

Margaret made a first proposal:

Margaret: There is no sequence, I don't think. If there is no sequence, then can't you just guess the next two numbers? The only thing it has in common is that one is higher than the other.

Mr. Solomon: (...) Oh, just because it's higher? Okay. What do other people think?

When Margaret introduced her idea, she qualified it by stating, "There is no sequence." Because the only commonality she saw is that the numbers increased, she concluded that there is no sequence. Her comment suggests that proposing a number just because it is "higher" than the previous one was not a "good" solution--that it was not mathematically satisfying. The notion that there should be a rule to determine exactly the next number was an implicit part of the

background of cultural assumptions in this class. Solomon tacitly confirmed this assumption by restating Margaret's explanation with a "just:" ("Oh, just because it's higher?") and also by immediately asking the class for alternative ideas. At this point, Solomon took on the role of recording the students' ideas on the overhead projector.

Maria: Did anyone else get this one?
*Naomi: Well, 8*8 is 64.*
Daniel: [raising his hand briefly] Um... Hold on one second.
Latisha: [whispering to Naomi] But where does the 27 come in?
Maria: But what does the 27 have to do with it?
Naomi: The 27 comes in from the 1.
Maria: 1 times 1 is 27?
Mr. Solomon: I just want you [to Maria and Naomi] to hold on one second; I don't want to lose it, I just want you to hold on one second [gesturing to David to say his idea]...

1, 8, 27, 64

As other members of the class began to engage with the problem, we see the simultaneity of ideas and conversations that characterizes much of classroom discussion. Daniel asked for time to think, but while Solomon was trying to "hold" the class, waiting for Daniel's idea, Naomi expressed a relationship that she noticed, Latisha and Maria questioned the validity of Naomi's relationship and refuted Naomi's attempt to link 27 with 1.

Daniel then proposed an iterative linear rule ((1 + 8)*3 = 27) that used the first two terms to generate the third, but he could not see how to generalize it. Even though he concluded that this particular rule would not work, the class started to play with iterative rules involving addition and multiplication. At a lull, Solomon asked:

Mr. Solomon: How about if I show you the next number in the sequence?
Daniel: No!
Maria: Yeah! Yeah!

This offer of the next term elicited conflicting reactions. For some students (e.g. Daniel) adding the fifth term would diminish the merit of the solution they would eventually come up with. For others (e.g. Maria) it would help them solve a problem which, so far, had been almost intractable. Students are wrestling with their issues of confidence in their ability to find a solution, the value they attach to the independent finding of a solution, and a sense of how much effort is worthwhile to put into a problem.

Jamal: I got it! Haaah! I got it.
Latisha: Then, what is it?
[Solomon reiterated Latisha's request to Jamal. Jamal refusal to provide it, triggered an interaction with Maria.]
Maria: How are you going to be a genius and keep it to yourself? I mean...
Jamal: [after Solomon's request] 7. The difference between- the differences between, um each number [Molly: 7, 19, 37] is what it has to do with.

Note how Molly reacted immediately uttering the sequence of differences ["7,19,37"]; she had probably already taken the first differences.

Jamal (to Solomon): Go ahead, put 'em, write 'em down there. 21.

Shawna: That's 19. [Jamal: That's 19].
Molly: 37. [Jamal: 37].
Maria: I see no.....

1	8	27	64
7	19	37	

Molly: There's, like, no pattern. That's what I did.
Jamal: Oh, I thought it was 7, 21 - see, that's why I messed up...all right.
Jamal: I thought it was 21. I thought it was 21.
Maria: [simultaneously] You don't got it. You don't got it.
Jamal: Yes I do.
Latisha: Okay, next.

Jamal admitted that he had been mistaken because he thought that the second term of the differences was 21 and not 19. The refutation of Jamal's idea was in part a repeal of his attitude, but his contribution did bring to the group the notion of playing with successive differences. Molly confirmed that she had tried this out but that no patterns came up. This approach, different from the previously dominant one of trying out addition/multiplication rules, would become a key idea for the ensuing conversation. Again, the group picked up on idea which at first glance had been rejected.

Mr. Solomon: Anybody else, anybody else want to try anything, before I put one more. Just say anything at all in the world.
Shawna: Well, no numbers, like, I mean, I forgot how you say it, it's a num- like, you know, 3 or 2 can't go into 7, 3 or 2 can't go into 19, can't go into 37.
Mr. Solomon: (...) What are those called?
Maria: A prime number!
Shawna: Yeah, prime, yeah.
Mr. Solomon: Okay, so the, the consecutive differences are prime, that's something you noticed.
Shawna: Yeah.
Mr. Solomon: Good. All right. Do you notice a pattern in those differences?

While approving Shawna's noticing of the difference being prime numbers, Solomon's question seemed to ask for a sequential property, implying that her answer was not 'sufficient.' Then Maria proposed a sequential property but she felt that there were not enough numbers to ascertain it:

Maria: Right, and then the 7, 9, 7, but we only have three numbers, so... I mean you can't really go much on -- I mean three differences. If you give us the next one, that's what I'm saying, if it has 9 as the, the last digit, then maybe we could figure something out. [A discussion ensues about whether Mr. Solomon should provide the next number or not. Jamal opposes it; Maria, Molly, and Mona are in favor]
Daniel: 'Cause, I was looking at the pattern of those, um differences right there [on the overhead]: 7, 19, 37. I said that it could be going like. See how, like, the last digit is like, 7, then 9, then 7.
Latisha: [quietly] I just said that.
Mr. Solomon: Yep. So what would you say the next dig-...
Daniel: It would be like 9. And, and, the, the number on the, um, at the beg- in front of the 7 would be like a zero, and it goes up one, and then it [Maria: Ooooo!] goes up two from there which would be 3, and then it will go up 3 from

there, which will be 6, and that's 69.
Maria: The next one would be 59! Cause look! 0, 1, 3, 5, 7
Daniel: I had 69.

Daniel proposed that the next difference was 69. His idea, triggered by Maria's previous pointing at the second digit sequence (7, 9, 7) was that the first digit increased by 1, by 2, by 3 and so on (so that it is 0(7), 1(9), 3(7), 6(9)) whereas Maria thought that the first digit could be the sequence of odd numbers after 0 (0(7), 1(9), 3(7), 5(9)). Daniel proposed 69 a few more times, but his idea was never picked by the class. Solomon then asked for all the guesses about the next term and wrote them on the transparency. Nadia proposed 121, Daniel 133, Shawna 113, and Maria 123.

Mr. Solomon: Well, I'll give you a hint. It's definitely not all four of them.
Class: Is it one of them?
Daniel: Nadia! I know why you said 121!
Mr. Solomon: Can someone make an argument for one of them?

At this point I was still thinking of this as a problem with only one answer. While I may have been willing to entertain different suggestions, I still had the 'right' answer in my head.

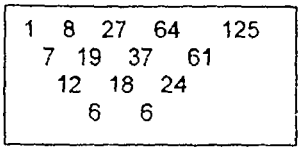
Naomi: I said 123 because, um... Oh yeah, because it was going, the um, the 10, in the 10's place of the difference, where it was 19, where the 1 and the 3, of 19 and 37, and then it was, like, plus 59...

1	8	27	64		123
	7	19	37	59	

Maria: Um hm, that's what I got, too.
Naomi: Because, you know, 1, 3,...
Mr. Solomon: Okay, that could work.

This is the first time that a proposed fifth number in the sequence is taken as a workable solution. Solomon asked other students to argue for the other proposed numbers.

Nadia: Okay, well, I didn't stop at finding the difference between the numbers given. I found the difference between the differences. Which I got 12, and then I got 16, from, wait, did I get 16?
Mr. Solomon: I think it's 18.
Students: [simultaneously] 18.
Nadia: 18. Okay wait. Then my, wait, my numbers might change then..6. 18. Wait a minute, wait a minute [writing]. [Pause] Wait a minute.



1	8	27	64		123
	7	19	37	59	
		12	18		

Maria: This is ridiculous! Differences from differences!
Mr. Solomon: No, this is actually...
Maria: No, it's probably right, but I'm saying that it's ridiculous that you're making us do something like this. [Laughter]

Even though the differences of differences idea came from Nadia, Maria still claims that Solomon is "making them do" this ridiculous thing. During this approach, Solomon tried to eliminate minor arithmetic mistakes that could get in the way of Nadia's idea.

Nadia: Okay, wait, wait, wait, let me come back, let me change that number.
Shawna: 37, and the next one, like, difference 37 and 59 is 22, right?
Mr. Solomon: Well, if, if we go with Naomi's thing of that being 59.

Shawna: Oh.
Mr. Solomon: Well, no, I'm just... Right.
Nadia: All right, then I got 125.
Shawna: Well, let's go with that, let's go with that, and what's the difference between those two?

Mr. Solomon: So if we go with that 59, then the difference is 22.
Shawna: And, so there'd be a difference of 6 in all of those, right? No, no, no.
Mr. Solomon: Will you not give up! Look! Look what the problem is. It's not a difference of 6, it's a difference of 4, so...

I thought that Nadia's path could be fruitful, but she was not convinced of that, so that a mathematical error could have easily derailed her and this idea might have been lost. It felt like it was both a good and unstable idea that it was worth the intervention of saving it.

Jamal: This is crazy! This is crazy.
Maria: Differences of differences!
Nadia: It would be 125.
Mr. Solomon: (...) Well, let me, let me say one thing first. Um, given a sequence like this: 1, 8, 27, 64, there is not one correct answer. For example, you could define your sequence, as, you know, however you define this difference here [first difference], and come up with 123. That's not the answer I was thinking of, but that doesn't mean that it's not the right answer. ...
Nadia: So this is like an open-ended question.
Mr. Solomon: (...) the book, for example, really may have a specific answer, because this, this set of numbers (...) has sort of a mathematical suggestion. It is a very frequently seen set of numbers, which, when I show you, you're gonna say "Oh, duh!" so there is an answer that would come to mind quickly, but that does not take away from...

Although I did end up talking about differences and knew something about the use of differences in determining the kind of polynomial equation, they were not fresh in my mind and I was not confident that I knew how a constant third difference indicates a cubic function.

Mr. Solomon: (...)[pause] Let me say a couple things. Here's the sequence that this usually suggests, okay: 1^3 =1, 2^3 = 8, 3^3 = 27, ...
Maria: Oh, yeah, I knew it!
Jamal: I knew it!
Maria: I really did, I really did. We did learn this!
[Mr. Solomon explained to the students that finding a constant in the successive differences indicates the order of the polynomial.]
Jamal: Ooohhhh!
Mr. Solomon: So, what actually you just discovered is this method that people use to find out what kind of function describes their sequence. So, just by taking successive differences, if you kept doing this, and said, Oh! it's always 6, that would automatically tell you that you've found a 3rd degree function.
Jamal: So if this 4th one, if you had to take a 4th one it would be like a 4th power?
Mr. Solomon: That's a 4th degree function. And one of the things that we clearly

need to talk about is why that's true.
Jamal: Why you never told us that? 'Cause they have that on the SAT's.

Discussion

Often we talk about open-ended problems as if open-endedness were an intrinsic quality of certain mathematical problems, or as if we must choose between stating a problem as closed or open-ended. Was this problem, finding the next terms in the sequence 1, 8, 27, 64..., 'open-ended'? We find this dichotomy misleading; instead, we hold that it is the discussion surrounding a problem that holds the potential for open-endedness. The complicated set of interactions in this episode (as in any classroom mathematical discussion) are informed by the students' ideas about the problem, as well as by factors such as their cultural backgrounds and the social dynamics of a group of teenagers. Their contributions made the discussion open-ended. They were comfortable simultaneously trying out four ideas with four different answers.

At a few points throughout the episode, Solomon offered to tell the students the answer. Each time, at least one of them refused vehemently-they wanted to get it themselves. When he finally did explain the significance of constant differences, they did not feel like this piece of mathematics had been given to them. Rather, they had scratched away at some larger mathematical principle which Solomon placed in a broader context for them. Having explored and made progress on the problem and having developed a set of ideas about it, Solomon's telling was a confirmation of an idea that they felt some ownership over. In agreement with Chazan and Ball (1995), there was a mix between telling them and letting them discover it. The process of co-defining a direction–constant differences was not the topic planned for that day–led to the creation of a ground in which meaningful 'telling' was possible.

As varied contributions are generated by the group there is an interactive dynamic out of which an overall and changing direction emerges: certain ideas are picked up (e.g. Daniel: "I see that the (1 + 8) * 3 = 27"), others are abandoned or temporarily suspended, some participants shift to a leadership role (e.g. Maria: "Did anyone else get this one?), others seem to withdraw, the conversational atmosphere becomes competitive (e.g. Maria: "You don't got it. You don't got it." Jamal: "Yes I do."), productive, reflective (Nadia: "So this is like an open-ended question"), or agitated. In such an effervescent context, the teacher tries to contain certain forces and to stimulate others. A retrospective account can always embellish the interaction with clean rationales and formal chains of reasoning that led the teacher to make one or another "move;" however, the resulting image is unreal. No chain of reasoning can account for the teacher's instant recognition of imminent risks and possibilities and his ability to be responsive to a future that is yet to come. Solomon started the conversation expecting an easy recognition of the sequence of cubes and ended up discussing methods to recognize polynomials While this was not the execution of a pre-conceived plan, it was not a random chain of events either. The evolving sense of direction was co-developed by Solomon and some of the students. Maria, for example, made many commentaries on both the mathematics and the quality of the conversation itself ("I mean you

can't really go much on three differences. If you give us the next one," "How are you going to be a genius and keep it to yourself?" "This is ridiculous! Differences from differences!"), or Latisha who, exasperated by the discussion with Jamal, asked the group to move on ("Okay, next."). Solomon and the students were trying to have the conversation 'go somewhere' while, at the same time, trying to understand what that "somewhere" could and should be. Even the final interaction of the episode suggested some possible future directions for this conversation: deeper understanding of the difference-of-differences method (Solomon: "And one of the things that we clearly need to talk about is why that's true"), or how to get better scores on a test (Jamal: "Why you never told us that? 'Cause they have that on the SAT's").

THE DEVELOPMENT OF CRITERIA FOR PERFORMANCE INDICES IN THE ASSESSMENT OF STUDENTS' ABILITY TO ENGAGE CULTURAL COUNTING PRACTICES

Stephen Sproule
RADMASTE Centre, University of the Witwatersrand

This research explores grade seven students' ability to engage the counting strategies of various cultures. The purpose of the research is to develop performance indices for assessment of student performance. The performance indices have been created from the results of developmental research conducted with the students. The results of the research are presented as a scoring rubric and substantiated by student work.

Recently, Vithal and Skovsmose (1997) raised a number of concerns related to the implementation of ethnomathematics or critical mathematics within a school system or mathematics curriculum. The new South African mathematics curriculum, intended for gradual implementation over the next seven years, will include pedagogical attention to mathematics as a culturally situated activity. Thus a national curriculum will explicitly require teachers to highlight mathematics as a human endeavor by including activities that illustrate the mathematical practices of various cultures and focus directly on the cultural origins of the practice.

In the research reported in this paper I have developed various counting systems (as one aspect of a culture's mathematical practices) into classroom activities to introduce the cultural component of the new curriculum in a mathematics classroom. The purpose of these activities is the development of criteria for performance indices for teachers to use in their assessment of their students' ability to engage and operate within the counting practices of different cultures. To ensure that the performance indices are grounded in the practices of students this research answers the question: What mathematical approaches do students who are familiar with an English counting style apply and develop when they encounter number systems and counting strategies originating in other cultures and languages? The complete research agenda also focuses on the students' awareness and appreciation of the cultural nature of mathematics. This is not reported in the paper due to space constraints.

South Africa remains in educational transition. A new mathematics curriculum, currently in implementation, has adopted an outcome or performance based approach to education. In this paper I describe research that is related to a specific outcome of the new curriculum that requires students to understand mathematics as a human activity embedded in a socio-cultural context. The specific outcome states that students should, "demonstrate understanding of the historical development of mathematics in various social and cultural contexts" (Department of Education, p.4, 1997)

1339

Although recognised by Presmeg (1998), and Vithal and Skovsmose (1997) as a limited approach to incorporating cultural mathematics practices into the curriculum, the Department of Education (1997) has adopted curriculum outcomes that are concomitant with a "histories of mathematics" approach. It appears that their intention is to provide students with a more global appreciation of mathematics as a human endeavor situated in a socio-cultural context. One aspect of the education process that will require change as a result of the changing curriculum expectations is the assessment strategies employed to evaluate student development. Clearly, traditional forms of assessment are not suitable for the stated curriculum outcome.

To improve students' abilities to count and work in various culture's counting systems and to provide teachers a means to assess their students' development I have employed an *educative assessment* framework (Wiggins, 1998). Student assessment has traditionally only served as a means to audit student knowledge. Delandshere and Petrosky (1998), amongst others, highlight the need for assessment to become an integral part of the learning process.

Assessment tasks offer a useful means to achieve an educative role for the assessment process. Using Wiggins's (1998) notion of educative assessment, the tasks illustrated in this paper may be considered *educative assessment tasks*. The intention of such tasks is not that students perform competently from the onset of the assessment (or learning) process but that students working through a selection of tasks develop competent performance through progressive engagement with the educative assessment tasks. In this process a "growing collection of evidence" of student learning is provided to the teacher for student auditing (Swan, 1993).

Within a performance oriented curriculum, auditing student work and providing meaningful feedback to students requires additional effort from the teacher. Supporting teacher efforts prior to and during the implementation of new assessment strategies is vital (Izard, 1993). One of the documented forms of assistance provided to teachers is the scoring rubric (e.g. Stenmark, 1989). These range from generic rubrics to content or process specific rubrics. Implicit in the purpose of my research is the need to assist teachers in the implementation of educative assessment tasks. Consequently, a qualitative scoring rubric illustrating levels of performance and the associated criteria has been developed and reported in table one.

Research methods

The use of developmental research in instructional developments and accompanying research is well documented by Gravemeijer (1994), is further explicated in practice by, amongst others, Cobb (1998) and resonates with research done by Presmeg (1998) on students' capacity to recognise mathematics in their own cultural contexts. I suggest that developmental research can also be successfully applied to the development of educative assessment tasks. Considering that educative assessment is as concerned with learning as auditing performance, the application of a developmental research methodology is as appropriate for the development of

assessment practices as it is for the development of instructional practices. Consequently, this research may be considered developmental research.

Participants

The school at which the research was conducted is situated in an upper-middle income neighbourhood of a large South African city. However the school draws students from all levels of the socio-economic stratum. Students from three of Ms. B's grade seven (approximately 12 years old) mathematics classes participated in the study. The students came from diverse cultural backgrounds representing traditional South African communities as well as recent immigrant populations. The students also demonstrated a wide range of mathematical ability while completing the tasks.

Assessment Tasks

The educative assessment tasks used in the research were created by applying an "anticipatory thought experiment" (Cobb, 1998) to cultural mathematics practices evidenced in Ascher (1991) and Zaslavsky (1996). Seven educative assessment tasks were used over 5 weeks with the participating students. Each task offered the student an opportunity to mathematically engage the counting system of a different culture. The scoring rubric presented in table one has been developed from student activity on all seven tasks. In this paper I illustrate the performance indices by drawing on student activity from the following three tasks:

1. *Yoruba Counting*: Students were provided the Yoruba words for 1 through 5, and seven sporadic examples ranging from 10 to 50. The equivalent English statements for the examples from 10 to 50 were also included. The Yoruba counting system operates on a 5 and 20 cycle. Students were required to use the examples to interpret the structure of the counting system, write the Yoruba word for 12, 16 and 35 and write the equivalent English statement for 55 and 100.
2. *Nahuatl Counting*: Students were provided the equivalent English statement for 12 examples of Nahuatl numbers ranging from 6 to 104. The Nahuatl counting system operates on a 5 and 20 cycle. Students are required to use the examples to interpret the structure of the counting system, write the equivalent English statement for 9, 13, 19, 38 and the numbers 50 to 60.
3. *Computer Numbers*: Students were provided with the postal code bar codes (figure one) used by the US Postal Service to assist the computerized mailing process. Students were required to write their own postal code using the bar codes, translate numeric postal codes to bar coded postal codes and vice-versa.

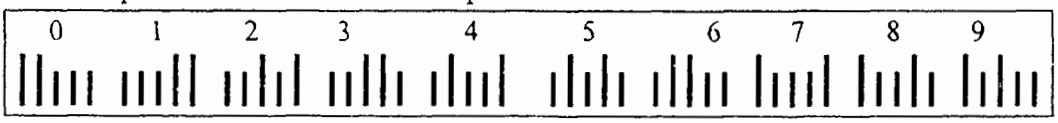

Figure 1. Bar codes for digits 0 to 9 used by the US Postal Service.

The other tasks included working with the Inca's quipu, creating a 5 cycle counting system, sharing the words for numbers from your language (other than English) and using hand gestures to represent numbers. More complete details, evidence and exemplars from student work will be provided during the presentation of the paper.

Data Collection

Data was collected from students' written responses on the worksheets and from recorded in-class didactic exchanges (Sproule, 1998). The written responses were used to organise the broader classification of student performance. The didactic exchanges were used to enhance and evidence the criteria for attainment of each performance index. Conclusions related to the performance indices and the associated criteria were triangulated using both data sources.

Results

Throughout the results section reference will be made to the summary of performance indices presented in table one. In keeping with the educative assessment framework the performance indices indicated in table one are directed at student development rather than a grade or mark. Following table one I evidence each performance index with examples of student work.

Table 1. Criteria for attainment of mathematics performance outcomes.

Performance indices	**Criteria for attainment of mathematics performance index**
Student's work exceeds curriculum expectations	The students is able to: • Identify and explore additional relationships and patterns in the number systems. • Offer informed additions or alternatives to the counting practices of a culture. The student does not impose these additions but is able to offer them as suggestions. • Identify similarities and differences between their own counting practices and the practices of other cultures. • Perform some of the four basic operations in unfamiliar counting cycles. • Create a multi-cycle counting system while engaged in one of the creative tasks (e.g. a 5 and 20 cycle system).
Student's work satisfies curriculum expectations	The student is able to: • Interpret the counting practices of the culture correctly and apply the practices consistently. • Recognise mathematical reasons for cultural counting practices. • Identify more than one possible solution when the information given about a culture's counting system is insufficient. • Describe the origins and progress of numerals in various cultures. • Translate numbers from other counting cycles to language of instruction and vice-versa. • Differentiate the properties of numerals in various counting systems. • Create all numerals in a 5 cycle counting system while engaged in one of the creative tasks.

Student is required to revise his/her effort.	The student: • Introduces additional features into the counting system that are beyond the features of the given information. • Demonstrates a careless inconsistency with the practices of a particular culture when counting or translating their counting system. • Creates a new word, without a cyclic nature, for every number while creating a cycle five counting system. Once a student has been requested to make revisions to their work their performance will then be classified as requiring additional learning experiences or satisfying the curriculum outcomes. • Only identifies the mathematical properties of individual counting systems. • Judges the relative size of the numbers based on the (syntax of the) words used within a language. • Made arithmetic errors in completion of the task.
Student requires additional learning experiences.	The student: • Develops procedures or counts in a manner inconsistent with the given information. • Develops an internally inconsistent counting strategy. This is most commonly demonstrated by an inconsistency between the numbers 1-10 and numbers larger than 10. • Reverts to a 10 cycle counting style while engaged in a counting system that is grounded on a different counting cycle. • Creates a non-cyclic counting system during one of the creative tasks.
Student requires attention to previous outcomes.	The student is unable to: • Express the structure of a cycle 10 number system. • Adopts an additive structure (e.g. Roman numerals) for a place value counting system.

Student's work exceeds the curriculum outcomes

David demonstrates performance that exceeds the expectations of the curriculum. He mathematically explored patterns in the postal bar codes.

I: Which other ones go together?

S: Zero and 1, 2 and 4, 3 and 6.

I: Does 2 and 4 go together?

S: No sorry 2 and 9, and 4 and 8.

I: And how about 7

S: 7 doesn't go with one.

I: They decided not to let 7 go with one. Which one does 5 go with?

S: None, it doesn't do with any either. Because 7, they can not because they have used all their

combinations up and if they do it exactly the same it will be the same as 7.

David identified that the bar codes for 0 and 1, 2 and 9, 3 and 6, and 4 and were mirror images of each other (lines 2 and 4). Furthermore he recognised that the bar codes for 5 and 7 were mirror images of themselves and that all possible combinations were used in the construction of the 10 digits (line 8).

Student's work satisfies the curriculum expectations

The criteria outlined in table one for this performance index have been derived from two sources. The stated curriculum outcome formed the initial foundation of this index. Secondly, students' work that provided evidence of satisfying the curriculum outcome but that was not specifically stated in the language of the curriculum was included. For example, the ability to identify more than one possible solution when the information given about a culture's counting system is insufficient (table one).

I: Jabo, tell me what you've done there?

J: These, Nahuatl, of Mexico they like use five, a multiple of five then add-on other numbers. So you can see we wrote here **six means five plus 1**, and then 15 is a multiple of five and 20 is just 20 because it's a multiple of five, but when you want to **say 51 you go 2 times 20 then you add 10 plus 1**. 2 times 20 is 40 plus 10 is 50 plus 1

I: And how about 56.

J: Okay, 2 times 20, then you write plus, you could write plus 10 plus six. Or you could write 15 plus 1.

I: Which one do you think they do?

J: Plus 15 plus 1

Jabo consistently applied the examples of the counting practices of the Nahuatl provided in the task to the questions posed. He provided an appropriate response for 6 and 51 (line 2). The examples provided gave an inconclusive process for constructing 56. Jabo provided two possible solutions (line 4) and then (correctly) decided on the solution he thought was closest to the examples provided (line 6).

Student is required to revise his/her effort.

In a number of cases students' work required revision or additions. This performance index does not suggest that the student will undertake the required revisions independent of the teacher or other forms of assistance. An example to illustrate the index has been taken from a student's work on the Yoruba counting system. The student had correctly completed the other questions but had written 16 as 15+1 rather than "4 from 20" as suggested by the examples in the task. I intervened to encourage her to revisit this problem.

I: What does their 15 mean?

S: 15, they have got eedogun.

I: And what does that mean in English?

S: 5 from 20, so may be, I see there minus that

I: Yes, so what do you think they would do with 16?

S: To get to 16, they would say 20, no 4 from 20, minusing so there would be 20 minus four.

The student was able to revise her response (line 6) based on the probing questions I posed during the didactic exchange. Without further learning activities, but with appropriate intervention the student was able to correct her response.

Student requires additional learning experiences.
This performance index was applied when the nature of the students' errors suggested that additional learning experiences in this area might be most appropriate for their continued development. To illustrate this index I have used students' inconsistencies and the students' penchant for using a 10 cycle counting system (table one).

Inconsistencies: In the Nahuatl Counting task students wrote (in English) the numbers 50 to 60 as they thought the Nahuatl people would describe them. One student provided the inconsistent response given below.

50 = 10 + 40	51 = (2*20) + 10 + 1
52 = (10 * 5) + 10 + 2	53 = 25 + 25 =50 + 3

The student continued to apply an erratic collection of strategies to describe the numbers up to 60. The strategy used by the student was therefore classified as internally inconsistent. Considering that all counting systems demonstrate an internal consistency, this student required additional learning experiences. Similarly some students' strategies were internally consistent but were not consistent with the examples provided on the worksheet (e.g. 36 means 20+(15+1) and 51 means (2×20)+(10+1)). This is evidenced in the example below.

50 = 50	51 = 50 + 1
52 = 51 + 1	53 = 52 + 1
54 = 53 + 1	55 = 55 etc.

Reverting to a 10 cycle strategy: In the Yoruba Counting task students were asked to provide the English equivalent for the Yoruba numeral for 55 (5 from 3 times 20) and 100 (5 times 20). Examples of students' responses are given below:

55 = 10 * 5 + 5	**100** = 10 from 10 * 11
= 5 from 6*10	= 10 * 10
	= 10 *2 * 5

These students had reverted to a 10 cycle counting strategy possibly because it was more familiar. The given 5 and 20 cycle system was applied to smaller numbers but discarded for 55 and 100.

Student requires attention to previous outcomes.
This index is used as a description for students who demonstrated a lack of understanding of the counting system used in the language of instruction. As illustrated in table one, it is primarily evidenced by students who introduced an additive counting style rather than adopt the learned place value system.

For example, in the Yoruba Counting task students were asked to write the Yoruba word for 35. A number of students wrote "ogun eewaa aarun" which literally means 20, 10 and 5. The Yoruba people would have used words that mean "5 from 40."

Conclusions

In the reported educative assessment tasks students had an opportunity to engage various culture's counting strategies as an initial experience for developing an understanding of mathematics as a culturally situated activity. Table one provides a summary of the students' capacity to engage such tasks and is intended as a starting point for teachers as they attempt to assess students in the new curriculum. The effectiveness of educative assessment as a means to include the cultural nature of mathematics in the school mathematics curriculum continues to be investigated.

A LONGITUDINAL STUDY OF CHILDREN'S THINKING ABOUT DECIMALS: A PRELIMINARY ANALYSIS

Kaye Stacey and Vicki Steinle
Department of Science and Mathematics Education
The University of Melbourne

Abstract

This paper reports preliminary results of a longitudinal study of children's understanding of decimal notation. A large sample of students completed a short test that enabled their understanding to be classified into four categories and changes over periods of up to two years to be tracked. When they attained expertise, students almost always retained it, even if it is simply following memorised rules. A small core of students retains "longer-is-larger" misconceptions. In contrast, students seem to move in and out of "shorter-is-larger" misconceptions. Improvements and hypotheses to be investigated in the future are noted.

Introduction and Background

It is now well documented that many students throughout schooling and indeed many adults have difficulty understanding the notation used for decimal fractions. The recent Third International Mathematics and Science Study showed that internationally about a half of 13 year old students could select the smallest decimal number from a multiple choice list of five decimals (data held at the Australian Council for Educational Research). Similar results have been known for many years in several countries. The aim of this paper is to present preliminary results from a longitudinal study that is tracing the development of students' thinking about decimal notation. This is of interest in its own right because being able to interpret decimals is important in a variety of everyday contexts (e.g. interpreting digital displays and calculator answers) as well as for mathematical tasks such as rounding and using significant figures. It is also a case study of how students' understanding and misunderstanding develops with progress through school and in the context of various types of instruction.

There are several ways of classifying the erroneous rules that students may apply when ordering decimals (Resnick, Nesher, Leonard, Magone, Omanson & Peled, 1989; Sackur-Grisvard & Leonard, 1985). The coarsest classification is that some students select "longer is larger" (e.g., deciding 0.125 is larger than 0.3) whilst others select "shorter is larger" (e.g., deciding 0.3 is larger than 0.496). Stacey and Steinle (1998), working with interview and written data, traced the various ideas behind

these erroneous rules, identified further misconceptions and developed a diagnostic test. This Decimal Comparison Test takes about five minutes and asks students to select the larger from 30 pairs of carefully chosen decimals. It enables ten patterns of thinking to be diagnosed. Some of these patterns of thinking are "longer-is-larger" misco ..ptions, some are "shorter-is-larger" misconceptions and others belong to neither of these. Steinle and Stacey (1998) present evidence that some misconceptions about decimal notation appear to be the result of instruction. In other cases, these misconceptions arise when ideas interfere with each other. Although future analyses will use the refined classifications, this paper reports student progress only in terms of four major categories:

- longer-is-larger misconceptions (resulting from any of five identified patterns of thinking and possibly others),
- shorter-is-larger misconceptions (resulting from three identified patterns of thinking and possibly others),
- apparent-experts (may possess excellent understanding or may apply correct rules not understood or may have an identified misconception (Steinle et al (1998))
- unclassified (since the criteria for classification are quite stringent, this large group includes students thinking about decimals in unknown ways and others who are inconsistent).

Cross-sectional data (see Figure 1, taken from Stacey and Steinle, 1998b) provides a picture of the incidence of various ways of thinking about decimal notation and how it varies with age. The Longer-is-larger category decreases from Grade 5 (32%) to Year 10 (5%), the trend suggesting that it is unlikely to be common in adult life. The Shorter-is-larger category plateaus at about 10%, which suggests that this general belief may continue into adulthood. The percentage of task experts also plateaus to about 60% in Year 10, which suggests that there are many adults who have difficulty understanding decimal notation. The task expert category of Figure 1 is somewhat smaller than the apparent-expert category used in this paper, because students with identified misconceptions have been removed from it and placed with unclassified students to form the category "Other". This adjustment is of the order of 5% and so Figure 1 can be taken as a reasonable guide to the number of students in the four categories used in this paper. This paper moves from the cross-sectional analysis to the beginning of a longitudinal analysis, which traces the movement of individuals in the overall data and reports on two questions:

- do students stay in the same category or move frequently from one to the other?
- what are the common paths through the misconceptions to attaining expertise?

The longitudinal sample and testing

This section presents preliminary results of the longitudinal study from 1995 to 1997. The sample was originally selected to contain a good mix of schools and to maximise the possibility of following students when they changed from primary (Years 0 to 6) to secondary school (Years 7 to 12) at approximate age 12 years. It consists of classes from:

- one state secondary school in a low socio-economic area and its three "feeder" primary schools,
- one church secondary school in an middle socio-economic area and its main feeder primary school,
- one private girls school in a high socio-economic area with both primary and secondary students,
- two large state primary schools situated in the same middle socio-economic area and the two high schools to which their students mainly progress and
- one church girls' secondary school in a high-middle socio-economic area.

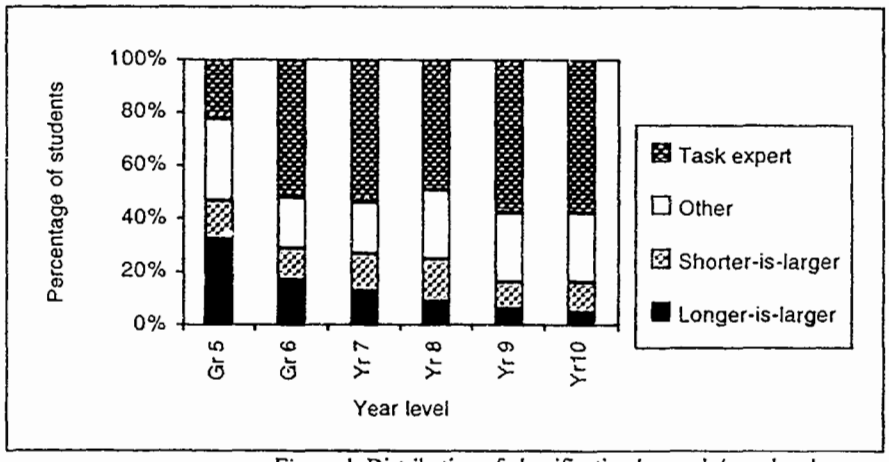

Figure 1: Distribution of classification by grade/year level

Students were tested with the Decimal Comparison Test at most once every six months, making a total of five testing times in the data under consideration, from the end of 1995 to the end of 1997. However, schools tested less often than this, for various reasons including different dates for joining the program. In this period, no individual student or class completed the test more than four times. The year level distribution of students is shown in Table 1. Note that many students are counted more than once, some up to four times each. In total, 5383 tests have been analysed, although there is no longitudinal data yet for many students. The large numbers in the lower year levels is due to selecting students whose progress could be followed until 1999.

Table 1. Year level distribution of students completing test 1995-1997

Year level	Year 4	Year 5	Year 6	Year 7	Year 8	Year 9	Year 10	Total
Number of students	336	965	874	1690	658	497	363	5383

The number of students who have completed the Decimal Comparison Test exactly one, two, three and four times is shown in Table 2. The students who have completed only one test play no further role in the analysis in this paper, as it aims to track change of individuals from one test to others. For this analysis, the first time an individual undertook the test will be called Test 1, the second time will be called Test

2 and so on. The tests are numbered for the individual, rather than by the date administered. Therefore for some students Test 1 was in 1995 while for others it was in 1996 or 1997. For some students, Tests 1 and 2 have been taken six months apart, whereas for others they may be one year or even 18 months apart if the student was absent on some testing days. This is an unsatisfactory feature of this preliminary analysis that will be addressed in subsequent work.

Table 2. Number of students by number of tests completed.

Number of tests	One test	Two tests	Three tests	Four tests
Number of students	1590	1198	307	119

Results

Changes of classification over consecutive tests.

Table 3 illustrates the changes in classification that occur over consecutive tests. The abbreviations A, L, S and U refer to apparent-expert, longer-is-larger, shorter-is-larger and unclassified groups, respectively. The cross-tabulation shows the movement of students who have tested in one category to other categories at the individual's next testing. The numbers are amalgamated from all tests. The data is therefore from Test 1 followed by Test 2, from Test 2 followed by Test 3 and from Test 3 followed by Test 4. As noted above, these changes are mostly over a period of about six months, but will also include changes over longer periods where students missed out on intermediate testing. This anomaly in the data will be eliminated when the final analysis is done, to give a better measure of change over six months.

The 426 students who have done the test more than twice contribute several times to the data. To illustrate, there were 165 instances where a student showed longer-is-larger thinking at one test and was an apparent-expert when next tested. Some of these individual students will have been tested again and contribute to the table again, in the group of 835 students who are apparent-experts on the prior classification.

Table 3. Changes in classification over consecutive tests (N = 2169)

Earlier classification	**Later classification**			
	A	**L**	**S**	**U**
A (N= 835)	732 (88%)	15 (2%)	29 (3%)	59 (7%)
L (N= 732)	165 (33%)	334 (46%)	94 (13%)	139 (19%)
S (N = 348)	125 (36%)	44 (13%)	120 (34%)	59 (17%)
U (N = 254)	98 (39%)	49 (19%)	50 (20%)	57 (22%)

Table 3 shows that from one test to the next, almost all of the apparent-experts stayed as apparent-experts and about one third of other students became apparent-experts. Nearly half of the longer-is-larger students (in fact two-thirds of those who did not become experts) re-tested as longer-is-larger. The shorter-is-larger students moved more than the longer-is-larger, but still about one third stayed in the same category.

Amongst those who did not become experts, over half remained as shorter-is-larger. As might be expected, the unclassified students spread most evenly across the other misconception categories. It will be important to repeat this analysis separating students by age group, as age is likely to be an important determinant of the speed and direction of change.

Changes of classification over at least one year.

Table 4 is similar to Table 3 except that it shows the changes in classification that occurred between testings typically at least twelve months apart. The numbers are amalgamated from Test 1 to Test 3 and Test 2 to Test 4. Therefore individuals who have been tested four times (there are 119 of these) contribute twice to the 545 comparisons in the table. The comparisons in this table come from students across a wide age range. About two thirds of the sample were in Year 4 or 5 at first testing. The oldest was a small group tested once per year in Year 8, 9 and 10. Some of the data is over one year, from students who were tested regularly, but where tests were missed it is over a period of up to 2 years.

Table 4 Changes in classification over at least one year (N = 545)

Earlier classification	**Later Classification**			
	A	**L**	**S**	**U**
A (N= 135)	125 (93%)	2 (1%)	1 (1%)	7 (5%)
L (N= 271)	104 (38%)	94 (35%)	23 (8%)	50 (18%)
S (N = 80)	44 (55%)	9 (11%)	19 (24%)	8 (10%)
U (N = 59)	25 (42%)	14 (24%)	8 (14%)	12 (20%)

Table 4 again shows that almost all of the apparent-experts re-tested as apparent-experts whilst about two-fifths of longer-is-larger students and unclassified students and over a half of the shorter-is-larger students became apparent-experts. This is consistent with shorter-is-larger thinking being somewhat more sophisticated than longer-is-larger thinking. Of those classified students who do not move to being experts, most stayed in their original category (56% of longer-is-larger and 52% of shorter-is-larger) but there was some movement into other misconception categories, not just towards expertise. The unclassified students spread most evenly across the other misconception categories.

We had previously expected that it would be more likely that longer-is-larger students would become shorter-is-larger than vice versa, because we hypothesised that students may move into the more sophisticated misconception on the way to expertise. However, since movement is equally frequent in both directions in both Tables 3 and 4, the data does not support this hypothesis. A further analysis using the finer grained classification system and broken down by age is required.

Changes of classification over two years.

Table 5 is similar to the previous two tables except that it shows the changes in classification that occurred from Test 1 to Test 4. In this sample, the only students who had been tested four times were from the two large primary schools in the middle socio-economic area. They were all tested initially in Year 4 and for the fourth time in the second half of Year 6 or in Grade 5 initially and for the fourth time in the second half of Year 7, when they had moved to a nearly secondary school. For this reason, the Table is labelled as indicating changes over two years.

Table 5. Changes in classification over two years (N = 119).

Earlier Classification	**Later Classification**			
	A	**L**	**S**	**U**
A (N= 16)	16 (100%)	0 (0%)	0 (0%)	0 (0%)
L (N= 74)	46 (62%)	10 (14%)	5 (7%)	13 (18%)
S (N = 11)	9 (82%)	2 (18%)	0 (0%)	0 (0%)
U (N = 18)	15 (83%)	0 (0%)	2 (11%)	1 (6%)

Table 5 again shows that all the students who were apparent-experts at first testing stayed as apparent-experts. These students are likely to have been among the most able students (having achieved early expertise in Year 4 or Year 5) so it is not surprising that they test again as experts at the fourth testing. Most of the shorter-is-larger and unclassified students became apparent-experts over the two years, which again supports the observation that these students have more sophisticated thinking than the longer-is-larger thinkers. In the latter group, only about two in three achieved apparent-expert status. At this level of analysis, there is no evidence to support the hypothesis that students who tested initially in one category, but do not move to expertise, stay over two years in the same category. However a closer look at the initially longer-is-larger students who move to the unclassified category is warranted. Because of the strict definitions employed for categorisation, it is possible that some of the 18% of formerly longer-is-larger students may still hold broadly longer-is-larger ideas yet not meet the criteria for that classification. This analysis would give a better insight into whether these students are essentially stuck in the one category or are on the way to expertise.

How representative is this group of students who have done the test four times? There are several reasons why they may be a better group than the rest of the sample. To be present on the four days of testing indicates that are likely to be regular school attenders with relatively stable schooling. The fact that their teachers have made the effort to test four times indicates commitment on their part. By Test 4 in Years 6 or 7, there are 86 (72%) apparent-experts and only 12 (10%) longer-is-larger thinkers. These proportions do indeed seem somewhat better than the proportions reported previously for the whole sample and summarised in Figure 1 above. This bias will require careful treatment in the next analysis.

A first attempt at following individuals

Table 6 is an initial view of the paths that students take through a series of tests. It displays data from the 119 students who completed the test four times (the same data set as Table 5). As noted above, these students were either in Year 4, moving through to Year 6 or in Year 5 moving through to Year 7. Each cell shows the number of students in the category at that particular test. There are, for example, 86 students (72% of the total of 119) testing as apparent-experts at Test 4. At Test 1, 16 students tested as apparent-experts. The table also records that all 16 of these were apparent-experts at Test 4. Similarly there were 34 apparent-experts at Test 2 and 32 of these individual students were apparent-experts at Test 4. Combining the information in Table 6 with the data in Tables 3, 4 and 5, we see that there is very little movement out of the apparent-expert category, suggesting that students retain knowledge of how to complete the test.

Table 6. Numbers of individuals in each category at each of the four testing times and, in brackets, the number of those students who retested in the same category at Test 4.

	Test 1	Test 2	Test 3	Test 4
Apparent-expert	16 (16)	34 (32)	48 (45)	86
Longer-is larger	74 (10)	48 (6)	33 (8)	12
Shorter-is-larger	11 (0)	23 (4)	19 (2)	7
Unclassified	18 (1)	14 (2)	19 (7)	14

Most of the students who have tested as longer-is-larger initially have also become experts by Test 4. The number in this category steadily reduces. However, Table 6 indicates that there is probably a small core of students who remain persistently in the longer-is-larger category. This will be further investigated with the finer grained analysis and is expected to be a larger effect in a less selective sample.

The shorter-is-larger category shows a different pattern. This category grew in Tests 2 and 3, but the low numbers who persisted in this category in Test 4 indicate that students move in and out of it over time. This is consistent with our experiences when we interviewed students from a class of Grade 5 and 6 students (not in this sample). These students had recently been studying fractions and so it seemed that the number of shorter-is-larger students who interpreted decimals as fractions (reciprocal thinkers) was inflated by the recent experience. The pattern of pathways for students who are unclassified seems similar to the shorter-is-larger pattern.

Discussion

The purpose of this paper was to report a preliminary analysis of data showing students' progress in their understanding of decimal notation. Several ways in which the analysis can be made more revealing have been highlighted: by following individuals, by following classes so that teaching effects can be observed, by

separating the analysis by age group and by using the finer classification system. This will be done when an extra year has been added to the data set, so that there are more long runs of data from individuals and more histories of intact classes.

The preliminary analysis has provided the following results to be confirmed later. There is quite marked stability of classification. Of course there is a general trend towards expertise, but those students who do not achieve expertise tend to remain in the same category. Even after a passage of at least a year (i.e. first to third test) about half of the students retaining a misconception are classified in the same way. This is a significant result given the stringency of the classification criteria and it confirms our informal data (from interviewing previously classified students) that the test, although taking only a few minutes, is highly reliable.

Students in different classifications behave differently. Apparent-experts nearly always stay in this category. This would be expected of students who "really understand" decimals. However, at least in the context of this test, the skill of decimal comparison is well retained even by those who use a rote-learned rule (e.g. compare digits from left to right or add zeros).

A small group of students seem to persist in the longer-is-larger category. On the other hand students seem to move in and out of the shorter-is-larger category and are more likely to move to expertise. Unclassified students are similarly likely to move towards expertise, contrary to a previous finding on a group of 50 students (Moloney and Stacey, 1997) they were more likely to move to expertise than the shorter-is-larger students. Following individual paths will help in unravelling students' thinking further and eventually providing better guidelines for teachers.

Background

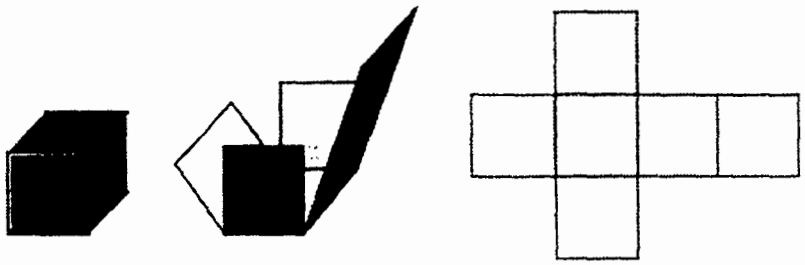
Many scholars have argued that visual and imagery based processes play an important role in mathematical learning, problem solving and reasoning (e.g., Clements & Battista, 1992; Dreyfus, 1992; Hershkowitz, 1989). A full understanding of the nature of students' mathematical competence and creativity requires examination of not only computational and logical problem-solving abilities, but also associated visual skills. Spatial transformation tasks have long provided a useful medium for investigating students' visual processes related to mathematical competence.

Translating between three-dimensional solids and their two-dimensional representations is one kind of processing that is particularly important to mathematics. Michelmore (1980) argues that "it is of great value to be able to visualize and represent three-dimensional configurations and to comprehend the geometrical relations among the various parts of a figure." In particular, problems related to the *development of solids* afford students opportunities to develop the visual skills mentioned by Michelmore. Problems of this type often require students to make translations between 3D figures and their 2D *foldouts* or *nets* by focusing on the relationship among the various parts of the solid both in 2D and in 3D. A net is a diagram of a hollow solid consisting of the plane shapes of the faces so arranged that the cut-out diagram could be folded to form the solid (Borowski & Borwein, 1991).

Even though problems regarding nets are included in some textbooks and on some assessments, only a few research studies have examined students' reasoning about nets. These studies (e.g., Bourgeois, 1986; Little, 1976; Mariotti, 1989; Potari & Spiliotopoulou, 1992) indicate either that students' thinking about nets is affected by the complexity of the geometric figures and/or that some nets of a given solid (e.g., a cube) may be more difficult than others. However, the reasons for these variations in difficulty of tasks related to nets are not clear. Mariotti (1989) hypothesizes that "constructing the correct net of a solid implies coordination of a comprehensive mental representation of the object with the analysis of the single components (faces, vertices and edges)" (p. 263). The findings of her study support this hypothesis as students appear to be more

* The work reported in this paper was supported in part by a grant to the University of Pittsburgh from the National Center for Improving Student Learning and Achievement at the University of Wisconsin for the Benchmarks of Student Understanding (BOSUN) Project. The award was received through the Educational Research and Development Centers Program (PR/Award Number R305A6007) administered by the Office of Educational Research and Improvement, U.S. Department of Education. The opinions expressed herein are those of the authors and do not necessarily represent the positions of the Center, the Office of Educational Research and Improvement, or the U.S. Department of Education.

successful in recognizing those nets that require only relatively few transformations from the solid to the net. However, there is little information with respect to how students coordinate and analyze the components of a 3D solid when transforming it into a 2D net or vice versa.



The purpose of our study was to build on previous findings and to deepen our understanding of students' work on problems which involve translations between 3D figures and their 2D net-representations. We focused on students' problem-solving strategies when *constructing* different types of nets. It is important to know the approaches that students take when faced with a task that requires them to construct (and not only recognize) different nets for a given solid and to examine the difficulties related to each type of net with respect to the strategies students use.

Method

The task shown in figure 1 was administered to eight eighth-grade students in the U.S. in a clinical interview setting[1]. It can be shown that there are only 10 possible nets for a cube (figure 2). Previous studies (Mariotti, 1989) have shown that the E-net is the most intuitive and familiar, and therefore, it was chosen to serve as the example for this study. Each student was asked to think aloud, and to explain each stage of his or her solution processes. All interviews were audiotaped and detailed notes were kept for each student's work.

Make a Net

The picture shows a closed cube that can be opened up to give a net:

One can open up a cube in many different ways and get different nets. In the space below draw ***different*** nets that could have come from a closed cube. If you find it necessary you may use the model of a cube.

Figure 1: The task used in the study

Each student was first given the task without any manipulatives, and was asked to solve and explain the problem. When students were no longer able to make progress in this way, they were offered cut-out manipulative nets to use. In the first case, we say that the students worked in mental mode (M-mode). In the second case, we say that students worked in concrete mode (C-mode). When working in the C-mode students were allowed to cut and tape a net or a cube in any way they preferred (a cube could be obtained by folding and taping a cut-out

[1] This was the first of six tasks related to nets that were given to students. Students had approximately one hour to solve all six tasks and the time each student allocated to each task varied.

net using the inverse procedure of the one demonstrated in Figure 1). Students' responses were analyzed for the students' solution strategies and the mode in which the students worked (M- or C-mode).

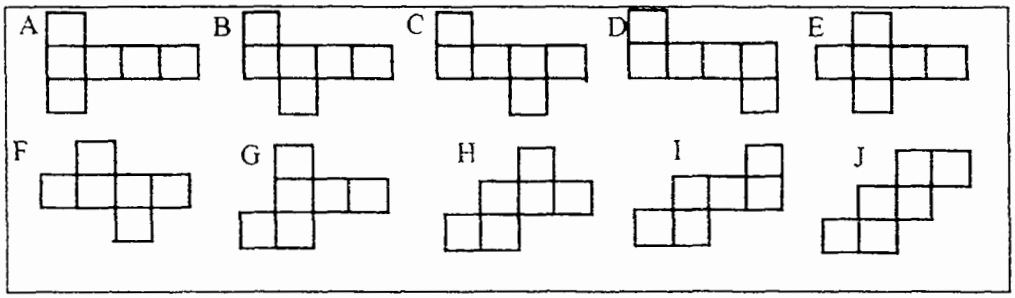


Figure 2: The ten possible nets for a cube

Results

All eight eighth-grade students produced a net while working in the M-mode, and most produced several more nets in M-mode. Seven students also obtained nets in C-mode. The students produced an average of about five nets each.

Two main approaches to the problem were observed: working in 3D with the cube, and working in 2D with the net. When *working in 3D* students indicated verbally or with hand movements that they were attempting to produce different nets by unfolding the cube in different ways. For instance, students indicated that they opened up the cube as is shown in figure 1, or by "rolling" it into a net. Students could work in 3D either mentally (mentally visualizing the unfolding of the cube and noting the resulting net) or with the use of concrete materials (literally cutting a paper cube in different ways and showing the resulting net). When *working in 2D* students focused on producing a net on the 2D plane and then translated that net into a cube. Once again, students could work in 2D either mentally (drawing a possible net and then mentally checking whether this can be folded up to form a cube) or with the use of concrete materials (by taping together paper squares to form a net and folding them up into a cube).

Furthermore, when choosing to approach the task either from a 2D or 3D perspective, students demonstrated that they could use different strategies which could be roughly classified under two categories: *trial-and-error strategies*, and strategies involving *systematic changes of either the net or the cube* (Table 1).

The most interesting strategies are those in which a systematic way of producing nets was used. As table 1 indicates, students used systematic ways to solve the problem in both 2D and 3D. The first systematic strategy we observed in 3D was to unfold the cube in different ways; this was used both by students who worked in the M-mode and by students who worked with concrete materials in the C-mode. The second systematic strategy in 3D was only used by students who worked in C-mode. In this case, students built a cube with a face missing and then systematically taped the cut-off face to different edges in order to obtain different nets. For example, when RA cut off one of the faces and formed "a cube with a missing face", say the front face, he systematically connected the cut-off face first to the bottom edge and then to the right edge. Each time the student would open up the cube to obtain a new net. Students who employed this strategy appeared to

have a good understanding of the concept of a net, how it can be formed, and how it can be changed.

Transformations in 3D	Transformations in 2D
a Systematic changes of a cube - systematically fixing different face of a cube as a bottom and unfolding the cube to obtain the new net - removing one or more of the square faces of the cube creating a partial net cube (a cube with missing face(s)) and considering how the cut-off face(s) can be connecin a way that it would result to a new net	*a. Systematic changes of a net* - keeping four squares attached together in a row and moving the other two squares (one on the top the other underneath) around that row (nets A - F in figure 2) - fixing one square as a "bottom" and moving the other squares accordingly - fixing a pattern of squares and adding more around
b. Trial-and-Error - randomly unfolding the cube and checking whether this action resulted in a new type of net.	*b. Trial-and-Error* - randomly drawing or connecting together six squares and checking to see whether these would fold up to a cube.

Table 1: The different strategies used by the students

In 2D the most commonly used systematic way of changing the net was to move squares around a given pattern. Similarly to the students who realized that by connecting a face to different edges of an open cube resulted to different nets, students who engaged in this strategy realized that by connecting a square next to different parts of a partial net they may produce different valid nets.

Five students chose to draw/construct a "line-of-4" and to systematically move the two remaining squares along that "line-of-4" (figure 3). This strategy occurred both in the M- and the C-modes. Some students were able to justify their strategy and the validity of the nets they produced by explaining that the "line-of-4" connected squares when folded wraps around to create a "cube with missing sides" and the two squares can be attached anywhere along each of the sides to create the "missing sides" of the cube. In this case, students appeared to be confident about the effectiveness of their strategy, and often did not worry about checking the validity of the nets they produced. We must also note that despite the fact that five students seemed to be drawn to this strategy, none of them completed the systematic construction of all six nets (A-F nets) which can be constructed using this strategy.

Another common systematic strategy for producing nets in 2D was to perform rotations and reflections of a net. Students constructed nets that were obtained by rotating or reflecting a net that they constructed. Most of the students who drew or constructed nets that were only rotations or reflections of one net indicated that they understood that their nets were not different from each other and that they could actually be obtained by moving a concrete net around the table. For these students the drawing of rotations or reflections of any net was probably a response

to the requirement of the problem to produce as many nets as possible. Thus, they drew rotations or reflections of each new net they produced. Some students, however, did not appear to identify the equivalence between a net and its rotations.

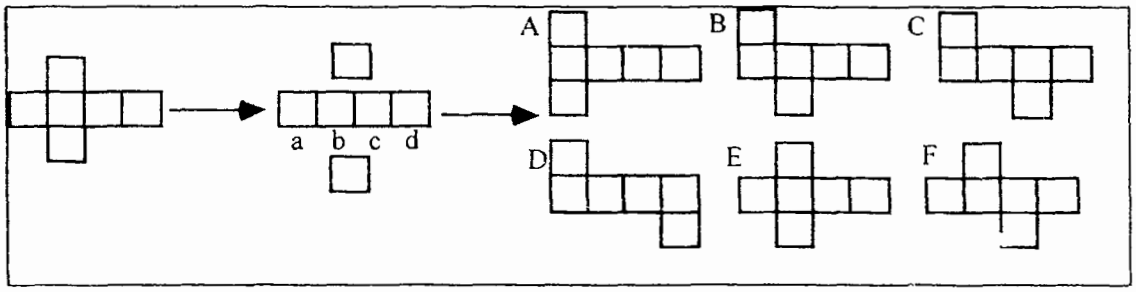

Figure 3: A systematic construction of nets A - F

A second goal of this study was to identify which are the nets that present students with the most difficulty, and also to identify the strategies that students use to obtain the "difficult" nets of the cube. Previous research (Little, 1976, Mariotti, 1989) indicated that students find the E-net to be the easiest. Mariotti (1989) in particular, suggests that the number of transformations on each element of the cube as it is "unfolded" represents an index of difficulty. The E-net is easy because it can be straightforwardly "opened up" (as shown in figure 1), while, for instance, to obtain the D-net one needs to "follow a "rolling" strategy where the composition of more transformations is involved" (Mariotti, 1989, p. 262).

Since we gave students an E-net as part of the task, it is not possible to confirm Mariotti's findings directly. But it is interesting to note that almost all of the students produced an E-net as one of their solutions. Table 2 shows all the nets that each of the students in our study produced in the order they produced them, and also describes the mode (mental or concrete) and the strategy they used to produce each net (for example, student ST produced 3 nets: A-, B-, and G-nets. The first two, A- and B-nets were produced in M-mode while she systematically moved two squares along a "line-of-4" squares in 2D. The G-net was produced when she mentally unfolded the cube in a way that was different than the one shown in figure 1). As the table indicates, half the students (SD, RA, CJ, and AH) responded to the task by first re-producing the E-net. Their verbal protocols suggest that they mentally unfolded the cube in the most straightforward way, thus, confirming the first part of Mariotti's findings.

In Mariotti's study, though, students found the second net (here indicated as the D-net) to be difficult. Mariotti explained this difficulty by stating that "the case of type [D] figures [are harder] because in the process of reconstruction each element is transformed many times successively. To solve the task it is necessary to follow, in one's own mind, the transformations of the single element, so that the number of transformations represents an index of difficulty. As a remark it is interesting to observe that the presence of a symmetry in the situation is not always noticed and used" (p.264). However, the D-net, was not as difficult for students in our study as Mariotti's results would have predicted. Along with the A-, B-, C-, E-, and F-nets, this net was also relatively easy for students to produce. In fact these are the nets that students were more likely to produce first (not considering the E-net that was

already given). Apparently, the unexpectedly common use of the systematic strategies in 2D, particularly the use of the "line-of-4" strategy, in which students kept four squares attached together in a row and moved the remaining two squares along those four, helped students easily obtain these nets, without having to resort to translations between the 3D cube and the 2D nets.

Name	Nets	Mode	Strategy	
ST	A, B, B	M	Moves 2 squares along line of 4	2D systematic
3 nets	G	M	Unfolds a cube systematically	3D systematic
SD	E, E, E, E	M	Unfolds cube randomly	3D trial and error
5 nets	C, B, D, A	C	trial and error	2D trial and error
RA	E,	M	Unfolds cube randomly	3D trial and error
7 nets	B, B, C, F, A	M	Moves 2 squares along line of 4	2D systematic
	G, H, C	C	Unfolds cube with missing face	3D systematic
AW	A, E	M	Unfolds cube randomly	3D systematic
4 nets	D, B	C	Moves 2 squares along line of 4	2D systematic
	Two incorrect nets	C	Trial and error	
VR	A, B, C, D, E, F, J	M	Moves 2 squares along line of 4	2D systematic
9 nets	Incorrect net	C	Trial and error	2D trial and error
	G, H	C	Corrects the previous error	2D systematic
AM	A, E, E, A, A,	M	Moves 2 squares along line of 4	2D systematic
7 nets	C, F, B	C	Moves 2 squares along line of 4	
	G, G, H, H	C	Trial and error	Trial and error
CJ	E	M	Unfolds cube randomly	3D trial and error
3 nets	H, G, G	C	Trial and error	2D trial and error
AH	E, E	M	Unfolds cube randomly	Trial and error
3 nets	H, G, Incorrect net	C	Trial and error	

Table 2: Distribution of nets students produced with respect to the types of the nets and the strategies used

Table 2 also indicates that the most commonly produced nets were the A and B (6), G (5), C and H (4), D and F (3), and J (1) nets. None of the students produced any I-nets. However, when we look at the strategy that students used to produce these nets, it is clear that when students worked systematically (i.e., the nets were not produced accidentally) then they were more likely to produce nets that maintained the "line-of-4" characteristic rather than other types of nets. The A-net, one of the most commonly produced nets, was also the net that was produced first by half of the students. It was produced by all the students who systematically changed the net either in 2D or in 3D. In fact, 5 of the 6 students who produced this net did it while making systematic changes to nets in the M-mode. Finally, it is interesting to note that, while nets A, B, C, D and F were most commonly produced when students worked systematically, nets G and H were produced by trial-and-error as frequently as they were produced systematically (see Table 3).

	A	B	C	D	F	G	H	I	J
Systematically	5	5	3	2	3	3	2	--	1
Trial & error	1	1	1	1	--	2	2	--	--
Total	6	6	4	3	3	5	4	--	1

Table 3: Distribution of nets with respect to production strategy

Discussion

One of our goals for this study was to examine the difficulties related to this task with respect to the strategies students use. Brown and Wheatley (1997) argue that students' ability to decompose and recombine images, that is the ability to break down a visual image into simpler parts and then recombine those parts into new images, is an important component of imagery in problem solving. Indeed, in the problem under consideration, it was necessary for students to notice that the given net is composed of squares that can be separated from one another and recomposed again into a different formation. However, our students did not simply decompose the net into squares. Rather, the most successful students worked using patterns of squares in a systematic manner. In fact, our students used primarily one specific pattern, the "line-of-4" pattern. Hershkowitz (1989) identified three types of visual reasoning when introducing and understanding mathematical concepts: (a) based on the whole figure, (b) based on non-critical attributes, and (c) based on critical attributes. The results of our study support the findings of Hershkowitz in the context of reasoning about correspondence between 2D and 3D representations of a cube.

Those students who attempted to find a systematic way of producing new nets focused on finding some critical characteristics of the net that remain invariant in all the nets and correspond to critical characteristics of the solid. It may be the case that students perceived the "line-of-4" as a core invariant characteristic of the cube-net; when folded-up this line of squares forms the core of the cube while the two other squares fill in two empty faces. Further, it is possible that students also perceived the "line-of-3" (perpendicular to the "line-of-4" in the given E-net - figure 1) as another critical characteristics of the net. This may explain the frequency in which students produced an A-net (the A-net maintains both characteristics) and produced it first.

Further we may attribute the common production of the G-net to the students' attempt to maintain the invariance of the "line-of-3" characteristic (the G-net is the only one among those that do not maintain the "line-of-4" that maintains the "line-of-3"). The hardest nets to obtain in the M-mode were the I- and J-nets, those that do not maintain either of the two salient, and presumed by the students to be constant characteristics of the E-net. Similarly, the drawing of symmetric equivalent nets can be attributed to an attempt to find and use more invariants in the net. When students focused on finding and fixing as many invariant characteristics as possible, students produced equivalent nets (notice, for example, how AM produced multiple copies of the A-net when working systematically – see Table 2).

Finally, another issue that deserves attention is the fact that none of the students who chose a systematic way of approaching the task completed the construction of all six nets (A-F nets) which can be obtained using this strategy. This could be due to the limited time that students had to solve the problem. Nonetheless, this issue brings up questions regarding students' ability to work systematically when faced with problems that are highly visual or spatial. Despite the fact that in six cases students attempted to use systematic ways of producing nets (five in 2D and three in 3D; two student worked systematically both in 2D and 3D), their attempts were often disorganized resulting in the omission of some nets and the reproduction of others. The difficulty that students faced in approaching this problem systematically is an area that deserves further investigation.

COMPARING STUDENTS' RESPONSES TO CONTENT SPECIFIC OPEN-ENDED AND CLOSED MATHEMATICAL TASKS

Peter Sullivan, Elizabeth Warren, Paul White

Australian Catholic University

The results reported here are one component of a larger project that seeks to explore a range of aspects of the classroom potential of content specific open-ended tasks. We propose a way of discussing such tasks, and justify our focus both on open-endedness and the focus on content. In particular we compare the responses of students to comparable closed and open-ended tasks, and also explore the effect of using specific contexts for such tasks. We propose a method for exploring differences in facilities of open-ended and closed tasks and suggest that both types of tasks can contribute to effective classroom programs.

The research is based on three assumptions: tasks are the critical prompts for mathematical activity, tasks that are to some extent open are more likely to produce rich activity (Christiansen & Walther, 1986), and explicit attention to mathematics is a key characteristic (Cyril, 1998).

This is an investigation into the student responses to tasks which are, on one hand, open-ended to stimulate high quality thinking, and, on the other hand, content specific to emphasise the mathematics being learned. It is intended to make inferences from the results on the potential of such tasks both for classroom use and for assessment.

Open-ended Tasks

There is no agreement on classification of tasks. The following discussion seeks to situate the tasks used as the focus of this investigation in the context of other related tasks, and to clarify some terms and the way we use them.

We use the word *task* rather than the more common word *problem*. It is possible to have problems that are closed, and it is also possible to have open tasks that are not problems in that a solution path is known to the student, but which nevertheless provoke rich mathematical activity.

We take the *task* to be the statement presented to students that serves as the prompt for their work. Their *activity* is the thoughts and actions in which they engage in response to the prompt. The *goal* is the result the students seek as a product of their activity in response to the task statement. Each has the potential to be open or closed. *Closed* implies there is only one acceptable pathway, response, approach, or line of reasoning. *Open* refers to the existence of more than one (preferable many more than one) possible response.

While the direction of the *activity* can be fixed or closed we are only interested in tasks that stimulate open activity – that is, students will ordinarily follow different

1414

approaches to the task goal. Tasks that stimulate closed activity may well contribute to a effective mathematics curriculum. Nevertheless, we see that at least some opportunities for working on tasks that stimulate open activity by students are important. We suspect that open activity fosters some of the more important aspects of learning mathematics, specifically investigating, creating, problematising, mathematising, communicating, and thinking, as distinct from merely recalling procedures.

Our focus then is on open goals, and we use the term *open-ended* to describe tasks that have such goals.

We recognise that tasks that have open statements contribute to a broad and rich curriculum and have potential to make a significant contribution to mathematical learning. Examples include investigations (Wiliam, 1998), the use of problem fields (Pehkonen, 1997), problem posing (Leung, 1997), and the open approach (Nohda & Emori, 1997). Nevertheless this is an investigation of tasks that have a specific focus on aspects of the mathematics curriculum. The content specific nature of the tasks implies that the statements need to be closed.

Content Specific Open-ended Mathematical Tasks

There are a number of advantages of having the content focus explicit. One advantage is that the students' attention is drawn to the mathematics and so their learning may be more directed, as well as making the role of the teacher clearer. A further rationale for the content focus of these tasks is that, with the current attention to testing and explicit statements of curriculum outcomes in many countries, teachers feel an imperative to be able to identify the mathematics content being addressed.

The term *content specific open-ended tasks* can be illustrated by means of some examples:

A number has been rounded off to 5.6. What might be the number?

The mean height of four people in this room is 155cm. You are one of those people. Who are the other three?

Find two objects with the same mass but different volume.

We believe that such tasks make a useful contribution to a mathematics curriculum in that they:

- provide similar advantages to less content specific open-ended tasks, and even many of the advantages of tasks with open statements in that students can investigate, generalise, seek patterns and connections, communicate, identify alternatives;

- address conventional content explicitly and so are more easily integrated into mathematics curricula;

- have a teaching focus sufficiently similar to what teachers usually do and so are easy to implement; and

- provide a bridge to tasks with open statements for the students.

In earlier research on the use of such tasks, Sullivan, Clarke & Wallbridge (1991) found that:

- pupils can respond to such tasks at a range of levels especially if prompted by the wording of the task;

- the quality of response within a single grade levels varied, and that student responses improved in higher grades;

- students at all levels gave better answers to questions which drew on content which had been learnt some years previously;

- students can learn from the activity; and

- students often gave only one response even if they could have given more.

Sullivan, Bourke and Scott (1997) conducted a detailed investigation of a classroom implementation using a program based solely on content specific open-ended tasks. Most tasks posed were open-ended, and there were few teacher explanations. The students engaged in personal constructive mathematical activity and there were no management or organisational difficulties created by the approach. Observation of individual students and interviews confirmed these impressions and indicated that teaching based on open-ended tasks is suitable for both students who are confident at mathematics and for those who lack confidence.

It seems that open-ended tasks offer significant possibilities for stimulating the active involvement of students in learning and doing mathematics in classroom situations.

As it happens, there is some opposition to the concept of such content specific open-ended tasks. Becker and Jacob (1998) quote a Prof Wu who was critical, inter alia, of the following curriculum statement:

> Students understand and use the relationship between concept of perimeter and area, and relate these to their respective formulas. (Becker & Jacobs, 1998, p 6)

Wu claimed that "There is no relationship whatever between perimeter and area, ... unless it is the isoperimetric inequality" (Becker & Jacobs, 1998, p 6). Wu had previously (Wu, 1994) been critical of problems like:

> *If the perimeter of a rectangle is 30m, what might be the area?*

He claimed that since students could not give complete answers, the question should not be asked. We disagree. It is precisely the exploration to the link between perimeter and area that is the strength of this task. Indeed, the failure to compare and contrast the related concepts seem to be at the heart of many of the difficulties which students find in responded to perimeter and area questions.

Ultimately the worth of a particular task or task type can be judged on the quality of the responses which the students give, and whether they engage in thinking mathematically for themselves. That is the focus of this investigation.

Comparing Responses of Students to Open-ended and Closed Tasks

The results reported here are from a larger project that seeks to explore responses of students to comparable open-ended and closed tasks. This aspect of the project sought to compare responses of students to tasks that address similar content, and to explore the effect of situating tasks in particular contexts. These aspects have potential to inform understanding of the classroom potential of such tasks and particularly to suggest ways in which such tasks can be productively integrated with the rest of the mathematics program. The key variable is the quality of responses students give to such tasks.

Responses were sought from approximately 1200 students from schools in three Australian states. Data were also collected in Indonesia but these are not reported here. In each state, more than two schools responded to the tests. Classes were selected to maximise comparability by gender mix, socio-economic status, urban location, school size, and experience of the teachers. The responses presented are from students in Year 8 classes in each of New South Wales, Queensland, and Victoria.

Seven instruments requiring written responses were developed. Each differed according to the mix of open-ended/closed and context/context free tasks. In addition to seeking to compare responses to similar open and closed tasks, the test forms sought information on the effect of the use of contexts in the phrasing of the tasks. Generally, the same students completed more than one test form. Where possible the tasks were designed to be comparable with items from large-scale tests used elsewhere.

The tasks were piloted in three states to minimise difficulties with the wording, and to ensure that the content was compatible with the syllabi. From the pilot results we included a specific prompt to cue more than one response to the open-ended tasks. This has a disadvantage in classroom situations in that it may limit the potential for students to generalise answers. In this case, it gave us a better indication on whether students could produce multiple responses. We also found that the mix of tasks seemed to have little effect.

The tasks on each of the instruments were scored individually. The closed tasks were scored as either correct or incorrect. Each of the open-ended tasks were scored using the following codes:

i one or two correct responses
ii some correct, some incorrect
iii three or more correct responses

The tasks were basically grouped around three contexts: to gauge the effect of using *differing units* of measure; to ascertain children's understanding of the interrelationship between *perimeter and area*, and third to determine children's

understanding of the relationship between *embedded rectangles*. Only the results of the first of these are reported here.

In each case both open-ended and closed tasks were constructed, and each of these were posed in context and context free formats. The open-ended tasks used a prompt "give at least three answers" since during trialing we observed that many students were reluctant to give more than one response.

The following presents the results with tasks selected from various test forms to facilitate comparisons.

Responses to the *Differing units* Tasks

The tasks requiring the use of differing units were designed to be comparable to the following item taken from Department of Education (1991).

A rectangular rug has an area of 2 square metres. The rug is 40 centimetres wide. How long would it be?

5 m *8 m* *20 m* *50 m*

The Department of Education (1991) study reported that 52% percent of year 9 students responded correctly.

Table 1 presents the four tasks derived from this item, and shows the percentage of correct responses for each task.

Table 1
Responses to different unit *tasks*

Task	Type	Response Code	% of correct responses	n
A rectangle has an area of $2m^2$. It is 40cm wide. How long is it?	Closed No context	Correct	7	226
A rectangle has an area of $3m^2$. What might be the length and width of the rectangle? (give at least three answers)	Open-ended No context	i ii iii	8 6 9	226
A rectangular rug has an area of $2m^2$. The rug is 40 cm wide. How long is the rug?	Closed Context	Correct	15	315
A rectangular rug has an area of $3m^2$. What might the length and width of the rug?	Open-ended Context	i ii iii	11 10 23	315

The number of correct responses seems low, and certainly lower that the Department of Education (1991) question. Two possible explanations are that the one additional year of schooling makes a difference, and that the multichoice format made the earlier item easier.

More students responded correctly to the closed task when posed in context (although the facility is still very low) and when posed context free.

The responses to the open-ended tasks when posed in context are much higher than the context free ones. In context, 44% of students gave one or more correct responses to the context task, compared with 23% for the form which did not use the "rug" context. It seems that the rug context has assisted some students in this case.

In each case, the students gave more correct responses to the open-ended task than to the closed ones. It appears from the results that the open-ended task may have been easier than the closed task for these students. An examination of the types of responses for each task gives some insight into why the open-ended question seemed easier. The following presents responses given by of students who gave correct responses.

For the closed tasks:

some converted to 0.4 m then calculated correctly
a few converted to 20 000cm2
many converted 40 cm to 4 m
some converted both to "non standard units"

For the open-ended tasks:

all of those who gave one or more correct responses used 3m x 1m
many gave 1.5m x 2m as one of their responses
most other correct respouses used decimals in some way
some gave 2m x 1.5m as one of their answers

Nearly 50% of students gave a response that was correct numerically but used incorrect units. This suggests that the need to use compatible units of measure may have been the main source of difficulty.

Many students were able to give three responses. Even though there were still fewer correct responses to the open-ended task than one might hope, there were more than for the closed task.

Based on these responses, and on discussion on the elements of the tasks, the components needed for success on each were delineated. Figure 1 summarises the components, with the elements common to both items recorded in the middle column of the table.

Steps to solve the closed tasks only	Steps common to both tasks	Steps to solve the open-ended tasks only
Match information to dimensions	Visualise the shape(rug)	Select 2 numbers whose product is 3
Convert m^2 to cm^2 OR	Read	Recognise multiple possibilities
cm to m	Comprehend	Generalise
Do division	Formula for Area (A=LxW)	
	Reverse the formula (LxW=A)	
	Encode	
	Record	

Figure 1: Components for each task.

In this case, is possible that the closed task is more difficult because of the need to convert from one unit to the other and then to do just that. Difficulties with the units may have impeded students from exhibiting their understanding of the area concept. The open-ended task does not necessarily require unit conversion, and it seems that most students who responded correctly did so without converting. Hence, the open-ended task gave more information about students' understanding of area but gave little information about their facility with unit conversion. The use of an appropriate prompt may be needed to elicit this information.

In the classroom, the open-ended task may be useful for initial exploration of the area concept with either non whole number sides or mixed units, and the relationship between differing units of measure. The closed task seems to be potentially useful as an assessment item, assuming students have had the necessary unit conversion experiences. A brief analysis of texts at this level suggests that there are few exercises on area or perimeter that require unit conversion.

Conclusion

This part of the project sought to compare student responses to comparable closed and open-ended questions. One one set of data is presented here, but these concluding comments refer to all of the results.

One goal was to explore the effect of context on the students' responses. For the closed tasks, the context seemed to help for one set, but made no difference in tasks that included diagrams. It is possible that the diagrams performed a similar role to the context. For the open-ended tasks, the context helped for two sets, but seemed to make a third set more difficult. It is suggested that in this case, since it dealt with a complex concept, that the context made the task more difficult.

Another goal was to compare responses to closed and open-ended tasks. In two sets, students found the open-ended tasks more difficult suggesting that these required thinking above and beyond that required for the corresponding closed tasks. In the other case the open-ended task was easier.

An analysis of the responses and a breakdown of the elements of the tasks seemed to explain these differences. The open-ended tasks which were more difficult required students to link two concepts and to use such links to conjecture and generalise. Such open-ended tasks may serve the role of stimulating students' thinking to higher levels.

Both the context and the open-endedness seemed to effect the focus and student response to the tasks. It seems that each of the type of tasks would contribute productively to classroom programs and teachers could be encouraged to plan to use contexts and open-ended questions productively. In some cases the open-ended tasks may serve as a useful preliminary exploration of topics; in other cases, they may be better left until later.

DYNAMIC SCAFFOLDING AND REFLECTIVE DISCOURSE: THE IMPACT OF TEACHING STYLE ON THE DEVELOPMENT OF MATHEMATICAL THINKING

Howard Tanner & Sonia Jones: University of Wales, Swansea

Abstract

The mathematical thinking skills project (Tanner & Jones, 1995) reported that classes which followed a course emphasising metacognitive skills were not only more successful than controls in assessments of those skills but also in assessments of mathematical development. However the size of effect was quite small, and ethnographic data revealed significant variations in teaching style from teacher to teacher. Further analysis identified four characteristic teaching styles. This paper discusses the effectiveness of the different styles with emphasis on the two most successful groups: the dynamic scaffolders and the reflective scaffolders.

Introduction:

The Mathematical Thinking Skills Project (Tanner & Jones 1995) aimed to develop and evaluate a thinking skills course to accelerate students' cognitive development in mathematics. The course was based on the earlier Practical Applications of Mathematics Project (Tanner & Jones, 1994) which had identified the metacognitive skills of planning, monitoring, and evaluating as necessary for practical problem solving.

We aimed to develop and evaluate an enrichment course for the first two years of secondary school (ages 11 to 13) focusing on the development of metacognitive skills.

Metacognition

Metacognition is a "fuzzy" and elusive term which is used to cover a range of ill defined interacting categories which share certain resemblances (Brown, 1987, p106). Metacognition has two aspects: (a) the awareness that individuals have of their own knowledge, their strengths and weaknesses, their beliefs about themselves as learners and the nature of mathematics; and (b) their ability to regulate their own actions in the application of that knowledge (Flavell, 1976; Brown, 1987).

The former aspect is passive in character and is characterised here as metacognitive knowledge or "knowing what you know". The second refers to the "active monitoring and consequent regulation and orchestration" of cognition (Flavell, 1976, p232) and is characterised here as metacognitive skill.

The earlier project (Tanner & Jones, 1994) identified classroom practices which might facilitate the development of metacognitive skills. These included the use of social structures to frame pupils' behaviour and constrain them to act as experts rather than novices, e.g. by slowing down impulsive behaviour and encouraging examination of several problem formulations; the development of a discourse in which differences in perspective were welcomed; the use of focussing questions in scientific argument; and the encouragement of reflective discourse for peer and self assessment.

One key practice was referred to as "start stop-go". Pupils were asked to read a problem, think in silence for a few minutes, and then discuss possible plans in small groups. The teacher then led a brainstorming session which focussed attention on key features. After the class had started work they were stopped at intervals and groups were asked to report on progress to encourage monitoring.

What were we trying to achieve?

These classroom practices were taken as the basis of a project to develop and evaluate a mathematical thinking skills course. The thinking skills targeted were metacognitive rather than cognitive. That is the course focused on the processes rather than the content of mathematics in the context of practical problem solving and modelling. It was hypothesised that *near transfer* would be found, meaning that students' metacognitive skills would be enhanced leading to improved performance in modelling problems. It was further hypothesised that the development of metacognitive skills would lead to improved mathematical thinking and that students would subsequently demonstrate *far transfer* through improved performance in the content areas of mathematics which had not been targeted by the course.

How do students learn to think mathematically?

Learning to think mathematically is more than just learning to use mathematical techniques, although developing a facility with the tools of the trade is clearly an element. From a constructivist viewpoint, the learner is considered as a sense-maker and an active negotiator of meaning and a distinction is often drawn between mathematical thinking and the knowledge base, strategies and techniques described as mathematics. Additionally, however, mathematical thinkers acquire a socially accepted way of seeing, representing and analysing their world, and an inclination to engage in the practices of mathematical communities (Schoenfeld, 1994, p60).

Cobb et al (1997, p269) claim that a "mathematical disposition" may be developed in an indirect manner through participation in "reflective classroom discourse". In reflective discourse, teachers should manage the interplay of social norms and patterns of interaction to create opportunities for pupils to reason for themselves and "engage in reflective thinking or reflective abstraction" (Wood, 1996, p102-103).

One of the issues which arises is the extent to which the teacher acts as a genuinely, neutral moderator of discussions amongst co-participants or as a director and guide of pupils' learning. There is an obvious power imbalance between teachers and pupils in classrooms and teachers' comments carry great weight. What is significant is the manner in which the power is expressed in action (Cobb et al, 1992, p486).

Two different forms of interaction can be described as scaffolding to support learning: *funnelling* and *focusing* (Bauersfeld, 1988; Wood, 1994). In *funnelling* it is the teacher who uses the thinking strategies and carries out the demanding tasks to lead the discourse to a predetermined solution. The social processes of the classroom hide the mathematical structure, which the pupil may only construct by choosing to reflect on

regularities in the actions performed. "Context- and problem-specific routines and skills" are likely to result (Bauersfeld, 1988, p37). Mathematical logic and meaning are replaced by the social logic and meaning of the interaction. In *focusing* the teacher's questions draw attention to critical features of the problem which might not yet be understood. The pupil then has to resolve perturbations which have thus been created (Wood, 1994, p160).

The discourse mode of teaching may lead to higher levels of understanding and thoughtfulness in mathematics. In "reflective discourse", teachers "proactively support students' mathematical development" by guiding and initiating shifts in the discourse so that "what was previously done in action can become an explicit topic of conversation" and thus "participation in this type of discourse constitutes conditions for the possibility of mathematical learning" (Cobb et al, 1997, p264 - 269). We intended the character of the discourse to lend social status to "the disposition to meaning construction activities" which is a "habit of thought" that can be learned (Resnick, 1988, p40).

The research design

The project mixed quantitative and qualitative methodologies. In a quasi-experiment 314 students aged between 11 and 13 from six schools followed a mathematical thinking skills course and were compared with matched control groups using pre-tests, post-tests, delayed tests and structured interviews. However, as the activities and teaching approaches were novel for most of the teachers involved, the project had many of the characteristics of action research.

The teachers of the experimental classes attended an induction day and then 4 action research network meetings spread throughout the five months of the intervention at which teaching experiences and progress were discussed. Thus statistical data collected from the written tests were supported by qualitative data collected during meetings, in interviews with teachers and pupils, and through participant observation by the researchers in experimental lessons.

Written test papers were designed to assess pupils' cognitive and metacognitive development based on a neo-Piagetian structure. The metacognitive skills of question posing, planning, evaluating and reflecting were assessed through a section in the written paper entitled "Planning and doing an experiment". Metacognitive self knowledge was also assessed by asking students to predict the number of questions they would get correct *before* and *after* each section (referred to here as *forecasting* and *postcasting*). Fuller details may be found in Tanner & Jones, 1995 or Tanner, 1997.

The overall results

Multivariate analysis of variance (MANOVA) was used to analyse the three levels of test (ie: pre, post and delayed) and two types of class (ie: control and intervention). A covariate approach (using pre-test scores as covariates) was used to add power to the analysis by adjusting for the small inequalities which existed between groups at the start of the quasi-experiment. For simplicity, only the multivariate results are given here (Table 1) (but see Tanner & Jones, 1995 or Tanner, 1997 for further details).

In assessments of the active metacognitive skills of planning, monitoring and evaluating both the control and the intervention classes improved over the period of the quasi-experiment. However the intervention classes improved more than the control classes in the post-test and this improvement was sustained in the delayed-test. The effect size was small (0.19), but significant at the 0.1% level for the written tests (Table 1).

As these active metacognitive skills had been taught in similar practical mathematical modelling contexts, such "near transfer" might be considered unsurprising. Its achievement was non-trivial, however, as the pupils were required by the assessments to form their own problems within open situations, plan, identify and control variables, choose simple strategies, monitor their work, collect and organise their data, find relationships, evaluate and reflect on their results.

In the assessments of Passive metacognitive knowledge or "knowing what you know" the results were not clear cut. Although the intervention classes improved in their forecasting more than the control classes in the post-tests and this improvement was sustained in delayed-testing, the effect of type of class was not significant at the 5% level. The postcasting of the intervention classes improved more than the control classes in the post-tests and this improvement was sustained in delayed-testing. This was significant beyond the 5% level but was limited to an extremely small effect size of 0.02 (Table 1).

Table 1: Multivariate tests of significance for the effect of type of class

Variable	Hotellings	F value	Hypoth DF	Error DF	Sig of F	Effect size
Metacog skill	.235	43.67	2	371	.000	.191
Forecast	.013	2.30	2	363	.101	.013
Postcast	.022	3.78	2	341	.024	.022
Cognitive dev	.021	3.89	2	369	.021	.021

The assessment of mathematical cognitive development showed a similar pattern to the active metacognitive skills but a smaller effect. The intervention classes improved more than the control classes in the post-test and the advantage was largely sustained at the delayed-test but the effect size (0.02) was extremely small (Table 1).

The content of the cognitive section of the written paper had not been taught directly by the course. Furthermore, as the intervention classes had experienced less teaching in their normal mathematics curriculum during the quasi-experiment, it might have been expected that the control classes would generally have outperformed the intervention classes. This small overall effect is claimed, therefore, to be an example of mathematical thinking skills paying for themselves through far transfer.

Although the overall results show a positive result for the intervention, albeit with a small

size of effect, when the results of individual classes were examined a far more complicated pattern emerged. It became clear that some classes had made very large gains over their controls whilst others had achieved little more or even less than their controls. Further analysis was conducted in the light of the qualitative data collected.

The four teaching styles

Analysis of the qualitative data collected through participant observation led to the classification of the teachers into four characteristic groups according to the teaching styles employed (see Tanner, 1997 for detailed descriptions).

The *taskers* focused on the demands of the task rather than the targeted metacognitive skills. The *rigid scaffolders* focused on planning, but rather than helping pupils to develop their own plans, aimed to develop the teachers' preferred approach. The scaffolding support provided by their questioning constrained pupils' thinking, funnelling them down a pre-determined path. These two groups of teachers were the least successful. The *taskers'* classes showed no advantage over their controls in any test. The *rigid scaffolders* showed an advantage in only the metacognitive delayed test with a very small effect size (0.09). This paper focuses on the other two groups of teachers.

The *dynamic scaffolders* made full use of the social structure of "Start-stop-go" to frame their pupils' behaviour and constrain them to act as experts rather than novices. Their scaffolding was dynamic in character and was based on participation in a discourse in which differences in perspective were welcomed and encouraged. The most significant participant in the discourse was the teacher, who validated conjectures and used focusing questions to control its general direction ensuring that an acceptable whole class plan was generated. The participation framework was equivalent to "legitimate peripheral participation" within an apprenticeship model of learning (Lave &Wenger, 1991), and the autonomy and responsibility of the pupils was limited by the teacher's desire to negotiate a plan to a pre-determined template. Although a whole class plan was developed, the negotiation and participation was sufficient to ensure that students referred to "our plan" in terms which indicated a sense of ownership. The discourse focused on both procedural knowledge and conceptual knowledge and during the planning and monitoring sessions, articulation and objectification of explanation was encouraged, making the explanation itself the object of the discourse. This was the only form of evaluation or reflection used by the *dynamic scaffolders*, however, and is characterised as "reflection in action" as opposed to "reflection on action" (Schön, 1990).

The *dynamic scaffolders* were very successful in accelerating the development of the active metacognitive skills of planning, monitoring and evaluating in the context of mathematical modelling, that is in near transfer, with a small to medium effect size (0.36) which was significant beyond the 0.1% level (Table 2). However they failed to achieve a significant advantage for their classes in either passive metacognitive self knowledge or "far transfer" into the content areas of mathematics. It is conjectured that, although active metacognitive skills may be necessary in the learning of new knowledge, they are not sufficient. Metacognitive self knowledge may also be necessary for far transfer.

Table 2: Multivariate tests of significance for the effect of type of class for *dynamic scaffolders*

Variable	Hotellings	F value	Hypoth. DF	Error DF	Sig of F	Effect size
Metacog skill	0.550	21.27	2	77	.000	0.36
Forecast	0.040	1.52	2	76	.226	0.04
Postcast	0.015	0.53	2	70	.590	0.02
Cognitive dev	0.020	0.80	2	78	.453	0.02

The reflective scaffolders also used the social structure of "Start-stop-go" to lead the discourse in their classrooms. They granted their pupils more autonomy, however, encouraging several approaches to the problems rather than constraining the discourse to produce a class plan. Pupils thus had to evaluate their own plans in comparison with the plans of other groups in the posing, planning and monitoring phases of the lessons. The participation framework had fewer of the characteristics of apprenticeship, with pupils taking a greater responsibility for an end product of their own design rather than limited responsibility for an element in the design of a "master". The characteristic feature of the *reflective scaffolders*, however, was their focus on evaluation and reflection. During interim and final reporting back sessions, scientific argument was encouraged to make the explanation an object of the discourse. Peer and self assessment was encouraged through group presentations of draft reports before redrafting for assessment. They deliberately generated a reflective discourse (Cobb et al, 1997) after activities to encourage self evaluation and reflection on process. Collective reflection does not equal reflected abstraction, but it is conjectured that during collective reflection, opportunities arise for pupils to reflect on and objectify their previous actions as they engage in reflective discourse (Cobb et al, 1997).

The *reflective scaffolders* were very successful in accelerating the development of active metacognitive skills, achieving near transfer in practical modelling situations with a medium size of effect (0.4) which was significant beyond the 0.1% level. They also succeeded in accelerating the development of passive metacognitive self knowledge in forecasting and postcasting. The effect sizes were very small (0.07 and 0.14), but significant beyond the 5% and 1% levels respectively (Table 3). They were the only group of classes to achieve this and it is conjectured that this was due to their emphasis on self evaluation and reflection. The *reflective scaffolders* also succeeded in accelerating development in the content domains of mathematics measured by the cognitive test, again the only group of classes to achieve this far transfer. The size of effect was small (0.21), but was statistically significant beyond the 0.1% level and approximated to a year's development (Table 3).

Table 3: Multivariate tests for the effect of type of class for *reflective scaffolders*

Variable	Hotellings	F value	Hypoth. DF	Error DF	Sig of F	Effect size
Metacog skill	0.652	43.34	2	133	.000	0.40
Forecast	0.073	4.73	2	130	.010	0.07
Postcast	0.161	9.82	2	122	.000	0.14
Cognitive dev	0.272	18.09	2	133	.000	0.21

Discussion

The "Dynamic scaffolders" were operating a model of cognitive apprenticeship which included authentic tasks, student autonomy and dynamic scaffolding but although they were very effective in teaching for near transfer, they failed to achieve far transfer. Individual construction was subordinated to the dynamics of the apprenticeship model, whereas the *reflective scaffolders* encouraged both cognitive apprenticeship and individual construction. The dynamics of "Start-stop-go" were internalised through participation in social processes. Learning this procedural knowledge was achieved through an apprenticeship model, organised and controlled by the teacher. Through participating in a scientific discourse led by an expert using dynamic scaffolding, pupils learned to internalise the processes of scientific argument and "argue with themselves". They also learned that mathematics "made sense" and that they could "make their own sense" of what occurred by making their own tentative conjectures and constructions and linking them with prior schemata.

Participation in reflective discourse encouraged reflective abstraction and the objectification of explanation. It is conjectured that the processes of mathematisation and problem solving, once objectified through individual construction, were thus knowledge rather than mere information and thus capable of being used elsewhere. Collective reflection provided both a social model and an opportunity for reflected abstraction. The reflective discourse focused on the processes of mathematisation, abstraction and generalisation in the service of understanding structure. Participation in reflective discourse may have encouraged the development of a mathematical disposition or point of view (Schoenfeld, 1994; Cobb et al, 1997) which might be expected to be transferable.

The active metacognitive skills of planning, monitoring and evaluating are generic rather than specific and these skills can survive near transfer to similar modelling contexts. It is conjectured that participation in reflective discourse can encourage objectification and the development of metacognitive self knowledge thus enhancing the transfer potential of such skills. It is further conjectured that the combination of active metacognitive skills and passive metacognitive knowledge supports both the application of old mathematics to new contexts and the learning of new mathematics.

Learning to Question: A Major Goal of Mathematics Teacher Education

Dina Tirosh, Tel-Aviv University, Tel Aviv, ISRAEL

Abstract. *Mathematics education departments make efforts to revise their teacher education courses in response to recent documents that call for dramatic reforms in the teaching and learning of mathematics. This paper briefly describes the "Student Thinking About Rational Numbers" (STAR) course, it then analyzes three episodes drawn from the beginning, the middle and the end of the course, focusing on transitions in prospective teachers' understanding of mathematical procedures, shifts in their conceptions of what counts as an acceptable mathematical explanation, and developments in their awareness of the strengths and the limitations of practically -based and mathematically-based explanations. Finally, some implications for mathematics teacher education are drawn.*

Prelude

Janet, a beginning elementary fifth grade school teacher, described the standard multiplication-of-fraction algorithm in her class, and asked her students to work out several examples. Some minutes later one of the most talented students asked:
David: It is so easy to multiply fractions. I just multiply the tops and the bottoms. I don't understand why we can't add fractions in a similar way.
Janet demanded some clarifications:
Janet: I don't understand your question...
David: For instance, if I have to add ½ and ¼ , I can add the 1 and the 1, and then the 2 and the 4, instead of doing all the complicated things with the common denominator.

Janet interpreted David's question to indicate that he still faced difficulties adding fractions. She immediately reacted:
Janet: If it is still hard for you, David, we should all do some more examples...
David: I know how to add fractions. My question is why we do it in such a way. It is strange that addition is complicated while multiplication is easy.

Janet was quite shocked. She certainly agreed that adding fractions was much more demanding than multiplying them. Yet she regarded these standard algorithms as self-evident and incontrovertible. After class, Janet discussed her "shocking experience" with two of her experienced colleagues, and they both confirmed that such a question is rarely asked in mathematics classes. Janet reckoned that David might ask the same question in the next meeting, and believed it was her responsibility to come up with an appropriate answer - but she was unable to come up with any. She did not know what to do.

Recent Reforms Encourage Students to Ask Questions

How will Janet proceed? What will she do? Let's leave her for a while, and discuss her colleagues' comment that such a question is uncommon. David's question, and many other "why-type" questions (e.g., Why ½ is bigger than ¼?, Why invert and multiply?, Why .2=.20?, Why is division by zero undefined?) are indeed rarely asked

in most classes. The traditional sequence of mathematics instruction, consisting of providing answers to the previous day's assignment, teacher's brief explanation of a new content, and working-on a new assignment while the teacher moves around the class answering questions, fails to encourage students to understand why things are the way they are (e.g., National Council of Teachers of Mathematics, 1991).

A major recommendation that emerged as a result of the recent calls for dramatic reforms in the teaching and learning of mathematics is that teachers should welcome students' questions (e.g., Australian Education Council, 1991; NCTM, 1991). The professional standards for teaching mathematics, for instance, envisage mathematics classes in which students and teachers are actively engaged in exploring mathematical situations. According to these recommendations, teachers are expected to ask, and to stimulate students to pose questions such as "Why is it true?", "What would happen if..." What if not?" (NCTM, 1991). The professional standards and other reform documents recognized that this kind of teaching is significantly different from the traditional one, and that such changes require that teachers have long-term support and adequate resources. Those who participate in the preparation and the professional development of teachers are faced with many related issues, including: What knowledge will enable teachers to bring their instruction in line with the current recommendations for reform in instruction? What processes could foster change in teachers' conceptions of mathematics and mathematics instruction? This paper describes the "Student Thinking About Rational numbers" (STAR) method course, which was developed to address these issues.

The STAR Course

The goals of STAR clearly resonate with those set by the various reform documents: (1) encourage a view of mathematics as a human-made domain; (2) enhance prospective teachers' knowledge of mathematics; (3) promote prospective teachers' knowledge of students' conceptions; and (4) advocate a view of mathematics classrooms as learning communities in which individuals develop personally meaningful mathematical ideas as they participate in the interactive construction of mathematical meanings.

STAR is structured around a large data-base of activities aimed at developing prospective teachers' understanding of mathematical concepts, increasing their knowledge of children's conceptions, and enriching their repertoire of instructional strategies. These activities have been developed on the basis of the large body of recent knowledge regarding children's and prospective teachers' mathematical conceptions and ways of thinking about rational numbers. Most tasks included in the data-base are "why-type" questions, presented as if they were asked by elementary school students. Prospective teachers are generally encouraged to work in small groups, to suggest responses and to present them in class. This constitutes the basis for discussions on mathematical and pedagogical aspects of mathematics instruction.

A first version of this course was developed in 1994. Since then, the ways of thinking about and with rational numbers as they are revealed by prospective teachers during

the courses are sources of inspiration for constant modification of already developed activities and for the formation of new ones. Currently, the information related to an activity in the data-base is presented in three parts: a description of the activity; general description of related research findings; and suggestions for discussions that could originate from the activity. The data discussed in this article are from a class of 24 prospective elementary teachers who specialized in teaching mathematics in their second out of the four year teacher education program. Preprogram data suggest that before the course, the vast majority of the prospective teachers tended to perceive mathematics as consisting of rules and procedures that students should practice and memorize. I shall concentrate on three episodes that occurred at different times during the course and focus on transitions in the prospective teachers' views regarding mathematical concepts, and on the gradual development in their awareness of strengths and limitations of practically-based and mathematically-based explanations.

Activity 1: Can Fractions Be Added In An Easier Way?

It has often been reported that students tend to add fractions by "adding the tops and adding the bottoms" (e.g., Carpenter, Cobitt, Reys, & Wilson, 1976). The first task that the prospective teachers encountered related to this tendency:

Task 1. You are discussing operations with fractions in your class. In the course of this discussion, Ken says, "It is so easy to multiply fractions. I don't understand why we don't add fractions the same way: adding the tops and adding the bottoms"?

Participants were advised to discuss Ken's question in small groups and to present their responses in class. Here we focus on the first part of the class discussion, highlighting the negotiations between the participants on what counts as an explanation to this question (All names used for study participants are fictive):

Teacher: How would you respond to Ken's suggestion?

Sandra: I'll explain that adding fractions is different from multiplying fractions. I'll explain that when we add fractions, we do not add the tops and the bottoms, we have to find the common denominator.

Rachel: We decided to explain that it is impossible to add two fractions, unless they have the same denominator.

Mary: We would explain that in addition you must have the same family of fractions, but in multiplication it is not necessary.

Sandra, Rachel and Mary did not explain "why". Jane and Sharon commented on this:

Jane: I'm sure Ken will not appreciate these explanations. They do not tell why he can't add fractions in the way he suggested... I never thought about it... I add fractions the way I was told... It's the rule...

Sharon: I also never thought about the reasons for adding fractions the way we do. It's a strange question. It is also strange to think about adding fractions in a different way. I can only explain how to add fractions but not why, or why not.... Do students really ask such questions? That's scary!

There was general agreement with Sharon and Jane's remarks. The majority of the class acknowledged that they accepted the standard addition-of-fraction algorithm as a

rule and never questioned it. This was a turning point in the discussion. The participants started providing practically-based and mathematically-based arguments against adding the tops and adding the bottoms.

Karen: I will take a sheet of paper and demonstrate that when we take ½ of the paper and add to it ¼ of the same paper we get ¾ of the paper. But when we add the tops and the bottoms we get another sum: 2/6.

Anna: Your explanation shows that we get different answers when we use these different methods. It does not explain why the tops and bottoms method is not correct. I have another explanation [she wrote on the board]:

$2 \times 1/2 = 1$ and $2 \times 1/2 = 1/2 + 1/2 = 1$ but if we use the tops and bottoms method, we get $2 \times 1/2 = 1/2 + 1/2 = 2/4$, so we get a contradiction.

Betty: Karen also showed that if we use the tops and bottoms method, it leads to a contradiction. She showed that if we add ½ and ¼ in the tops and bottoms method, we get less than ½, and this is impossible. We add to ½ a number that was not zero, and not negative, so the sum must have been bigger than ½.

Karen: You got me wrong. I meant something totally different. I used the sheet of paper because I'm sure children in elementary school need concrete examples. We can also make a cake in class, taking ½ kilogram of wheat and ¼ kilogram of sugar, weighting these quantities, showing that we get ¾ kilograms, and not 2/6.

The teacher then decided to draw the participants' attention to the profound differences between Karen's explanation and those of Anna and Betty, introducing the notions of practically-based and mathematically-based explanations.

Teacher: What is the difference between Karen's and Betty's explanations ?

Ruth: Karen uses concrete examples from daily situations. Betty did not do that.

Teacher: And what about Anna?

Anna: My explanation also does not use daily situations. I prefer my type of explanation, because I get confused with these illustrations.

Teacher: Can we come up with more examples of concrete, practically-based explanations? Can we also find other mathematically-based explanations?

In this episode we observed four types of prospective teachers' reactions to the "why-type" question that they were dealing with: explaining how (instead of why); rule-based arguments; practically-based arguments; and mathematically-based arguments. The participants demonstrated that the sum resulting from adding the tops and adding the bottoms is inconsistent both with their daily experience and with the definitions of other mathematical operations. Toward the end of this session, the notions of practically-based and mathematically-based explanations were discussed

Activity 2: Can Fractions Be Divided In An Easier Way?

Division of fractions is often considered the least understood topic in elementary school, and children's success rate on these tasks is usually very low (e.g., Hart, 1981). Children tend to divide fractions by dividing the tops and dividing the bottoms (e.g., Tirosh, 1996). It is important to stress that when dividing fractions, unlike when

BEST COPY AVAILABLE

adding them, the standard "invert and multiply" algorithm and the "dividing the tops and the bottoms" method result in the same quotient.

The episode presented here took place twelve weeks after the course started. To put it in context, we should say that after working on addition of fractions, the class had dealt for several weeks with activities related to various models of mathematical operations. The twelfth lesson focused on intuitive models of division (see, for instance, Fischbein, Deri, Nello & Marino, 1985). The first task demanded the calculation of ½ : ¼ . One participant commented that it is strange that although multiplication and division are related, multiplication of fractions is so simple while division is so complicated. The instructor decided to take this opportunity and extend the discussion on definitions of mathematical operations. She requested the prospective teachers to consider this comment in groups and to report on the process they went through and their final conclusions.

All prospective teachers assumed that the quotient resulting from the "dividing the tops and dividing the bottoms" method would be different from that resulting from the application of the standard division-of-fraction algorithm. They tried "different types of numbers" and were confident that they would eventually find a "counter example". After about 10 minutes, Laurie commented:

Laurie: I think that in principle we can use the tops-and-bottoms method to divide fractions. We all tried many examples with different numbers, and always got the same results. So why do we have to invert and multiply? It is annoying to use the complicated way and not the easy one.

Laurie's comment suggested that she was quite confident that the tops-and-bottoms method is appropriate for dividing fractions. She based her decision on an accumulation of inductive evidence, involving comparison of results yielded from the method in question (dividing tops and bottoms) to results of a method that she regarded as correct (invert and multiply). She also expressed her view that the tops-and-bottoms method is much easier than the invert-and-multiply algorithm. Still, she appeared to feel obliged to obey a certain authority decreeing that division must be done in a certain way (invert and multiply).

Dana, however, presented a different opinion:

Dana: I think we can use this method in some cases, but in other cases we get stuck. I took ½ : ¼ . I divided the tops and got 1, but in the bottoms I got ⅓ . I couldn't go on and had to use the invert-and-multiply method.

The participants seemed to accept Dana's argument. Then, Victoria raised a "why-type" question which led to the following interchange:

Victoria: So we are stuck with the invert-and-multiply algorithm. I know how to do it, but I don't know why we do what we do.

Karen: We can use the measurement model. If we take ½ : ¼ we can think of how many ¼ make a ½ , and the answer is 2.

Anna: But, this does not explain why we first invert and then multiply.

Here, we see clear signs that Victoria differentiated between "describing how" and "explaining why". Her comment was made by the end of the lesson. For the next meeting, some participants brought to class a common teacher guide which suggested to use measurement problems and concrete materials to explain the invert-and-multiply algorithm. During this meeting, the prospective teachers worked in groups, attempting to understand the suggested explanation. After about 15 minutes, Anna commented:
Anna: This explanation holds only for some cases. It works only when the dividend is a multiple of the divisor.
Karen: I like the explanation in the teachers' guide. It illustrates the idea.
Anna: But it does not show why we can always invert and multiply.
Karen: It is always like that. When we teach that 1+2=3, we take one cube and two cubes to have three cubes. But, we can't do it with 1+ (-2).
Anna: We shouldn't show 1+2 with blocks. It will confuse the children later...
Betty: Right. Later they will think that 5-7 is 0, because there are no cubes left....
Karen: But what can we do? Children need concrete examples. They do not understand if we do not use something concrete...

A central issue in this snapshot is the legitimacy of using concrete materials that, due to their own properties (e.g., having physical dimensions) can potentially represent only some instances of a mathematical phenomenon. Karen conceived such concrete representations as essential tools that support the learning of mathematical concepts and procedures in elementary schools. Anna and Betty expressed their concerns about possible, long-term implications of the use of such models. Notably, accessibility to children and generality are two central issues in the research mentioned both for and against the use of practically-based explanations (e.g., Orton & Frobisher,1996). These argumentations were spontaneously raised by the participants as they reflected on suggested explanations of the invert-and-multiply method.

In this episode, the prospective teachers questioned the status of the invert and multiply method for dividing fractions which they had previously regarded as incontrovertible, and dealt with the possibility of using other methods to divide fractions. Gradual changes were observed in participants' conceptions of what could count as an explanation to "why-type" questions: "explaining how" and stating that "this is the rule that we have to follow" were no longer regarded as legitimate reactions, and practically-based explanations were evaluated on the basis of their generality and accessibility to children.

Activity 3: Can Zero Divided By Zero Be Zero?

Division by zero is one of the instances that violate the intuitive belief that every mathematical operation results in a numeric answer. Students and teachers tend to view this undefined mathematical operation as a "rule to remember" (e.g., Ball, 1990).

During the STAR course, a participant raised the issue of division by zero in the last session, which was planned to be devoted to general reflection on the course

Teresa: I have learnt to ask why mathematics is the way it is. I still don't know why it is impossible to divide zero by zero.
Many of the participants wanted to react. Molly was the first:
Molly: I think 0:0 should be 1, because any number divided by itself is 1.
Teresa: But I can say that 0:0 should be 0 because 0 divided by any number is 0.
Anna: I know why 0:0 is not 1 [she wrote on the board]:
$\frac{0}{0}=1$; But: $\frac{0}{0}=\frac{0+0}{0}=\frac{0}{0}+\frac{0}{0}=1+1=2$. So $\frac{0}{0}=1$ and $\frac{0}{0}=2$, so 1=2 .

The class seemed deeply impressed. Then, Shelly reacted:
Shelly: So, it could be 2. Because if 0:0=2 then 2·0=0 and that's correct.
Betty: No. This will not work, we can do what Anna did before, showing that 1=2=3...So 0:0 could not be one. We should find why 0:0 is not zero--- it must contradict something...
The class worked for quite a while. Then Laurie commented:
Laurie: We should try harder. We should look in books and ask people. But, in my mind it is reasonable that 0:0=0. Is it possible that those who determined that 0:0 is impossible thought that it could be either 0 or 1, and did not notice what Anna did about 0:0=1?

This comment represents a dramatic change in Laurie's attitudes towards mathematics rules. By the end of the course, she was willing to doubt the validity of a well established mathematical definition and to consider its revision. Other participants seemed enthusiastic about this possibility too.

This episode suggests that by the end of the course, the participants tended to view mathematical statements as human-made, arguable conclusions, and not as absolute, immutable truths. Traditional explanations of mathematical rules were also challenged and reexamined, taking account of their possible, long-term negative effects.

Epilogue

Let's return now to the prelude, and see if participation in STAR could have helped Janet solve her problem which was to explain why fractions are not added by adding the tops and adding the bottoms. This specific issue was dealt with in STAR, and it is therefore reasonable to assume that had Janet been a participant in STAR, she would have approached the student's question by using one or more of the practically-based or mathematically-based explanations discussed in the course. Participation in STAR could have helped Janet and other prospective as well as practicing teachers answering "why-type" questions that were discussed during the course, but one would expect that the contribution of such a course be more profound.

The paper suggests that engaging prospective teachers in joint work on "why-type" tasks encourage them to reflect on their own understanding of mathematical concepts and structures and to acknowledge the discrepancies between "knowing that" and "understanding why". The paper illustrates that participants in the course gradually developed new sociomathematical norms regarding what counts as acceptable mathematical explanations. Rule-based justifications were no longer accepted as

legitimate explanations, and practically-based and mathematically-based explanations were pursued and examined in light of their accessibility to children, their generality and their possible long-term effects on students' mathematical conceptions and ways of thinking (Yackel & Cobb, 1996). Episode 3 demonstrates that by the end of the course, participants in STAR were willing to question well-established mathematical statements which at the beginning of the course were perceived as unquestionable. The description of these episodes should transmit not only the changes in the participants' conceptions of mathematical explanations, but also their deep involvement and enthusiasm on the part of the prospective teachers.

A word of caution should be added here. The first paragraph of this epilogue, argued that it is reasonable to assume that participation in STAR would have helped Janet (and others) in answering the "why-type" questions that were discussed during the course. Yet, so far we have not followed participants in STAR into their own classes, and thus at this stage of our study we lack the information needed to evaluate the program's effects on participants' own teaching. The next stage of our research will concentrate on studying the various effects of STAR on the actual teaching of the participating prospective teachers.

Does the understanding of variable evolve through schooling?

María Trigueros

Departamento de Matemática Educativa
CINVESTAV-IPN, México

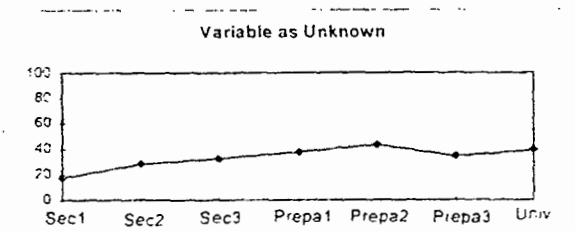
Abstract
Previous research has shown that even after several algebra courses starting university students still have serious difficulties in understanding the elementary uses of variable. Our concern now is to study how the understanding of variable evolves through schooling. For this purpose we conducted a study involving students aged 12- 18 years. Results obtained show that students' conceptions of variable do not substantially improve as more algebra courses are taken. We consider that students' difficulties are not of a cognitive or epistemological nature, but that they are a consequence of current didactical approaches.

Introduction

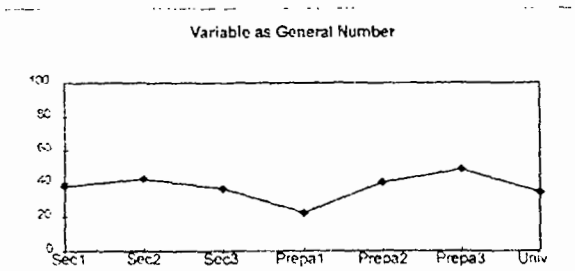
Many studies have been conducted to understand cognitive processes leading to the construction of the concept of variable. Special attention has been paid to students' difficulties at different school levels (Warren, 1995; Stacey and MacGregor, 1997, Boulton-Lewis et al., 1998). It has been found that even after several algebra courses starting university students still have serious difficulties in understanding elementary uses of variable (Ursini and Trigueros, 1997). Several questions arise from these findings. In particular we are interested in studying how the understanding of the concept of variable evolves trough schooling and in comparing the evolution of the different uses of variable to find out which, if any, is more strongly developed. In this article we present the findings of a study that addressed these questions.

Theoretical framework

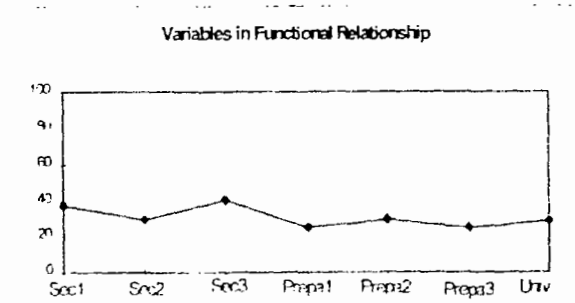
Variable is a multifaceted concept. It includes as a whole different aspects. In order to reach a competent handling of elementary algebra students need to cope at least with what we consider the most relevant of them: unknown, general number and variables in functional relationship. An acceptable understanding of these aspects requires some basic capabilities as those stressed by Ursini and Trigueros (1997) in their decomposition of the concept of variable. This decomposition points to the importance of interpreting, manipulating and symbolising each one of those aspects when dealing with algebraic situations. They stress as well the value of being able to handle the variable as a mathematical object integrating its different aspects in one concept and shift between them in a flexible way.



Methodology



In order to study how the understanding of the concept of variable evolves through different school levels, the questionnaire designed by Ursini and Trigueros (1998) was used with 98 students aged 12-18 years. The distribution of students was as



follows: 37 students in the three levels of Mexican middle education (12 – 15 years old); 30 students in the three levels of Mexican high school (16 –18); and 31 starting college students enrolled in social studies, business and economics majors.
Students' responses were classified as correct, incorrect and not answered in order to make a global quantitative analysis per group and per student. The mean percentage of correct answers given by the students of each level was calculated in order to be able to compare them (Lozano, 1998). Based on the theoretical framework a qualitative analysis of students' responses was made, and some students were interviewed. This analysis provided a general overview concerning students' capability to work with different uses of variable and information concerning the evolution of this capability.

Results and Analysis

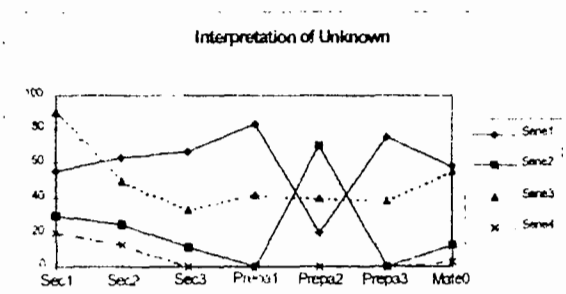
In the following graphs we present the mean percentages of correct answers given to the questionnaire by the students from different groups. In all the graphs the different groups are labelled as Sec1, Sec2, Sec3 for the first, second and third year of middle school; Prepa1, Prepa2, Prepa3 for the first, second and third year of high school; and Univ for the university group.

As can be observed in the graphs there is very little variation between the percentages of correct responses in the different groups. Moreover, the percentages scarcely exceed 40%. Overall these results show that during schooling students undergo a very slow evolution in their understanding of the different uses of variable. Even though a small raise in the curve for *variable as unknown* seems to indicate a slight evolution in students' understanding of this use of variable, a decrease in the curve for Prepa3 students shows that their understanding is not solid. This decrease might be due to the fact that at that school level students are not taking algebra courses but starting with Pre-Calculus or Financial Mathematics where variable as unknown is not emphasised any more. Regarding *variable as general number*, we observe that as students progress through algebra courses their understanding of this use of variable diminishes.

BEST COPY AVAILABLE

In the graph it appears as a decrease at Sec 3 and Prepa 1 levels. This result can be attributed to the emphasis given in those courses to procedures for solving equations. In contrast when students take other courses, like Analytic Geometry or Calculus (Prepa 2 and Prepa 3) the understanding of general number slightly improves. But it decreases again, as it can be seen, for college students. These fluctuations reveal, as in the case of variable as unknown, that their understanding of the use of variable as general number is fragile and not consistent enough.

Variables in functional relationship are not well understood by students at any school level. It can be observed in the corresponding graph that the percentages of correct responses are very low. It is surprising to realise that students who have not taken any algebra course do better in these questions. This fact raises the question of the role that courses play in the development of mathematical concepts. It seems that students are more able to use their imagination and other resources when they have not been exposed to formal algebra courses.



In order to gain a better understanding of students' capability to interpret, symbolise and manipulate each one of the uses of variable considered, their responses were analysed according to these dimensions. This analysis enabled us to develop a classification of responses for each of the uses of variable and have a deeper understanding of how students' conceptions change through their education.

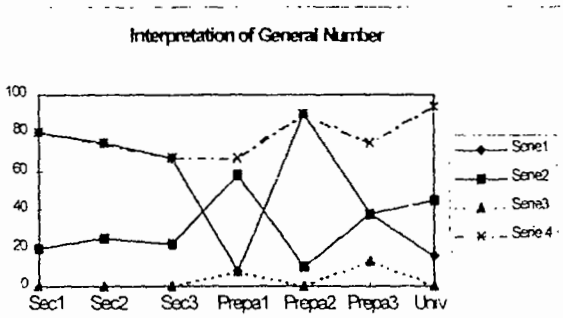
Interpretation of variable

In the case of *variable as unknown* we found that students:

- interpret the symbolic variable in an equation as an entity representing values that can be determined (serie 1);
- interpret the symbolic variable in an equation as an entity that can take any value (serie 2);
- recognise in a simple problem, leading to a linear equation, the presence of an unknown that can be determined (serie 3);
- recognise in a problem leading to a quadratic equation, the presence of an unknown that can be determined (serie 4).

The following graph presents the evolution of students' interpretation of variable as unknown.

As can be seen in this graph interpretation of variable as unknown gradually improves while students take algebra courses (serie 1). This coincides with a gradual decrease of the interpretation of the unknown as representing any value (serie 2). However, when students start taking other mathematics courses in which



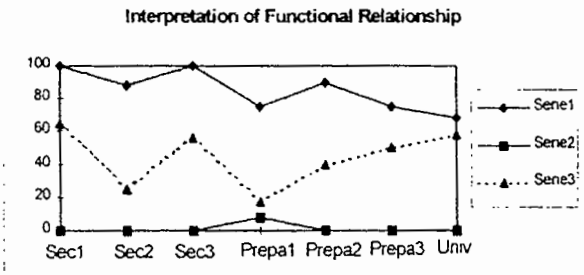
BEST COPY AVAILABLE

unknown is not emphasised and other uses of variable are present, they seem to experiment confusion. The interpretation of variable as representing an unknown value that can be determined decreases dramatically while its interpretation as representing any value increases. This provides evidence of the difficulty students have to deal with different uses of variable at the same time and the tendency to focus only on one of them at a time.

Even when working with very simple problems, students have strong difficulties in identifying and interpreting the unknown (serie 3 and 4). Again, it is amazing to realise that students perform much better before having been exposed to algebra courses (sec 1) and that their capability to interpret the unknown gets lost with schooling. A reason for this could be that algebra beginners, lacking in memorised algorithms and routines, face the problems without biases in a more intuitive fashion.

Regarding *variable as general number* we found that students:

- interpret the symbolic variable in an open expression or a tautology as representing any number (serie 1);
- interpret it as an entity representing a determined value (serie 2);
- interpret it as an undetermined object they can operate with (serie 3).
- can see a pattern (figure and/or number) (serie 4).



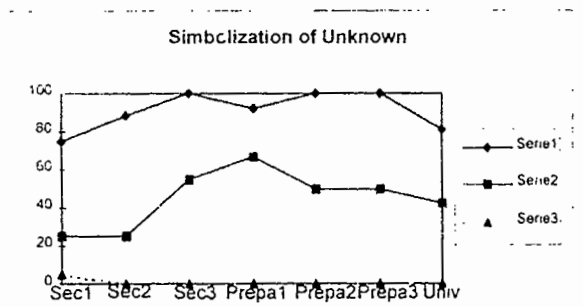
As can be observed in this graph when variable is used as general number students capability to interpret it correctly gradually decreases (serie 1), in spite of some fluctuations, while an incorrect interpretation of it as unknown increases (serie 2). We consider that this is a consequence of the emphasis given in algebra courses to variable as unknown. In accordance with the graph representing the interpretation of unknown, in Prepa 2 they recover temporally the capability to recognise a general number. However, it has to be consider that at this school level they tend to interpreted in that way any use of variable. In spite of many algebra courses students don't develop an understanding of the variable as an object they can operate with (serie 3). On the other hand in all levels they are acceptably good in seeing patterns (serie 4). This is considered (Mason et al., 1985) as a necessary step in the generalisation process, but they are not able to express it as it will be seen further.

For *variables in functional relationship* we found that students:

- recognise the correspondence between numerical quantities (serie 1);
- recognise the joint variation of related variables (serie 2);

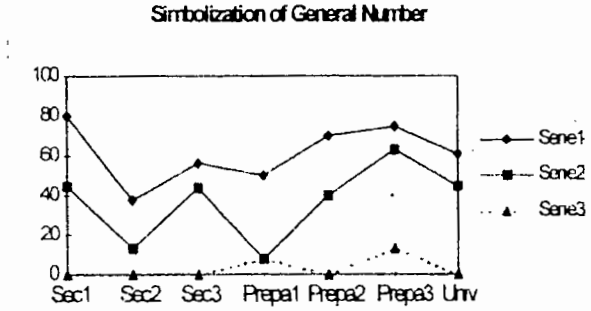
BEST COPY AVAILABLE

- think of the functional relationship only in terms of discrete values (serie 3).



In general students can interpret related variables as representing quantities in correspondence whichever the representation used (table graph analytic expression) (serie 1). However, as it can be observed, this capability slightly diminishes during the school years. The interpretation of variation in terms of discrete values (serie 3), although fluctuating, persists in all school levels. Clearly absent in all the school levels is the capability to conceive the joint variation of related variables (serie 2). These results indicate that the school mathematics courses do not address in a satisfactory way the idea of joint variation, which is a fundamental notion when dealing with functions.

Symbolisation of variable



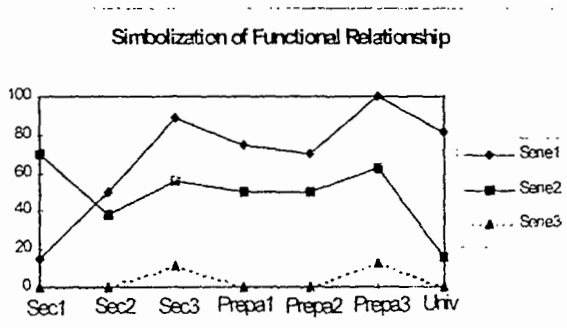
In the case of *variable as unknown* students' answers were organised in three groups:

- translate simple sentences to algebraic language (serie 1);
- pose an equation to solve linear problems (serie 2);
- pose an equation to solve quadratic problems (serie 3).

Almost independently of the algebra courses taken, students can translate simple sentences to algebraic language (serie 1). Students' capability to pose equations to solve linear problems (serie 2) gradually improves during the algebra courses (Sec 2, Sec 3 and Prepa 1) but it diminishes after these reaching prepa1) certain stability. At all school levels students are unable to pose equations to solve quadratic problems even when they are simple (serie 3). They have difficulties to identify the unknown of a problem and to link it with the data in a coherent way.

For *variable as a general numbers* three categories were found:

- translate simple sentences involving general number to algebraic language (serie 1);
- represent algebraically the general term of a numerical sequence (serie 2);
- represent algebraically the change involved when going from one step to the next in a numerical sequence (serie 3).

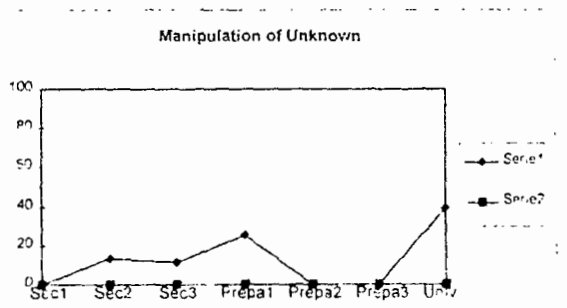


1442

BEST COPY AVAILABLE

This graph shows a fluctuating capability to translate simple sentences to algebraic language (serie 1). Only in the case of very simple numerical sequences students can produce the general term, although there are strong fluctuations in the different groups (serie 2). The symbolisation of change involved in the generation of a sequence causes great difficulties at all school levels (serie 3).

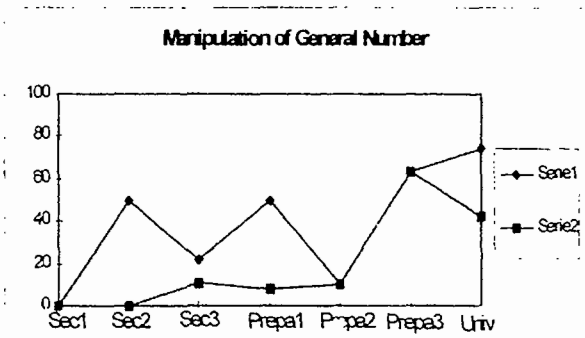
In the case of *variables in a functional relationship* students were able to symbolise the relationship when:



- a simpie verbal expression was given (serie 1);
- a table was given (serie 2);
- when a verbal problem was presented (serie 3).

These results suggest that students learn to represent algebraically simple verbal expressions involving a functional relationship as they progress through algebra courses (serie 1). But this is not the case when they deal with verbal problems (serie 3). They have difficulties in recognising the joint variation of the variables involved and this seems to be an obstacle for symbolising a relationship. Again, it is amazing to find that younger students show a greater capability to symbolise information given in a table than university students (serie 2).

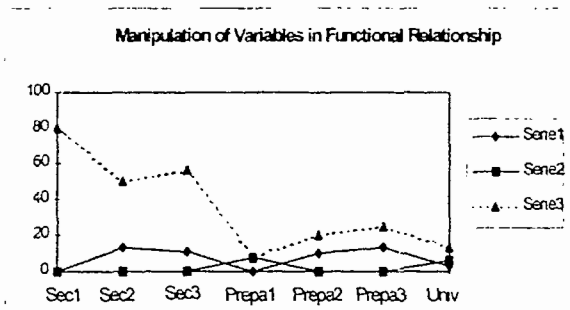
Manipulation of variable



The following graph shows students capability to manipulate *variable as unknown* when it appears in linear equations (serie 1) and quadratic equations (serie 2).

The lack of capability to manipulate the symbolic variable in any equation is striking. It is also evident that this capability almost disappears when students are not taking algebra courses, even though, as we have mentioned before, these courses strongly emphasise equation's solving.

In the case of *variable as general number* we classified students in two groups, considering those who could:



- simplify algebraic expressions (serie 1);
- expand algebraic expressions (serie 2).

Students' capability to manipulate general numbers varies a lot in different levels. However, the general tendency shows an improvement in this capability. Moreover, it seems that it is easier for them to simplify expressions than to expand them.

For *variable in functional relationship* students' responses were grouped as follows:

- substitute a number to the independent variable in order to determine the value of the dependent variable (serie 1)
- manipulate an analytic representation of a function to determine variation intervals (serie 2)
- manipulate an analytic expression in order to produce its graph (serie 3)

It can be observed that all students have difficulties to manipulate variables in functional relationship. This is apparent both when it is necessary to determine values by substitution (serie 1) as when intervals have to be found (serie 2). These results are intimately related with the difficulty students have in dealing with related variation. A striking decrease in the percentages reflecting the capability to draw a graph was also observed (serie3). Once more students starting their study of algebra perform better than those in upper levels, in particular they are much better than starting university students.

We suggest that the difficulties students have in manipulating variables is tightly linked to their difficulties in interpreting and using variables. At different school levels they are taught manipulation but, without understanding its usefulness, they are forced to memorise techniques and to use them when they consider it appropriate. A competent use of manipulation requires the understanding of the meaning of the role played by the variable within a specific situation.

Concluding remarks

This results show that students' conception of variable does not substantially improve as more algebra courses are taken. They do not develop a comprehension of variable

as a multifaceted entity in spite of the presence of the different uses of variable in algebra courses. It is important to remark students' incompetence to discriminate between different uses of variable and how their interpretation of variable is strongly influenced by the specific topic being treated in class at a particular moment.

These results suggest that instead of promoting a deep understanding of variable and the development of intuitive algebraic ideas, current teaching practices seem to obstruct them. Also it is important to stress that errors committed by algebra beginners are not remedied by instruction and they prevail up to university levels. Students seem to develop only one of the aspects proposed by Bell (1996) as characterising algebraic thought, namely, resolution of arithmetic problems by step-by-step methods working from given data to unknowns or by global perception and use of multiple arithmetic relations.

We consider that these difficulties are not of a cognitive or epistemological nature, but that they are the result of current didactical approaches. We suggest that the different uses of variable, as well as their relationship, should be made more explicit to students. Variable is a fundamental concept in understanding mathematics and other sciences. A reconsideration of the way it is taught is needed.

USING A HANDBOOK MODEL TO INTERPRET FINDINGS ABOUT CHILDREN'S COMPARISONS OF RANDOM GENERATORS

John M. Truran
University of Adelaide, Australia

Kathleen M. Truran
University of South Australia

The "Handbook Model" developed by the first author is used here to provide an integrated summary of research into children's comparison of random generators which is accessible to teachers but highlights the known complexities of individuals' responses. Linking psychology with pedagogy highlights the meaning of earlier, only partially successful, attempts to codify responses. Children's construction of probabilistic meaning in such situations must also take account of their inconsistent heuristics and approaches, the need for a generalisable non-numeric probability estimator, and the need to verify judgements in ways which allow for the uncertainties involved in any stochastic situation.

The Concept of a Handbook Model

J. Truran (1998) proposed using a "Handbook Model" for codifying research findings on specific topics and to contribute to the "model-building" stage of the development of "normal science" (Romberg, 1983) in mathematics education. The Model uses a prose summary to integrate findings within a hierarchy of contexts. It eschews a discursive style providing a general summary of reported findings in favour of the more segmented approach found in handbooks used within hard sciences. The hierarchy makes research findings readily accessible because each part of the text is tightly focussed, and the prose is an effective medium for expressing complexities. So the findings are more likely to be accessible to teachers with specific needs, and may more easily complement standard curriculum documents and textbooks. The Handbook Model provides one example of how mathematics education research might be expanded to encompass, not only psychological investigation, but also "teaching processes as an object of study as such, as well as the epistemology of mathematics from a teaching/learning perspective" (Balacheff, 1997).

Researching Children's Comparison of Random Generators (RGs)

Typically subjects are presented with two RGs and asked which they would prefer to use to obtain a desired outcome. Two seem to be sufficient for establishing the heuristics used—Spinolla (1997) used three and Ritson (1998) four, but without identifying new heuristics. Here we discuss only symmetric Two-Outcome Random Generators (TORGs), where each RG has finite numbers of favourable elements (called here "G", for "good") and unfavourable ones ("B", for "bad"). A typical example would be two urns: one containing 4 G and 3 B balls, and one containing 5 G and 4 B balls, summarised here as {4-3; 5-4}. The better choice (if there is one) is listed first and called "X", while the less good one is called "Y". Subjects know that "both are equally good" is an acceptable answer. Such cases are indicated by using a colon rather than a semi-colon, e.g., {2-3: 4-6}, and the smaller number of elements is listed first. We discuss here only comparisons between RGs of the same

form because children do not see mathematically identical RGs with different structures as being the same (K. Truran, 1994). For example, selecting a table-tennis ball from an urn containing six balls is seen as "different from [mathematically identical dice or spinners] because they roll everywhere and some could be in corners and you wouldn't know" (boy, Year 7, aged 12: 4). While not all of the methodological difficulties in this research have been addressed by all of the researchers discussed below, we consider that any methodological weaknesses are not sufficiently serious to invalidate the broad findings relevant to this paper.

Fischbein (1975, pp. 82–89) proposed that children might be making perceptual, not probabilistic, judgements. But J. Truran (1994) reported children's language which showed an awareness of the probabilistic nature of the task, and, for certain and impossible events (where proportional reasoning is not possible), that some children were moving towards formal mathematical language and the development of a probability scale. Furthermore, Cañizares, Batanero, Serrano & Ortíz (1997, p. 50) observed heuristics reported in the stochastics literature but not in the proportion literature, such as the "equiprobability bias"—two outcomes are seen as equiprobable regardless of the RG—(Lecoutre, 1992) and the "outcomes approach"—making a prediction about a single outcome rather than a statement about a probability function—(Konold, 1989). So comparison of probabilities may well require proportional or perceptual skills, but it also requires stochastic understanding.

Focus of This Paper

This paper examines, so far as space will allow, research into children's comparison of probabilities to develop conclusions which have sufficient generality to be useful for classroom teachers. Its purpose is not to construct a quantitative meta-analysis of the form described by Glass, McGaw & Smith (1981). Rather, it may be seen as a qualitative equivalent with a specific focus—using research to enhance pedagogy.

Summary of Research Findings

In Chapter 6 of Piaget & Inhelder (1951/1975) children's responses to such situations are classified within a developmental hierarchy based on their skill in co-ordinating the various elements of the situation (the numbers of each colour and their relevant totals), especially their ability to relate parts with wholes. Many similar experiments have followed from this, using three types of analysis.

Classifying Comparison Heuristics

The most common approach has been to determine the heuristics employed and to use some measure of complexity to arrange them in order. In general, the hierarchy has started by assessing children's ability to co-ordinate the parts and wholes of each RG, with higher levels based on whether their comparisons were additive (e.g., $a - b$ v. $c - d$) or multiplicative (e.g., a/b v. c/d). Freudenthal (1978, pp. 293–294) suggested that a/b v. c/d is cognitively easier than a/c v. b/d, especially when dimensions are involved, but this needs further investigation. In any case, some multi-

plicative approaches cause particular difficulties when denominators are 0. The principal purpose of most researchers has been to establish a hierarchy to be used as a measure of development, rather than to explain how the development occurs.

Way (1997) has summarised and codified six of these summaries, three from research into proportional reasoning, and three from research examining the comparison of probabilities. She defined ten categories, and made reasonable matches between these categories and those suggested by other workers. However, because the approaches differed markedly in the number of categories they defined, the match was inevitably far from perfect.

Matching Situations with a Cognitive Scale

An alternative approach has been to rank questions into a hierarchy, rather than responses, to claim that a subject who has correctly answered all questions up to a certain level has reached a certain stage of cognitive development. For proportion, this approach has been carefully developed by Noelting (1980) using a battery of comparisons covering "all possible variations of the particular situation" (p. 218) each of which was matched with a particular Piagetian level.

Noelting's approach has been taken up by Cañizares et al. (1997), but with a much more restricted range of questions. They found some conflict with Noelting's findings, possibly from the slightly different forms of their questions, and possibly because their stochastic setting brought subjective responses into play which would not have arisen in Noelting's deterministic problems.

Matching Heuristics with a Cognitive Scale

Finally, Watson & Moritz (1998) have used written reasons for responses to problems to assign cognitive achievement levels within the neo-Piagetian SOLO Taxonomy (Structure of Observed Learning Outcomes), based on the level of coordination of the relevant features of a problem. The size and longitudinal focus of the survey (with testing every two years) make its results of special value. Only one comparison problem was used ({6-4: 60:40}) and significant group improvements were found as children moved from Year 3 to Year 7, and Year 6 to Year 10. However, 37% of the children did not increase their assessed cognitive level of response in four years, which matches Ritson's (1998, p. 211) finding that some heuristics are remarkably persistent over time. Watson & Moritz also found that those who did develop did so in a remarkably diverse set of ways.

The Problem of Inconsistent Heuristics

These three different approaches have yielded no consistent general conclusions. Their striking common feature has been the diversity of responses offered. "Success in difficult items was due to strategies valid for this problem, but not for the general case," observed Cañizares et al. (1997, p. 54); "children as young as 5 years possess a repertoire of strategies to select from in reaction to the type of ratio pairs presented to them," said Way (1997, p. 574). Our personal experience suggests that

the heuristics are chosen to minimise computational de mands, as is suggested by the following examples from a Year 8 boy (aged 13: 7):

{2-3; 1-2}
Box X
Can you say why?
With box Y, for each G one there are 2 Bs and in this one it's, on one G there are 2 Bs and in the other one there is only one.

{2-1; 3-3}
Box Y.
Why box Y?
You've got equal chances in box Y and you are outnumbered in box X, no sorry I'm going for G, you've got more chance in X because there's more of them.

Because researchers tend to use small, familiar numbers, this hypothesis has not been examined in detail. Nor has the effect of replacing small numbers by larger and/or less familiar numbers. Yet Collis (1975) has shown that number size and ability to achieve "closure" are relevant for understanding real numbers, so are likely to be relevant here as well.

This inconsistency of response has several implications. Firstly, it strongly suggests that data from small numbers of questions with familiar numbers will be poor indicators of the level of cognitive development obtained. It is probably not possible to rank either responses or questions into a hierarchy. Certainly, Piaget's research team knew that their questions did not represent "a ladder of difficulties in the development of the theory of probability" (Folder "calcul. probab.", Box "Hasard", Archives Jean Piaget, Geneva).

Secondly, we need to be aware that children are often not conscious that their thinking is inconsistent as the follow example from a Year 8 boy (aged 12: 11) suggests:

{4-3; 5-4}
Both the same.
Why?
Because there is one more G in X than what you have B and one more G in Y than what you have B.

{2-4; 3-6}
The same again because you've got 4 B and 3 G, you've got 4 Bs which is double the two Gs and in Y you have got 3 G and 6 Bs so it is double the G again.
Is that the same sort of method that you were using on the question before that?
Yes.

Thirdly, researchers need to appreciate and investigate further the significance of this inconsistency for the classroom teacher. Working with proportion, Hart (1984) showed that specific teaching could help to eliminate additive comparisons, but the improvements tended to be ephemeral, possibly because of weakness in working with fractions. Given that there are so many heuristics employed, and that they tend to be employed sub-consciously, this result suggests that deliberate correctional teaching is unlikely to be successful.

The Value of a Graphical Probability Measure

To our knowledge, only one piece of research has tried to find an holistic w y of overcoming inconsistency of approach. Acredolo, O'Connor, Banks & Horobin (1989) asked children to place a mark on a probability number line to indicate the probability of success in a stochastic situation, thus allowing comparisons to be made indirectly by examining the relative positions of the marks. As a result children concentrated more on the relative values of both elements, and probably also on their totals as well, and performed much better than had been reported in research involving standard comparison of proportions, perhaps because they better appreciated that holistic estimates were required. This seems reasonable on theoretical grounds: the procedures were non-verbal, did not emphasise specific component numbers, dealt with only one proportion at a time, and encouraged closure at a point on the number line. But this valuable finding, which builds on the tendency which children already have to examine all of the relevant data, does not provide them with any reason for not reverting to their intuitive approaches.

Difficulties in Verifying Judgements

In stochastics, providing counter-examples to encourage accommodation (in the Piagetian sense) is difficult, especially in classrooms, Because large numbers of tests are needed, especially for naïve students. We propose two games—race-track and gang-plank—which our experience has suggested may be helpful, but this hypothesis has not been tested rigorously.

The games are inherently interesting, capable of elaboration, and encourage comparison of RGs. In a basic race-track game, two or more players operate their chosen RG in turn, and move forward one square if they obtain the desired outcome. In a basic gang-plank game one player stands in the middle of a gang-plank with an odd number of squares where the outer squares represent the ship's deck and falling off into the shark-ridden ocean respectively. A positive outcome allows one step towards the deck; otherwise, it is one step towards the sharks!

We know that individual experiences can prejudice judgements (the "availability" heuristic) as may be seen in this quotation from a Year 9 girl (aged 13:8) a few minutes after she had (a) played two gang-plank games with 2G 1 B, and had lost the first and won the second, and (b) made 9 successive draws from an urn with 2G 1B and obtained 4G and 5 B:

{1-2; 2-5}
Box X.
Why?
The smaller number seems to come up more. In box Y there's more B ones, there's a fair few more B ones than G ones and in box X there is still a better chance of coming up with a blue one.

{3-3; 4-5}
Box Y.
Why?
Coz the lesser number seems to come up more and in box X they're both equal.

Just as Hart (1984) found the calculator to be helpful in reducing the cognitive load for working with fractions, so it is likely that computer simulation may be helpful for testing decisions made when comparing probabilities in either the standard form or in that used by Acredolo et al. (1989). Pratt (1998, ch. 8) has shown that the opportunity provided by a computer-world for rapid, repeated experimentation is helpful for changing some children's interpretations, but for some children the micro-world may not be seen as an exact model of the real-world.

So at this stage, research can suggest that computer simulations of RGs in a game context may be effective in providing counter-examples which will discourage the inconsistent use of different heuristics, but these suggestion still need to be tested.

A Handbook Model Summary of the Research Findings

Here, as was also reported in J. Truran (1998), we have shown that children's responses to stochastic situations are inconsistent. A Handbook Model which is directed at teachers who have to think on their feet requires providing a unifying structure for interpreting such behaviour. Research and theory suggest that the stochastic nature of RGs should be emphasised by using an interesting context where judgements may be tested many times, and suggesting holistic ways for estimating probabilities to by-pass the known inconsistent intuitive approaches.

As with J. Truran (1998), to save space, and to highlight the main themes, references are omitted and terms defined in the main part of this paper are not redefined. Most may be easily deduced from the discussion above.

Comparison of Two-Outcome Random Generators (TORGs)

Deciding which of two TORGs to use to achieve a desired outcome in, say, a race-track or gang-plank game is valuable for investigating chance processes and for encouraging and then testing careful choices. Making a good choice in a situation like {a-b; c-d} normally uses skills which are related to fractions, ratio and proportion, but stochastic situations introduce extra constraints.

Children's Varied and Inconsistent Numerical Strategies

The probability scale is defined only between 0 and 1 inclusive, so some comparisons, such as {0-2; 0-4} involve values at its extrema. Such situations are useful for helping children to see the value of a probability scale defined in this way.

Many heuristics for making choices may be observed in classrooms, often from the same child. These choices are not fickle: they represent serious attempts to find a computationally easy solution, and hence vary with the numbers presented. The most common incorrect ones compare the absolute number of either Gs or Bs, or make subtractive comparisons like $b - a$ with $d - c$. Logically correct solutions used by children involve proportional comparisons using any of three basic approaches, viz., comparing $\frac{c}{a}$ with $\frac{d}{b}$, or $\frac{b}{a}$ with $\frac{d}{c}$, or $\frac{a}{a+b}$ with $\frac{c}{c+d}$. The first two of these fail for cases at the extrema of the scale if the denominator is zero; only the third is always appropriate, and is, of course, the standard way of measuring probability. It is the least likely to be used by naïve children because it involves both addition and division.

While it is useful for a teacher to recognise that all these heuristics might be used, it is even more important to realise that children do not use any one consistently. Rather they adjust their heuristics to the numbers involved, usually to achieve simple arithmetic, so the mere provision of a wide variety of a different situations is unlikely to lead by itself to children's developing a totally consistent and generalisable approach.

Possible Stochastic Strategies

Children may well use heuristics which arise specifically from the stochastic situation. These may include making purely subjective decisions, considering that both outcomes are equally likely (by analogy with coins), or thinking that they are being asked to make a prediction of outcome (perhaps based on previous experiments) rather than a long-term judgement based on the structure of the RG.

Problems of Verifying Proposed Solutions

Correct responses are hard to verify, because they may still lead to failure in an individual game, especially if the race-track or gang-plank is relatively short. Computer models can be an effective, time-saving aid here, but some children may not accept that they are true models of "real life" situations.

Pedagogic Implications

Many children do not develop sound comparison methods over time without assistance. Teaching designed to eliminate specific poor heuristics is unlikely to be of lasting value. Using computer models in "estimate-test-revise estimate" situations will often prove helpful, especially if the estimates are done by marking them on a probability number scale. This encourages the students to co-ordinate simultaneously all the relevant aspects of the problem. Race-games and gang-plank games can be good motivators.

Conclusion and Implications for the Future

We have shown that when comparing proportions in stochastic situations naïve children use a variety of approaches with little consistency. The "standard" probability approach is not intuitive, as implied by many curriculum documents, but may be encouraged with skilful teaching. We have presented a structure for conveying the research findings to teachers which sees psychological findings as relevant to the environment in which children construct their meaning of probability. Finally, by focussing on what pedagogues need from researchers, we have highlighted important gaps in the research findings, such as determining what classroom approaches are most likely to engender sound and stable understanding. Without decrying the value of pure research, we observe that such questions are more likely to be seen as worth funding by those who hold the relevant purse-strings.

ARE DICE INDEPENDENT? SOME RESPONSES FROM CHILDREN AND ADULTS

Kathleen M. Truran
University of South Australia

John M. Truran
University of Adelaide, Australia

This paper examines some understandings of the concept of independence of dice by comparing the results of an Italian study with that of four Australian studies. Roughly comparable groups produced quite different results, and similar reasons based on control were used to justify quite different responses. Some implications of these findings are discussed, especially with respect to the place of intuition in probabilistic thought and the lack of understanding of probability held by some by pre-service teachers.

BACKGROUND

Independence is an important and difficult probabilistic idea. "People seem to find it hard to consider an event as separate and detached from a series of similar events in which it occurs" (Cohen & Hansel, 1955, p. 178). "The belief that successive outcomes of a random process are not independent is supposedly one of the most common misconceptions about probability" (Konold, 1989a, p. 203). Yet independence is frequently given inadequate attention by researchers and teachers. Most research into children's understanding of independence has examined predictions of the next outcome in a sequence (e.g., Green, 1986). But Fischbein, Nello & Marino (1991) examined independence from a different perspective, and here we present and compare results from some replications of this study.

SELECTION OF A SUITABLE THEORETICAL MODEL

There are two principal models we might have used. Piaget & Inhelder (1951/1975) described understanding of probability using conceptual levels and claimed that a full understanding did not develop until about age 12. Fischbein (1975), on the other hand, claimed that effective probabilistic intuitions may be identified in children as early as pre-school age. But Green, working within a Piagetian framework, suggested that because of the deterministic aspect of mathematics, sometimes for probability 'performance declines with age' (1982, p. 774). Furthermore, speaking of young adults, Konold, Pollatsek, Well, Lohmeier, Lipson (1993, p. 193) have observed "that incorrect reasoning frequently occurs ... and that a subject can switch from correct to incorrect reasoning, while reasoning about what an expert would consider to be the same situation". Clearly neither of the principal models is totally comprehensive. Indeed, as Shaughnessy (1992, p. 485) has observed:

> [t]here are very few models of conceptual development in probability and statistics. ... The difficulty with building models in research on stochastics is that if a model were to try to incorporate the results of all the different types of studies by mathematics educators and psychologists, that model would run the risk of being so complicated that it may be of no practical use either to researchers or to teachers.

BEST COPY AVAILABLE

We have chosen to follow Fischbein's approach using intuition because such divergent responses are found at different ages, and because of the important finding by Fischbein et al. (1991) that some children do not regard the simultaneous tossing of three dice as mathematically equivalent to tossing them one after the other. For these children, when random generators (RGs) are operated together they are seen to lose any independence they might have.

Interestingly, the eighteenth century French polymath and encyclopaedist, Jean le Rond d'Alembert, also believed that the outcomes from successive and simultaneous tossings would be different (Todhunter, 1865, p. 279). If such a view was held by a trained mind at the time when the theory of probability was being developed, it is not surprising that it is held by many naïve children today.

FISCHBEIN'S STUDY

Fischbein et al. (1991) gave a questionnaire to c. 300 children attending schools in Pisa, Italy, aged from 9–14 years who were in Years 4 & 5 (Middle Primary) and 7, 8 & 9 (Junior Secondary). This was to obtain "a better understanding of the nature and origins of some probabilistic intuitive obstacles" (p. 523) prior to writing materials for teaching probability in Italian elementary and junior high school classes. Some of the students had experienced a formal teaching programme in probability, others had not (p. 529); only those students not involved in the teaching programme are included in our analysis. The questionnaire was given in the children's usual classroom setting, and comprised 14 questions, including:

> Are you more likely to get five on each of these three dice by rolling one dice three times or by rolling all three dice together, or are they both the same? Can you say why?

FOUR REPLICATIONS

We report four replications of Fischbein's question. An exact replication was not possible because the precise wording of the question was not reported, but the wording for a parallel question for two coins was:

> When tossing two coins which result is more likely: to get 'head' with one coin and 'tail with the other, or to get 'head' with each of the two coins; or is the probability the same for both results? (p. 532)

Given the problems of any translation, and the fact that children's reasons are cited in the paper, we believe our reconstruction is sufficiently accurate to permit the comparison of results. It is not clear whether Fischbein's students were interviewed or wrote their reasons on the questionnaires—the latter seems the more likely.

The first two replications were administered to Australian primary school students aged from 7–12 years, as part of a larger study investigating children's perceptions of the behaviour of different, but related RGs, and whether they see the outcomes of such RGs as independent. The smaller of the two replications was a pilot study, but both groups produced remarkably similar results, even though the children came from several different schools. None of the children had experienced prior

teaching of probability. Data was collected from group tests administered in a normal classroom, with each RG demonstrated at the time the question was asked, and then left in the children's view while they considered and made their responses. They wrote onto prepared sheets, and a random set of students was interviewed soon after to clarify their understandings.

The other two replications were given to sets of Australian Pre-service primary teaching students, with ages ranging from 19 to c. 50, in 1996 and 1998. These are discussed after the discussion on school aged groups..

RESULTS FROM SCHOOL AGED GROUPS

While ages and year groups in both school-aged studies are not identical, we believe that there is sufficient similarity to make credible comparisons. We are much more concerned with understanding the reasoning of those involved than with precise age comparisons. But where there are gross differences between groups of approximately equal age, we believe it is appropriate to try to find the reason. The results are shown in Table I, which is followed by some points of clarification.

Table I
Percentage distribution of "Best way to get 3 fives on 3 dice"—School Students

	Fischbein Year 4 & 5 n = 102	Truran Year 5 n = 43	Truran Year 5 n = 135	Fischbein Year 7, 8, 9 n = 139	Truran Year 7 n = 36	Truran Year 7 n = 98
No answer	12	0	0	16	0	0
Both the same	50	6	5	63	19	16
Successive	23	67	64	14	63	59
Simultaneous	13	27	29	4	13	20
Other (unspecified)	2	0	2	3	0	4
Combination	0	0	0	0	5	1
	100	100	100	100	100	100

The 'No answer' response in the Italian study was not found in our study, and may have been due to the way the test was administered. 'Successive' refers to rolling the three dice separately; 'Simultaneous' to all three dice being rolled together. The term 'Combination' was used to refer to the response of one student in our study who specified tossing two dice together and then one alone. It was claimed that a better result would occur that way, because three dice together were "too many".

DISCUSSION OF SPECIFIC RESPONSES

Two features of the results are of special interest. The first is that both sets of Australian students in our study made very different responses from the Italian ones; the second is that different children used the same reason—control—for choosing the different responses, 'Both the Same' and 'Successive'.

Both The Same

Most Italian students selected 'Both the Same' as the correct answer while very few Australian students did so. This is surprising: as part of our larger study students had been given situations where the option '... or are they both the same?' was

always offered. Where appropriate, this option was increasingly chosen with increasing age, so we had not expected responses that indicated such apparent lack of confidence in the independence of RGs. This suggests that the unexpected Australian responses indicate a real, wide-spread confusion about the ideas involved.

We cannot offer an explanation for this difference. We note that the results from Fischbein's work with students who had received probability teaching (not included in our table), were not markedly different from this naïve group. We shall meet a similar unexpected difference in the results from the tertiary students.

It is clear that the 'Both the Same' response increases a little with increasing age, but the difference and the sample sizes are rather too small, and the older Italian group is too diverse, to draw many conclusions from this.

Successive

Nearly $\frac{2}{3}$ of both the Australian year groups chose the "Successive" response, and it is also the most frequently chosen of the incorrect Italian responses. The reasons for this are not conclusive even though all of our students offered a reason for their choice. Some claimed that they had more control over successive tosses; a common response was, "If you throw the dice together they rub against each other, and the numbers change". They believed each die had an intended trajectory and outcome which 'rubbing together' would affect, and inhibit, their control of the die.

> AK (Year 7, F, 11:3) Well because when you shake them in your hand they sort of get all jumbled, and if you just concentrate on one at a time you have a pretty good chance. But all three, it's sort of a bit harder to concentrate on all three getting five, because it's not really that you would get five like that.
>
> M-AN (Year 5, F, 10:5) I think toss them one at a time because they won't bump into each other. Like if you get a five and another one bumps into it, you'd get another number. So I think one at a time.

Some Italian children expressed the same views.

> Because the dice do not knock against each other and therefore do not follow diverse paths (Year 7).

Simultaneous

Far fewer chose this strategy, but those who chose it, both Australian and Italian, believed they could better exert a constant influence on all three dice.

> AD (Year 7, M, 11:6) Because then you'd throw them the same height and the same way, so there's a better chance of getting all the same numbers.
>
> KS (Year 5, F, 9:8) Well probably if you had them all on one [uppermost before they were tossed] it be easier to get all fives. So if you're holding them on one and then you throw them all together they'd come down on fives.
>
> Because the same force is imparted (Year 5).
>
> One can launch in the same way (Year 7).

It is clear that the majority of children who did not choose 'Both the Same' did so because they believed they could exercise some control over the dice. However, these children expressed two quite different judgements about how best to effect this control. Fischbein et al. (1991, p. 529) found a slight tendency for more junior secondary students who had been taught probability to offer 'Simultaneous' than for those who had been taught.

It is not surprising that children have offered 'control' as a reason for their choices. This phenomenon has been reported by many researchers (e.g., J. Truran, 1985). One group has written

> The ability to calculate proportions as such does not necessarily signify an understanding of probability. A realisation of the impossibility neither of controlling or predicting the outcome of the immediate event is crucial (R. & R. Falk & Levin, 1980, p. 183).

The phenomenon was also found in response to other questions during the Australian study (K. Truran & Ritson, 1997). But, as well, although some of the Australian students had also expressed belief that there is a force, beyond their control, which determines the eventual outcome of an RG or that the RG itself 'knows' the result the child wants and behaves accordingly (K. Truran, 1995), they did not offer such explanations for this question. 'Animistic' responses have been extensively studied (Wollring, 1984), but, to our knowledge, the influence of question form on the persistence of such an approach has not been investigated.

What we find surprising in these results is that "control" has been used to justify two totally different responses. Perhaps the common feature, as we shall discuss in more detail later, is that children do not appreciate that randomness arises from the interaction of a *large* number of inter-dependent events.

Tertiary Group

Of the two tertiary groups few students had completed any Year 12 academic mathematics course. Both groups were studying a methodology subject including a single lecture and an associated workshop on probability. The 98 group also did a small probability experiment as part of an assignment. Responses to the question from the 96 group were written during a subsequent workshop, and were two or three lines long. Responses from the 98 group formed part of an examination where a response of about 15 lines was suggested. No students were interviewed individually. The 96 group had a weaker mathematics background than did the 98 one: increased employment prospects are attracting academically better students to teaching.

Table II summarises these results, which are mainly from young adults, and are strikingly different from each other. The responses of the 96 group are very similar to both Australian primary school groups, with nearly $\frac{2}{3}$ opting for 'Successive'.

While the vast majority of the 98 group gave the "correct" answer, the majority of the "incorrect" answers belonged to a new category—'Ambivalent'. Such responses

typically began with 'Both the Same', then went on to choose a different response, which seemed to be the preferred response. Two examples are:

> It doesn't matter it is merely chance that you will land all three on five. However, if one was to throw each die individually on the same angle from the same height and with the same force. The chances of rolling all three of five are increased. (98).

> It does not matter which method you use as there will always be a $\frac{1}{6}$ chance of rolling a 5. However it would be easier to control the experiment if you tossed one dice at a time (98).

Table II
Percentage distribution of "Best way to get 3 fives on 3 dice"—Tertiary Students

	1996 n = 87	1998 n = 140
No answer	0	0
Both the same	25	81
Successive	57	6
Simultaneous	18	3
Ambivalent	0	10
	100	100

Because the 98 students were advised to write about 15 lines we perhaps received more revealing answers than from those using questionnaires with limited response space, or from relatively focused interviews. Given that the independence of RGs had been discussed in the class lecture, it is possible that the responses represent a "textbook" response, followed by a more personal one. Ritson has observed that primary students 'coached' for an important exam shortly after revert to their 'real belief', and this may be what is happening here (K. Truran & Ritson, 1997, p. 239).

Some reasons for the 'incorrect' responses were the same as given by the children. But others are of some interest, given that these students will receive no further formal instruction in probability, and will be teaching in schools in two years time.

A few students provided no reasons for their 'incorrect' response, but relied on dogmatic assertion.

> The best and correct way is to toss all three at once (96).

> It is better to throw three separately. Throwing three together lowers the odds as the chance lessens as you add each die (98).

One gave an example of the 'Combination' argument, again without reasons.

> It wouldn't matter if I tossed all three dice at once or if I tossed them one at a time. ... It is much easier to obtain two fives if you are throwing two dice at a time as the chance to obtain a five is quicker and more possible (98)

Many students, even those who made the 'Both the Same' choice, saw this question as an actual experiment rather than a theoretical situation, in a way which is reminiscent of the 'Outcomes Approach' defined by Konold (1989b). Their concern

was with illustrating the idea to a class, which some saw as impractical because of the "long time it would take"

Finally, for some the question seemed other-worldly. Two asked if it were a trick question, and several stated, 'usually you would do them one at a time anyway'.

These findings corroborate that of Watson (1995, pp. 120-121) who wrote that "the inclusion of probability and statistics in recent years has meant that many high school teachers find that they are not adequately prepared by their own education to teach these topics". But the findings also have things to say about the nature of probabilistic intuition.

CONCLUSION

This question, whose very structure discourages the use of animistic responses, has been particularly valuable in bringing some misconceptions further into the open. Its moderately complex structure suggests that it may be one of the situations which Green described, as mentioned above, where performance declines with age.

While it is probably true that some probabilistic intuitions exist at a very early age, the results from this question show that they do not transfer well into a moderately complicated, but not unusual, situation. It is less clear that the students possess ways of judging whether a generator is producing random outcomes, even, for the adults, five years of secondary schooling (which will have included some work on probability) have not clarified these misconceptions. Since deciding whether two RGs are independent is essentially a subjective process (J. & K. Truran, 1997, pp. 90–92), and since we can see that this skill is not always intuitively acquired by many children and adults, it seems that it needs more explicit attention in schools. The suggestion from Konold quoted at the beginning of this paper that it is a lack of understanding of independence which is the principal problem becomes more precisely that it is a failure to know how to identify random generators. The principal problem seems to be a belief that the initial tossing is more powerful than the subsequent large number of forces which impinge on the RG.

Fischbein et al. claimed that:

> The general idea is then, that the outcomes *can be controlled* by the individual. The mathematical, probabilistic structure has not yet been detached from the concrete circumstances and considered in its abstract generality (p. 530).

We have earlier written that

> [s]uch strong beliefs in the physical behaviour of dice frequently over-ride any understanding of independence. Not only do RGs have no constancy of existence in the mind of many children [and adults], but when they are operated together, they are seen to lose any independence they might have had (J. & K. Truran, 1997, p 94).

We would now argue that the issue is deeper still. For both children and adults an understanding of how to decide if an generator is random is a critical pre-requisite

for developing a sound concept of independence. Such a skill is probably not intuitive, but learned.

One final comment. When we set this question we assumed (from our own childhood experiences) that subjects would normally toss dice using a cylindrical shaker. It has become clear that many use only their cupped hands. The extent to which this influences their responses is not known, but needs to be investigated. because the shaker ensures that many forces operate on the dice without direct human intervention.

Testing the Cultural Conceptual Learning Teaching Model (CCLT): Linkage between children's informal knowledge and formal knowledge

Wen Huan Tsai
National Hsin-Chu Teachers College, Taiwan
Tsai@nhctc.edu.tw

Thomas R. Post
University of Minnesota
Postx001@tc.umn.edu

The purpose of this research was to test the effects of teaching students arithmetic based on the Cultural Conceptual Learning Teaching Model (CCLT) and to create a learning environment for children to link their informal and formal knowledge of mathematics by using lessons based on their cultural activities. 625second graders in sixteen classes selected from four schools were involved in an experimental teaching design. Children who learned arithmetic based on cultural-conceptual activities scored higher than children who learned arithmetic based on nation-wide textbook in computation problems, word problems, and simulated problems. Children involving the CCLT group solved everyday task problems more flexibly, more accurately, and more efficiently than children in the control group.

Introduction

Several studies (Lave, 1989; Carraher, carraher, & Schliemann, 1987) have suggested that situation in which arithmetic problems occur play an important role in eliciting different types of strategies in solving problems. In-school situations are likely to elicit formal procedures, and out-of-school situations are likely to elicit informal procedures. There are growing evidences that schooling does not contribute to performance outside of school and that knowledge acquired outside of school is not always used to support in-school learning (Ginsburg & Allardice, 1994). Although this gap is evident, there are not enough researches trying to design a curriculum to bridge this gap. This study was to develop a learning-teaching model, the Cultural Conceptual Learning Teaching Model (CCLT), and tried to link children's formal knowledge and informal knowledge based on this model.

Developing the Cultural Conceptual Learning Teaching Model (CCLT)

Many researchers have suggested that the strategies of solving daily problems created by children could be used as a starting point to learn school mathematics (Bishop & Abreu, 1991; Hiebert, 1988). Children gain the informal knowledge through cultural activities of daily life. According to Resnick's view (1987), when teaching mathematics, teachers need to consider the cultural aspects that are meaningful ways for students to make sense of the abstract symbols of school mathematics. Brown, Collins, & Duguid (1987) also emphasize the importance of the relationship among activity, concept and culture. They suggest that learning must involve all of the three. Based on above points of view, this study develops a learning teaching model called the Cultural Conceptual Learning Teaching Model

BEST COPY AVAILABLE

(CCLT) (see figure 1). This model tries to combine individual, activity, concept, and culture together.

Figure 1 shows that CCLT contains three learning environments: construction environment, connection environment, and reapplication environment and six learning stages: play stage, construction stage, connection stage, re-application stage, practice stage, and reflection stage. Play stage provides some cultural-conceptual activities for children to do role-plays. In this stage, children share, take, negotiate, and construct their immediate experiences to solve arithmetic problems with peers and old comers (teacher or expert children). In the construction stage, the teacher designs a guide sheet that has structural objectives that need to be accomplished by students. In connection stage, based on children's experiences or strategies, teacher tries to connect children's experiences to mathematical symbols and procedures. In re-application stage, teacher provides another similar cultural-conceptual activity for children to re-apply the learned mathematical concept. In practice stage, children are provided some opportunities to practice school mathematics in everyday situations. In reflection stage, children are trained to monitor their thinking and to be aware of where and how they can apply school mathematics in their everyday activities. Authors call the learning model as Cultural Conceptual Learning Teaching Model (CCLT).

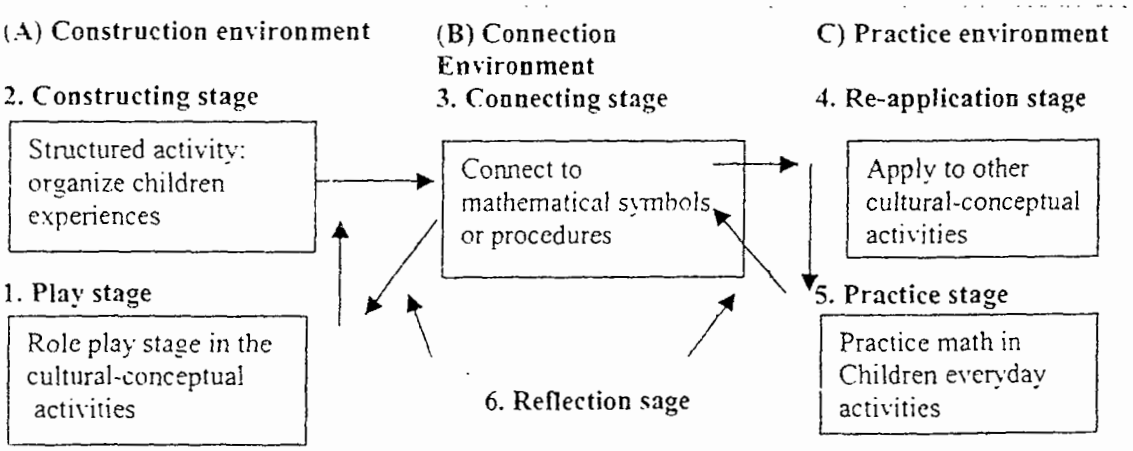

Figure 1: The Cultural Conceptual Learning Teaching Model (CCLT)

How to integrate children's cultural conceptual activities into classroom lessons and to improve children's learning of mathematics is the main purpose of this research. According to Piaget's view (1977), children's cognitive development depends on the cultural activities that are provided and the psychological development of children. Most children in elementary school are staying in the concrete-operation stage. Their thinking is closely tied to their immediate experiences. The environment of socioculturally organized activities in which children can learn is referred to as the zone of proximal development (Vygotsky). Therefore, there are two steps to develop the cultural-conceptual activities. In the first

step, the interview method is used to explore children's everyday cultural activities, social interactions, sign forms and cultural artifacts, and prior understanding, and to find out what kinds of children's cultural activities were related to the mathematical concepts of this study: three-digit place value, addition, and subtraction. In the second step, the cultural activities are organized according to those mathematical concepts. The conceptualized cultural activities were called the cultural conceptual activities.

According to Dienes' theory, mathematics learning contains four basic principles: dynamic principle, perceptual variability principle, mathematical variability principle, and constructivity principle (Post, 1992). This research modified the perceptual variability principle and the mathematical variability principle to design the cultural conceptual activities. Teaching activities are designed based on the dynamic principle and the constructivity principle. This study hypothesizes that children's learning arithmetic based on the cultural conceptual activities through the CCLT teaching model not only would improve their learning in school mathematics but also their abilities to solve everyday problem tasks.

Methodology

Sixteen-second grade classes in Hsin-Chu, a city of Taiwan, participated in this study. Half (n = 8) of the classes were assigned randomly to the treatment group and half to the control group. Teachers of the treatment groups participated in a one-week workshop, and met together on each Saturday within the period of study to design teaching activities. The researcher presented the interview data of children's everyday activities to the teachers of treatment group and designed the cultural-conceptual learning activities with their cooperation. There are five cultural conceptual activities in the CCLT model: Three activities of counting lucky money in an red envelope (New Year activity) and two activities of shopping and selling toys. The other teachers (n=8) were involved in a control group and participated in two 2-hour workshops focused on discussion of the arithmetic content of the national textbook.

Three different tests were used to get a broader understanding of the effects of teaching children arithmetic based on the CCLT model. They were Standardized Test (ST), Three Testing Conditions, and Interview Task Problems. The Standardized Test was developed by the Taiwan Provincial Elementary School Teacher Training and Research Institution. Three Testing Conditions contained Computation Problems, Word Problems, and Simulated Problems. The idea of testing conditions came from the research of Nunes, Schliemann, and Carraher (1994) but was redesigned and modified according to Ginsburg's (1982) classification of computation problems and Carpenter's (1985) classification of word problems. For testing the differences between the CCLT group and the control group in solving everyday arithmetic problems, students were required to accomplish the task problems. The task problems came from parts of Saxe's (1991) research problems and were modified by the researchers to fit the research questions of this study. There are two interview task problems: Identifying currency from a numeral (ICN) and identifying a numeral from

BEST COPY AVAILABLE

a pile of currency (INC). When students solved these task problems, their answers were recorded correct or incorrect and their strategies also were recorded. Each test, except the interview task problems, was taken by all. Four students were randomly chosen from four levels on the Standardized Test in each class as the target students to be interviewed. Three testing conditions and Interview task all contained three-digit and four-digit number. The three-digit problems were designed to test the teaching effect and the four-digit problems were designed to test the transfer of learning.

Results

Standardized Test

The Standardized Test was administrated before teaching and treated as the covariate for the other test. However, there is no statistically significant difference between the CCLT group (M=28.14; SD=1.98) and the control group (M=29.66; SD=4.10) on the Standardized Test (F (1,12)=2.20; P=1.64 >. 05). Therefore, the Standardized Test can not be used as the covariate for comparing the CCLT group and the control group.

Children's Different Achievement in Different Teaching Contexts

This section describes the hypothesis being tested that the CCLT group would score higher on the simulated problems than the control group. On the other hand, the control group would score higher on the computation problems and word problems than the CCLT group. The hypothesis has been rejected. Table 1 summarizes the means and the standard deviations of three test conditions.

Table1: Means and Standard Deviations of Test Results on the Overall Test, Three Digit Test Conditions, and Four Digit Test Conditions.

Three test conditions:	Treatment		Location	
	CCLT	Control	Urban	Suburban
	M (SD)	M(SD)	M (SD)	M(SD)
Overall Test:				
Computation Problems (I=24)	10.38(.33)	9.73 (.81)	10.34 (.50)	9.76(.75)
Word Problems (I=24)	8.45(.62)	7.66 (.71)	8.26 (.90)	7.85 (.58)
Simulated Problems (I=24)	8.48(.60)	7.64 (.74)	8.27 (.74)	7.86 (.80)
3D Test:				
Computation Problems (I=12)	7.30(.21)	6.58 (.51)	6.98 (.30)	6.63(.51)
Word Problems (I=12)	5.58(.43)	5.0 (.48)	5.43 (.58)	5.16 (.47)
Simulated Problems	5.54(.43)	5.01 (.49)	5.33 (.51)	5.23 (.53)
4D Test:				
Computation Problems (I=12)	3.35(.17)	3.15 (.32)	3.36 (.25)	3.14(.25)
Word Problems (I=12)	2.87(.22)	2.56 (.27)	2.84 (.34)	2.69 (.13)
Simulated Problems (I=12)	2.94(.23)	2.62 (.31)	2.94 (.28)	2.63 (.27)

M = Means, SD = Standard Deviation, I= item. 3D =three digit numeral; 4D =four digit numeral.

Table 2 summarizes the analysis of variance of different test conditions taken by treatment groups and locations. On the overall test problems, the three- digit test problems, and the four-digit test problems, the CCLT group scores significantly

higher than the control group. Therefore, this study indicates that students who learn arithmetic based on their cultural activities improve their learning of both formal mathematics (computation problems and word problems) in school and informal mathematics (simulated problems) outside of school better than the students who learned arithmetic based on the traditional textbooks. Another impressive result is that the CCLT group does the transfer of learning more ably than the control group. This research does not address the issue of the main effect of three test conditions so the researchers did not do the follow-up t-tests. Although this research does not focus on this issue, it is interesting to note that children in urban school performed better on both school transfer problems and out-of-school transfer problems than children in suburban schools.

Table 2: Summarization of Analysis of Variance of Different Testing Conditions by Treatment Groups and Locations

Testing condition	F tests						
	Between			Within			
	T	L	T × L	C	T × C	L ×C	T×L×C
Overall Test	9.81**	3.79	.95	86.11**	.14	.15	.76
3D Test	9.35**	2.05	1.17	108.36**	.13	.59	.20
4D Test	8.12*	7.35*	.40	31.67**	.38	.77	2.12

Identifying the relation between numeral and currency values

Children learn counting and summing up money and the price of each item of merchandise from everyday activities. The interview task problems are to examine children's ability to deal with the relationship between numeral and currency value. This task consists of ten items. Each of the items deals with three-digit or four-digit number. Each item is written on one card. Children's strategies for solving the task that deals with the relationship between numeral and currency value are analyzed as follows.

(1) Children's strategies used in solving the ICN problems.

When presented a card, each child was asked to pick the currency up from piles of fake money to match the given number on the card. Children's responses are classified into two categories: correct and incorrect. Children's strategies used in solving the task were identified as formal method and informal method. For instance, when a child was given the number 567, he solved it by picking 5 hundred-dollar bills, 6 ten-dollar coins, and 7 one-dollar coins (written as 5 × $100 + 6 × $10 + 7 × $1). This strategy is identified as a formal method. Other strategies were characterized as informal methods, such as one 500-dollar bill, one 50-dollar bill, one 10-dollar coin, and seven 1-dollar coins (written by 1 × $500 + 1 × $50 + 1 × $10 + 7 × $1). Formal methods were presented in textbooks, but children are found to have a preference for using informal method to solve everyday problems.

(2) Children's strategies used in solving the INC problems.

Children's cultural activities frequently deal with counting money. A task includes ten piles of fake money. Each pile consists of coins and bills with various values. A child was presented a pile of fake money at one time and was asked to count the amount. In the INC problems, five are three-digit numeral and five are four-digit numeral. Students' correct answers and strategies used in solving the problems were analyzed. Four strategies used by children were identified: grouping, grouping with iterating, iterating, and others. *Grouping strategy* means that students regroup the currency by the same bill or coin denomination, and then regroup the currency by thousands, hundreds, tens, and ones and then report the sum according to one, tens, hundreds, and thousands. *Grouping with iterating strategy* means regrouping followed by counting the currency one by one from one pile to another pile. Without regrouping, children's strategy of counting the given money one by one is identified as an *iterating strategy*. When the strategies are not included in the three strategies, they are identified as *others*. For instance, students who don't know the way of counting, even if they do the regrouping.

(3) The results of solving two interview task problems

Table 3 summarizes the means, standard deviations of correct answers given and frequencies of the strategy used by students, and ANOVA analysis for between-group differences in identifying ICN problems and on identifying INC problems.

Table 3: Summary of Means, Standard Deviation, and ANOVA Results for Between-Group Differences On Identifying the Relationship between Numeral and Currency Values Test

Sub tests (number of items)	CCLT M (SD)	Control M (SD)	F tests
Identifying ICN problems			
3D Test (5)	4.97 (.25)	4.72 (.92)	1.675
formal method	1.16 (1.05)	2.91 (1.30)	34.945***
Informal method	3.81 (1.03)	1.78 (1.29)	48.527***
4 D Test (5)	4.49 (.18)	4.47 (1.22)	5.285*
formal method	2.22 (1.01)	3.66 (1.01)	34.929***
Informal method	2.75 (1.05)	1.19 (.93)	39.784***
Identifying INC problems			
3D Test (5)	4.43 (.79)	3.03 (.90)	38.673***
Grouping strategy	3.6 (1.22)	1.00 (.84)	62.171***
Grouping with iterating strategy	1.41 (1.10)	2.97 (.97)	36.317***

*P < .05; **P< .01; ***P< .001; 3D = three digit numeral; 4D = four digit numeral.

Overall, children who learn arithmetic based on the cultural-conceptual activities perform significantly better than children who learn arithmetic based on the national textbook on four-digit problems of ICN, three-digit problems of INC, and four-digit problems of INC. No significant difference is found between groups in identifying three-digit problems of ICN. These results reveal that different teaching methods do not affect children in solving simple ICN problems but they do affect children in solving complicated larger number problems (four-digit problems). Different teaching methods also affect children's use of different strategies to solve the ICN and INC problems. Children in the CCLT group use informal methods to solve the ICN problems more often than children do in the control group. Conversely, children in the control group use formal methods more often than children do in the CCLT group. On the INC problems, children in the CCLT group use the grouping strategy more often than children do in the control group. Conversely, children in the control group use both the strategies of grouping with iterating and iterating to solve the INC problems more often than children did in CCLT group. These results reveal that different teaching methods lead children to using different strategies to solve their everyday problems.

Conclusion and Discussion

This study reveals that children who learn arithmetic through the CCLT learning model based on the cultural-conceptual activities score significantly higher than children who learn arithmetic based on the traditional textbook no matter what they solve computational problems, words problems, or simulated problems. Those results support Hiebert's suggestions (1988) that in school settings children's informal knowledge could serve as basis for the development of understanding of mathematical symbols and procedures.

Other evidence shows that there is no significant difference between two groups in solving the three-digit ICN problems, however, the treatment group solves the four-digit ICN problems at a higher rate than the control group. In fact, most of the children in Taiwan are often given several hundred dollars by their parents to buy foods, drinks, or school supplies for themselves, therefore both groups can solve the tree-digit ICN problems easily, but few children are given thousand dollar bills to buy things. This result indicates that connecting children's everyday experiences with mathematical symbols and procedures can improve children's transfer of learning when they solve the four-digit ICN problems.

The CCLT group uses more efficient and flexible strategies to solve task problems as compare with the control group. One possible reason is that the CCLT program provided an arena for children to assimilate, accommodate, negotiate, and reconstruct their rich experiences between peers and teachers more frequently than the control group provided, and in this way children in the CCLT group increase their understanding more than students in the control group. In the cultural conceptual activities, children are full participants and act as "whole persons to conduct their

business based on their prior understanding. This learning environment is very different from the traditional teaching based on the national textbook that follows the teacher's guide step by step. However, further studies need to consider how to increase the degree of students' participation in classroom and everyday activities. Students learning mathematics need to extend their learning to the entire social community, parent's involvement with children's mathematics learning, not just in school.

PROSPECTIVE TEACHERS' ACCEPTENCE OF THE ONE-TO-ONE CORRESPONDENCE CRITERION FOR COMPARING INFINITE SETS[1]

PESSIA TSAMIR

Kibbutzim Teachers' College Tel Aviv University

This paper examined the tendencies of 121 prospective teachers who had studied a Cantorian set theory course and 71 prospective teachers who had not, to declare that "1:1 correspondence", "inclusion" and "single infinity" are acceptable criteria for the comparison of infinite sets. It also investigated their tendency to accept illustrated comparisons conducted by 1:1 correspondence and the effects of these illustrations on the participants' acceptance of the three above mentioned criteria. The findings usually show significant differences between participants who had Cantorian set theory and those who had not. Prospective teachers who had studied frequently accepted 1:1 correspondence, both as a general method for comparing infinite sets and for specific comparison tasks. Yet, a substantial number of them declared that inclusion and single infinity are also suitable for comparing infinite sets. Moreover, many tended to reject the illustrated solution by 1:1 correspondence of an unusual comparison task.

The notion of actual infinity is a crucial one in mathematics and plays a major role in the theoretical basis of various mathematical systems. Still, its acceptance in the mathematical community was not smooth and simple. When Cantor introduced his theory of infinite sets late in the 19th century, a number of great mathematicians and philosophers, such as Poincaré and Gauss, fiercely objected to it. Moreover, even those who enthusiastically accepted the notion of actual infinity, like Cantor himself, Hahn, Russell, Hilbert, and Dedekind, highlighted its counter-intuitive nature: it goes against the grain of our everyday experience and of finite sets.

Indeed, research in mathematics education over the last two decades, has indicated that, when comparing infinite sets, students intuitively use a wide range of criteria, but generally neglect to use 1:1 correspondence for their comparisons (e.g., Borasi, 1985; Fischbein, Tirosh, & Melamed, 1981). Students' responses seem to be representation-dependent and influenced, for instance, by non-significant, visual aspects (e.g., Duval, 1983). Moreover, students reach contradictory conclusions by using various criteria, such as, "single infinity", (i.e., all infinite sets are equal), "inclusion" (i.e., a set that is included in another set has fewer elements than that set), and "incomparable" (i.e., infinite sets are incomparable). However, they usually are unaware of these contradictions (e.g., Tsamir & Tirosh, 1992).

Questions that arise are: how would an intervention that presents students with the Cantorian set theory, affect their tendency to accept 1:1 correspondence as the criterion for comparing infinite sets, and what kind of intervention should be used for this purpose?

[1] "Comparing infinite sets" here means comparison of the number of elements in infinite sets

BEST COPY AVAILABLE

The common view of leading, 19th century mathematicians who accepted the notion of actual infinity was that the problems rooted in its counter-intuitive nature could "easily" be overcome. Russell, for instance, claimed that:

> . . a little practice enables one to grasp the true principles of Cantor's doctrine, and to acquire true and better instincts as to the true and the false. The oddities then become no odder than the people at the antipodes, who used to be thought impossible because they would find it so inconvenient to stand on their heads.
>
> Russell, 1916/1988, Vol. 3, p. 1560

One may wonder how little "a little practice" exactly would be and how "true and better instincts" are actually acquired?

Mathematics educators reported a number of attempts to promote students' acceptance of 1:1 correspondence as the single criterion for comparing infinite sets. For instance, Tirosh (1991) described satisfactory results of a set theory course for middle school students. The course used, among other things, the cognitive conflict approach, which was based on research findings regarding students' intuitions about infinity. Two additional interventions centered on different representations of infinite sets. The first was aimed at raising cognitive conflict and promoting high school students' awareness of their inconsistent ideas when comparing infinite sets (Tsamir & Tirosh, 1994). The second presented a sequence of assignments advancing from an anchoring task to a target (counter-intuitive) task using the analogy approach (Yehoshua, 1994). In another intervention, Sierpinska (1989) presented suggestions to two girls (10 and 12 years old), for creating 1:1 correspondence between matching elements in infinite sets. One of the girls accepted the "pairing idea", while the other found it counter-intuitive. However, the subjects in all the above mentioned studies were younger than the students who study Cantorian set theory as part of their curriculum.

Nowadays, the concept of actual infinity is customarily presented at the college or university level to mathematics majors and to prospective mathematics teachers for secondary schools. It is usually introduced as an axiomatic system, by consistently and sequentially presenting axioms, basic notions, definitions and theorems within the Cantorian set theory, with reference to Zermelo and Fraenkel. Comparison tasks are discussed pointing to 1:1 correspondence or to the examination of the powers of the sets as the methods for determining equivalency within this theory. However, students' intuitive tendencies either to compare infinite sets by inclusion or to grasp infinity as a single infinity are usually neglected. Thus, it seems important to investigate prospective teachers' te lencies to accept these criteria for the comparison of infinite sets, before and after studying a set theory course.

Therefore, the questions posed in the present study were: (1) Do prospective teachers regard the criteria 1:1 correspondence, inclusion and single infinity as being suitable for the comparison of infinite sets? (2) Are illustrated ways of applying 1:1 correspondence accepted by prospective teachers for the

comparison of infinite sets? (3) How may the illustrated solutions affect the prospective teachers' acceptance of 1:1 correspondence, inclusion and single infinity for the comparison of infinite sets? and (4) Will there be significant differences between prospective teachers who already studied the topic and those who did not?

Methodology

Participants were 181 prospective secondary school mathematics teachers, sampled from Israeli state teachers colleges. Seventy-one of them had never studied Cantorian set theory [N-ST] and 110 had completed a year long Cantorian set theory course [C-ST] three months prior to this research.

The participants were given about 45 minutes to answer, in writing, a questionnaire, which consisted of the following parts:
Part I – an explanation illustrating the notions of 1:1 correspondence, single infinity and inclusion, asking the subjects to determine whether each of the criteria seemed suitable for comparing infinite sets.

Part II – five illustrations of the use of 1:1 correspondence to compare given pairs of infinite sets. Three of these were:

1. A={1/2, 1, 1 1/2, 2, 2 1/2, 3,.. }
   B={ 1, 2, 3, 4, 5, 6,.. }
2. B={1,2,3,4,5,6,...}
   E={3,4,5,6,7,8,...}
3. I={4,8,12,16,20, }
   J={1,4, 9, 16,25,.. }

Which all have the same number of elements ($\aleph_0$). One pair of sets related to the points on two concentric circles having the same number of elements (c). The last pair consisted of non-equivalent sets. The comparison dealt with the number of points in a segment (power c) with the number of midpoints in that segment, created by an infinite process of halving the segment and the sub-segments ($n \Leftrightarrow 2^n-1$, power $\aleph_0$). In all cases, participants were asked to state whether they found the suggested solution acceptable and to justify their judgments.

Part III – was a repetition of part I.

The participants received each part of the questionnaire only after handing in the previous one. After the written assignment, ten participants in each group were also interviewed orally, in order to get a better insight into their ideas.

Results

Part I: Declaring 1:1 Correspondence, Inclusion and Single Infinity as Acceptable Criteria for the Comparison of Infinite Sets

Table 1 shows that in stage I of the research, 1:1 correspondence was the criterion most frequently accepted by prospective teachers who had C-ST and inclusion was the criterion most frequently accepted by those who had N-ST. Single infinity was the least accepted criterion by both N-ST and C-ST participants. It should be noted that even among those who had C-ST, about 17% still viewed single infinity as suitable for comparing infinite sets and about 32% of them still viewed inclusion as suitable.

Participants' justifications for their use of the various criteria were of the following two types:

1. This criterion is the best – emphasizing that the suggested criterion must be used for comparing infinite sets. About half of those who accepted 1:1 correspondence presented such a justification. Interestingly, about 20% of the C-ST participants who regarded 1:1 correspondence as a suitable criterion, justified this claim in terms of 'power', by claiming that *"actually, in order to compare the number of elements one should examine the powers of the sets, but 1:1 correspondence is also quite OK"*.

Table 1

Frequencies (in %) of Accepting 1:1 Correspondence, Inclusion, and Single Infinity for Comparison of Infinite Sets in Parts I and III

Criterion accepted:	**1:1 Correspondence**		**Inclusion**		**Single infinity**	
Study of Set Theory	N-ST n=71	C-ST n=110	N-ST n=71	C-ST n=110	N-ST n=71	C-ST n=110
Part I	54.3	76.4	63.4	31.8	31.4	17.3
Part III	73.9	91.6	60.9	32.4	54.3	25.5

Moreover, about 60% of the N-ST and half of the C-ST participants who accepted inclusion expressed the idea that *"the use of inclusion is ideal because it allows you to reach definite conclusions"*. About 40% of the N-ST and half of the C-ST participants who claimed single infinity to be a suitable criterion, justified their claim by stating that *"infinity is always the same infinity, so obviously you should follow only this criterion"*.

2. Practical considerations – expressing a general attitude that any criterion may be applied when suitable. About 30% of the N-ST participants presented this explanation for each of the three criteria. Among the C-ST participants, about 20% of those who accepted 1:1 correspondence, 30% of those who accepted single infinity and 40% of those who accepted inclusion presented this line of reasoning. They claimed, for instance, that *"not in all cases is there inclusion, but when one set is included in the other, it is only natural to use this criterion"* or *"it is hard to find matching elements, but when possible, this method should be used to compare the sets"*.

The justifications given by the prospective teachers to explain their rejection of the various criteria were of the following four types:

1. Direct counter-arguments – excluding the use of a criterion due to its attributes or the nature of infinity. Most frequent claims were: (a) *"a criterion that always gives the same conclusion is useless"*. This was given by participants who rejected single infinity, about 40% of the C-ST and about 70% of the N-ST; and (b) *"even when I find 1:1 correspondence between matching elements, I can only control a finite number of "pairs", so I can never be sure*

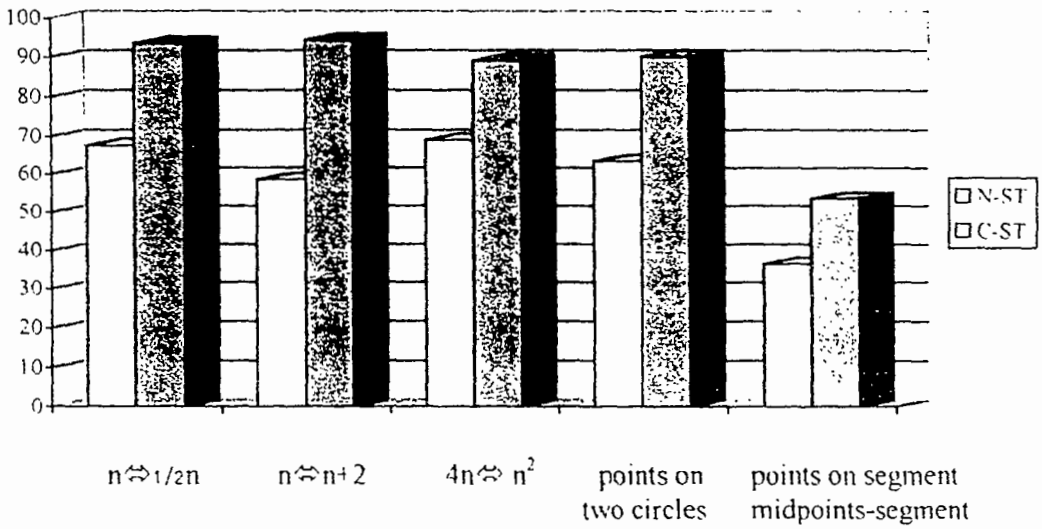
that the matching rule keeps working infinitely". This was presented by about 60% of all participants who rejected 1:1 correspondence.

2. Indicating another criterion as more suitable for comparing infinite sets. This line of justification was used by 15% of the N-ST participants who rejected single infinity because *"one should use inclusion"*; and by about 20% of the N-ST participants who rejected inclusion because *"there is one, single infinity"*. Among the C-ST participants, about 25% of those who rejected inclusion and 40% of those who rejected single infinity argued that power is the only correct criterion. Surprisingly, the idea of power even served about 20% of the C-ST participants who rejected 1:1 correspondence to explain their rejection. They claimed, for instance, that *"we have learned that only the powers of sets indicate the numbers of elements they have. Obviously, in order to compare the number of elements in two sets, one needs to know these numbers*".

3. Practical considerations – excluding the use of a certain criterion due to its practical limitations. About 30% of all participants justified the rejection of inclusion by claiming that *"the criterion is inadequate, as frequently there is no inclusion relationship between the sets"*. Similarly, about 30% of the N-ST participants who rejected 1:1 correspondence said, *"in many cases it is extremely difficult to find a way to match the elements"*.

4. Consistency considerations – expressing the need to preserve consistency. Only when rejecting inclusion did a few N-ST and C-ST participants claim that *"inclusion is not valid as it can contradict solutions arrived at by using 1:1 correspondence."*

Part II: Acceptance of Illustrations of Using 1:1 Correspondence when Comparing Infinite Sets



Graph 1 shows that for each of the four problems that presented equivalent sets, the tendency of C-ST participants to accept the illustrated 1:1 correspondence (about 90%) was significantly higher than that of the N-ST participants (about 60%). In problem 1 ($n \Leftrightarrow_{1/2} n$) $x^2=22.6$ DF=2 $p<0.01$, in problem 2 ($n \Leftrightarrow n+2$) $x^2=36.04$ DF=2 $p<0.01$, in problem 3 ($4n \Leftrightarrow n^2$) $x^2=13.2$ DF=2 $p<0.01$, and in problem 4 (points on two circles) $x^2=20.9$ DF=2 $p<0.01$. However, in the fifth problem, which dealt with an unusual presentation of non-equivalent sets, there were insignificant differences between the tendencies of N-ST participants and C-ST participants to accept the illustrated 1:1 correspondence. Only about 40% of the N-ST participants and about 50% of the C-ST accepted the suggested comparison of the number of points in a segment (power c) with the number of midpoints ($n \Leftrightarrow 2^n-1$, power $\aleph_0$).

Most prospective teachers provided no justifications for their acceptance or rejection of the given solutions. Nevertheless, among those who did give justifications, N-ST participants most frequently explained rejecting the given solutions to the equivalent sets by specifying another, more preferable, criterion.

Most prevalently they related to inclusion – *"One set is included in the other, thus they don't have the same number of elements"*, but they also mentioned single infinity – *"1:1 correspondence is unnecessary. It is known that infinities are always the same"*. However, C-ST participants who accepted the suggested 1:1 correspondence frequently confessed that the given solutions reminded them of rules they had studied. Those who rejected the suggested solution, however, usually accepted the equivalency, but said that power and not 1:1 correspondence was the criterion to be used.

Graph I

Frequencies (in %) of the acceptance of illustrated '1:1 correspondence' solutions

The one justification most commonly used to reject the fifth solution, used by all participants (both N-ST and C-ST) was that *"By endlessly choosing midpoints, one eventually deals with the whole segment. So, the collection of all midpoints matches the collection of all points."* Others used the single infinity idea, and a few prospective teachers argued, in all cases, that infinite sets are incomparable.

Part III: Re-Declaring 1:1 Correspondence, Inclusion and Single Infinity as Acceptable Criteria for the Comparison of Infinite Sets

Table 1 shows that when advancing from Part I to Part III there was an increase in the percentage of N-ST and C-ST participants who declared that 1:1 correspondence is suitable for comparing infinite sets. However, the growing acceptance of 1:1 correspondence was not accompanied by an increased tendency to reject the other criteria. The same rates of N-ST and C-ST participants as in part I viewed inclusion as acceptable, and surprisingly, more N-ST and more C-ST than before accepted the single infinity criterion

Usually participants either gave no justification or wrote that they had already explained their judgements in Part I. Prospective teachers who justified their claims often followed two lines of reasoning: (a) *"I was convinced by the illustrations in Part II that 1:1 correspondence can be very useful even in cases where I couldn't provide the matching rule"* or *"the previous examples [in Part II] reminded me"* (used by prospective teachers who rejected '1:1 correspondence' in Part I and accepted it in Part III); and (b) *"All these questions confuse me and make me believe that infinity is extremely strange. There is probably a single infinity"* or *"Inclusion seems more reasonable than creating a correspondence between an infinite number of pairs"* (used by prospective teachers who accepted 1:1 correspondence in Part I but rejected it in Part III). A few participants consistently expressed in both Parts I and III the notion of single infinity to reject 1:1 correspondence, while some others argued in both parts that *"infinite sets are incomparable"*.

DISCUSSION

The findings of this research, in line with those of previous research with younger students, indicate that prospective teachers intuitively regard the criteria of 1:1 correspondence, inclusion and single infinity as suitable for the comparison of infinite sets (e.g., Tsamir & Tirosh, 1992). Participants who had not followed a set theory course tended to view inclusion as most applicable, but even a substantial number of C-ST participants declared that inclusion or single infinity were acceptable.

Moreover, practical considerations and the availability of the various criteria played an important role in prospective teachers' decisions whether to accept or reject a specific criterion. However, similar, practical considerations led to contradictory conclusions. On the one hand "to accept" (e.g., *"It is not always possible to use 'inclusion', but as this is a criterion which is easy to use, it should be used when possible"*); and on the other hand "to reject" (e.g., *"Sets are not always inclusive, so this is not a good criterion"*).

Interestingly, C-ST participants used the consideration of powers to reject 1:1 correspondence as a valid criterion, failing to grasp that 1:1 correspondence is the notion underlying powers. Moreover, even the C-ST participants examined each problem in isolation with no regard to the contradictions which may arise when accepting more than one of the above mentioned criteria as being valid. Consistency was only rarely mentioned as the means by which to decide whether to accept a suggested criterion, and as a means to determine validity in mathematics (see also Tsamir & Tirosh, 1994).

After having been presented in Part II with illustrations of the use of 1:1 correspondence as a criterion for comparing infinite sets, in Part III there was an increase among all participants in the acceptance of 1:1 correspondence. However, the rate of N-ST and even C-ST participants who accepted inclusion was unchanged, while the rate of the acceptance of 'single infinity' rose. It seems that while "familiarizing" the N-ST with the correct solution and

"reminding" the C-ST participants of it strengthens their tendency to accept this criterion, it does not weaken their tendency to reject other criteria.

The findings also indicate that, as could be expected, prospective teachers who had studied Cantorian set theory exhibited a significantly higher tendency to accept 1:1 correspondence than prospective teachers who had followed no course. These findings were detected in both types of questions — when asked to state whether 1:1 correspondence is a suitable criterion for the comparison of infinite sets, and when asked to judge illustrated solutions to specific comparison tasks. However, this tendency was no longer apparent when the participants were presented with an unusual comparison task – the fifth problem in Part II. This problem was unusual both in that it intuitively triggered the single infinity notion and in that it was a type of problem not dealt with in C-ST courses.

In light of these findings, it seems that "showing students the right way" does not decrease their tendencies to accept incorrect, intuitive ideas when comparing infinite sets. Thus, students' primary intuitions should be taken into consideration when planning instruction. Students should be made aware of their tendency to view all infinities as equal and of their tendency to use considerations of inclusion. Moreover, they should understand that using more than one of these criteria to compare infinite sets will lead to contradiction. Some ideas for practical applications of these conclusions will be offered in the oral presentation.

-THE CONCEPT OF A VARIABLE; GAUGING STUDENTS' UNDERSTANDING

Elizabeth Warren, Australian Catholic University

This paper explores the use of written tests and semi-structured interviews in ascertaining students' understanding of the concept of a variable. A written algebra test was administered to 379 students and from the results students were selected for a semi-structured interview. The types of questions asked and the medium in which they were asked appeared to influence the responses given. It is conjectured that these issues must be considered when endeavouring to reach a richer understanding of the students' perception of the concept of a variable.

Algebra has long held a place of distinction in the mathematics curriculum (NCTM, 1989; National Statement for Australian Schools, 1991). Few have contested the importance of algebra as it is seen as 'the language through which most mathematics is communicated' (NCTM, 1989, p. 150). Critical to the algebraic domain is the variable construct. The literature identifies common misconceptions students experience when interpreting algebraic symbols.

Common misconceptions of the concept of a variable

Through his large-scale study of students' interpretations of literal terms, Kuchemann (1978, 1981) identified many misconceptions. These were:

Letter evaluated: Students assign numerical values to letters at the outset of a problem. For example, when asked to describe the expression $2+3x$ children often assign a value to x, such as 1, and compute the answer. Thus $2+3x=2+3\text{x}1=5$.

Letter not used: Here, students ignore the letters, or at best acknowledge their existence but without giving them meaning. For example, the algebraic expression $2x+8y+3x$ is equated to $13xy$. Such an answer is obtained by simply adding up all the numbers, then writing down each letter that occurs.

Letters used as objects: Here, students regard the letter as shorthand for an object or as an object in its own right. For example, $2a+3b$ represents adding 2 apples to 3 bananas. This is referred to in the literature as 'fruit salad' algebra (Booth, 1988).

Letters used as a specific unknown or constant: Students perceive the letter as a specific but unknown number. For example, the expression L+M+N would never equal L+P+N as N cannot equal P. Even though both N and P are acknowledged as variables they must always be different values from each other as they are represented by different letters of the alphabet.

Letter used as a generalised number: Here, students perceive the letter as representing, or at least as being able to take, several values rather than just one. For example, if students are asked to list all the possible values for the expression $x+y=10$, they will list more than one of the whole numbers which will satisfy the condition.

Kuchemann (1981) found that most students (aged 13-15 years) could not cope consistently with items that required the use of the letter as a specific variable.

A further three misconceptions identified in the literature were as follows:-

BEST COPY AVAILABLE

Changing the variable symbol as changing the referent. That is, different variables must take on different values. For example, the expression $3n$ is not the same concept as $3x$ as n and x could never be equal (Booth, 1984; Chalouh & Herscovics, 1983; Wagner & Parker, 1993).

Assigning numerical values to letters according to their rank in the alphabet, for example, a=1 and z=26, or if x=3 then y=4 and z=5. (Booth, 1984; Chalouh & Herscovics, 1983).

Assigning the letter as a subdivisional label, for example, 3a refers to the first part of the problem (Chalouh & Herscovics, 1983).

Misconceptions also occur when examining expressions. Some of these are:-

Closure: Some students exhibit a need to have a 'single' answer. For example, a+b becomes ab (Chalouh & Herscovics, 1988).

Equal sign: In arithmetic '=' tends to mean compute,. 'makes', or a place for the answer. Students fail to recognise the equality relation between the left and right hand side of the equation (MacGregor, 1991).

This research is a replication study. Kilpatrick (1993) claimed that mathematics education 'has suffered from a lack of replication studies [which] ... would help confirm and refute conclusions drawn from previous work.' This is particularly imperative in ascertaining students' understanding variable of the variable concept. Most of the misconceptions identified in the literature were delineated from the results of large studies involving written tests. The types of questions asked and the medium in which they were asked could influence the responses given. Through written responses students may not be able to exhibit their full understanding or misunderstanding of the concept of a variable. This paper goes beyond pure replication. It compares the results from written responses and a semi-structured interview and explores how each contributes to reaching a richer understanding of students' perceptions of the concept of a variable.

Methodology

This study comprised whole class testing to select students for in-depth interviews. The sample for the whole class testing comprised 379. The students' ages ranged between 12 years and 2 months and 15 years and 10 months. Half of the sample were in their first year of algebraic studies and half were in their second year. Both schools chosen for the study consisted of students from lower-middle socio-economic status, with a variety of ethnic backgrounds represented.

Whole class test: The whole class test was administered as a written test and completed within a one-hour period. The test consisted of three components, namely, generalising from visual patterns, generalising from tables of data, and understanding the concept of a variable. The results from 3 of the 8 questions selected for the variable component of the written test are discussed in this paper. These 3 questions were believed to probe students' view of the variable, their need for closure of algebraic expressions, their propensity to concatenate algebraic expressions, and why students allowed "= constant" to limit possible values for the variable. These questions were also used in the semi-structured interview.

Semi-structured interview: The results for each component were ranked and three students were selected at the 1st, 25th, 75th and 100th percentile for each of the written components. Each interview was videotaped and transcribed.

Instrument The selected questions were:

Question 1. *This question is about t+t and t+4.*

(a) *Is t+t ever larger than t+4? If so when?*

(b) *Is t+4 ever larger than t+t? If so when?*

(c) *Are t+t and t+4 ever equal? If so when?* (Modified Harper, 1979)

This item was modeled on an item used by Harper (1979) and Quinlan (1992). The item used in their studies was as follows:

This is a question about t+t and t+4

(a) *Which is larger, t+t or t+4? WHY?* *(b)* *When is t+t larger?*

(c) *When is t+4 larger?* *(d)* *When are they equal?*

In the interview stage of the pilot study, concern was expressed about the inconsistency in the wording of the Harper item. For example, *"When is t+t larger?"* seemed to alert to the fact that perhaps *t+t* could be larger. This proved confusing for students who had chosen *t*+4 for part (a). Hence the question was reworded so that such inconsistencies no longer existed.

Question 2. *For a school excursion, 3 buses take f students each and 4 cars take g student each.*

(a) Give the total number of students taken by these buses and cars.

(b) One car leaves early with g students. How many students remain? (Quinlan, 1992b)

This question was created to obtain information on students' ability to interpret the meaning of letters when they referred to quantities as objects rather than mere numbers (as in question 1) and to carry out operations on numerical variables without knowing their values. This question was not reworded for this study.

Quest 3. (a) *If c+d=10, tick ALL the meanings that c could have:*

3 *10* *12* *7.4* *the number of apples in box*

an object like a cabbage *an object like an orange*

(b) If c+d=10, what happens to d as c gets bigger?

(c) If c+d=10, and c is always less than d, what values may c have

The origin of this item is threefold. It is based on the CSMS project question (Hart, 1981) *"What can you say about c if c+d=10 and c is less than d,"* (Kuchemann 1980, p. 67) and on Harper's (1979) equation task, *"If x+y=10 when is x less than y."* Kuchemann (1980) regarded this question as one which required students to view letters as generalised numbers. Quinlan (1992, p. 106) added parts (a) and (b) to the original question. Part (a), measured the types of possible meanings students are prepared to accept for alphabetic symbols in algebra. Part (b) tested students' understanding of the covarying relationship between the two variables (i.e., as the value of *c* varies so does the value of *d*). This question was adapted for the semi-structured interview. In the semi-structured interview students were asked *"If p+m=12, put a ring around all the possible values p can have. 4, 12, 15, 0, 3.9, -2, an object like a pear, the number of children in*

the class." Students were then asked to articulate their reasons for including or excluding certain values.

Results

Written component For each part of question 1, students were required to give two responses. Students were asked to reply either in the affirmative or negative to the question and then elaborate on their response with an appropriate reason. Table 1 summarises the results for this question.

Table 1 *Percentage of Students who correctly responded to Each Part of Question 1*

Question 1	Correct response	Valid reason
(a) Is t+t ever larger than t+4? If so when?	46.4	28.8
(b) Is t+4 ever larger than t+t? If so when?	45.9	29.0
(c) Are t+t and t+4 ever equal? If so when?	43.0	36.1

Less than half the students answered this question. The results indicate that giving a valid reason for the equality situation was easier than the other two situations. The rewording of the Harper Quinlan question appeared to result in a greater percentage of students reaching correct solutions. While Quinlan (1992) found that 50% of his sample (517 students) responded correctly, 241 of these had completed at least 2 more years of schooling with 108 students being in their final year. Thus only 27% of students with comparable formal algebraic studies correctly responded to the Harper Quinlan question.

Responses to both 2(a) and 2(b) seemed to fall into four distinct levels Table 2 presents a description of the levels together with the percentage of students whose responses were considered to be at that level.

Table 2 *Levels of responses to Question 2 & % of correct responses*

Level	Description	2 (a)	2(b)
0	Did not attempt or assigned a number	29.0	31.4
1	Incorrect algebraic response	14.5	21.4
2	Correct response but the need for closure	7.7	10.8
3	Correct response	48.5	36.4

Students found 2(a) easier to respond to than 2(b). This question was not reworded for this research and results were similar to those obtained by Quinlan (1992).

Table 3 summarises the percentage of students who chose the various options in 3(a)

Table 3 *Percentage of Responses to each Choice for Question 3(a)*

	Choice						
	3	10	12	7.4	number in box	object cabbage	object orange
Accepted	76.5	51.5	11.9	66.5	40.4	22.7	21.4

The majority of students accepted 3 and 7.4 as possible values for the variable *c* but were less confident in allowing *c* to be 10. When *c* is 10 the value of *d* is zero. Only twelve percent accepted *c* as 12. When *c* is 12 the value of *d* is negative. These findings seem to indicate that the nature of the product, "equal ten," of the equation plays a significant role in limiting the permissible values for the associated variables. This could reflect reluctance by the students to assign zero or negative values to the variable *d*. This trend was difficult to delineate in the Kuchemann (1980) format of the question. This issue was investigated in the semi-structured interview. Only 40.4 percent of the students accepted that *c* could be the number of apples in a box, whereas up to 22.7 percent allowed *c* to stand for an object such as an orange or cabbage. This seems to indicate that the students had difficulty in accepting the variable as a generalised number and in differentiating between this interpretation and the variable as an object.

Levels were developed for classifying responses to 3(b) and 3(c). For 3(b), the levels indicated whether the students could see the covarying relationship between *c* and *d* in the equation $c+d=10$. 68.3% of the students reasoned correctly that *d* would get smaller. For 3(c), the levels indicated the possible values students would accept for *c*. Table 4 summarises the results for this question.

Table 4 *Levels of Responses for Question 3(c)*

Level	Description	% response
0	omitted response or incorrect list of numbers e.g., 1,2,3,4,5,..10	29.4
1	one or two numbers as response e.g., 3,4	4.5
2	1,2,3,4 – included only integer responses	42.9
3	included 0, negatives and/or fractions	20.6
4	< 5	2.1
5	< 5 and included 0, negatives & fractions	0.05

As can be seen from the above results very few students responded correctly to question 3(c). Over half of the students tested gave at least four values for *c*. Kuchemann (1981, p. 108) found that nearly 40% of his sample of 14 year old students (n=1000) gave only one value for *c* and that 30% gave four or more. For this study, approximately 43% of the students gave four values for *c*. As indicated by Quinlan (1992), it appears that the inclusion of the first two components helps students frame appropriate answers to (c).

In summary, these 3 questions from the written test indicated that the rewording of questions can influence the responses given. Also, when examining the relationship between two variables in an expression of the form $x+y=c$, where c is a constant, the value of the constant seems to play an important role in the permissible values students will accept for the variables themselves. Students exhibited a reluctance to choose values for either *x* or *y* that were greater than c. Even students who were considered by their teacher to be very capable of understanding algebraic concepts, included the letter standing for an object in a number of their responses. A very small percentage of the

students perceived the variable as a generalised number. Most students tended to see the variable as being represented by up to 4 specific integer values. These trends were investigated further in the semi-structured interview.

Semi-structured interview Twelve students were chosen to be interviewed on their understanding of the concept of a variable. The following section presents a summary of students' perceptions.

Variable as an object: The results for question 3 from the written algebra test indicated that 22.7% of students allowed c to stand for 'an object like a cabbage' and 21.4% allowed c to stand for 'an object like a orange' (see Table 3). From an analysis of the written responses, some of the more able students seemed to hold this misconception. The inclusion of "object like a pear" in the third interview question probed why students accepted the variable as standing for an object. Not one of the twelve students interviewed accepted p as "shorthand for pear." When questioned, those students who ringed 'an object like a pear' seemed to assign a number to p. For example, Jason at the 1st percentile said, "Yes it could be about the number of pears and number of apples." Michelle, also at the 1st percentile said, "Could be 14 pears." One student at the 100th percentile could clearly articulate why 'an object like a pear' was not a valid option. Mary said, "Object like a pear and 12 have no relationship," indicating that she viewed 'pear' as an object and not as a number. The two other students at the 100th percentile said, "p could be an object like a pear only if m was 11 pears and then you would have 12 pears." The interview seemed to indicate that, contrary to the belief held when analysing the written component, simply ringing 'object like a pear' did not necessarily mean students saw p in expressions like $p+m$ standing for pear, but rather as 'a pear', that is, 'one pear'. This seems to indicate that relying solely on written responses could lead to erroneous conclusions with respect to students' understanding of variable concept.

Specific unknowns: From the students' responses there seemed to be a growth of acceptable values for the variable. Students at the 1st and 25th percentile made decisions about the two expressions $t+t$ and $t+4$ using one specific value for the variable. Adam said, "$t+t$ is bigger when $t=5$, $t+4$ is bigger when $t=2$ and they are the same when t equals 4." By contrast, one student at the 75th percentile reached a conclusion by using a series of specific unknowns for t (e.g. "$t+t$ is bigger when $t=5, 6, 7, 8\ldots$).

Generalised number: For the expressions $t+t$ and $t+4$, two students at the 75th percentile and three students at the 100th percentile immediately articulated the general case, that is, "$t+t$ is larger when t is greater than 4, $t+4$ is larger when t is less than 4 and they are equal when $t=4$." It was conjectured that they had an understanding of the variable as a generalised number.

Closure: For question 2, 3 students at the 1st and 25th percentile wrote $c+f=$, indicating a need for closure. All the students at the 75th and 100th percentile did not need to close the expression, writing $c+f$.

Product component of an equation: For the expressions $p+m=12$ it seemed that the '=12' component of the question was not the only factor that limited the number of acceptable

values for p. The addition sign before m also seemed to play an important role. The six students at the 1st and 25th percentile failed to accept 15 for the value of p. A common response was "15 plus anything is over 12," indicating that the value of m must be positive as it was preceded by '+'. Of particular interest was the fact that they all accepted '-2' as a value for p. One student stated that, "-2 was alright as it is below 12."The other six students at the 75th and 100th percentile accepted 15 as a valid value for p, stating that m would need to be negative.

Concatenation of algebraic expressions: Three students exhibited a need to concatenate the variables. All of these students were either at the 1st or 25th percentile. For question 1, Chris at the 1st and James at the 25th percentile indicated that they would have '*cf* trucks'. When comparing t+t and t+4, Chris also suggested that, "t+t is 2t and t+4 is 4t so t+4 would be bigger."

In summary, the results of the interviews indicated:-Students at the 1st and 25th percentile were characterised by their need to evaluate, close and concatenate algebraic expressions, and by perceiving the variable as representing a specific unknown. Two students at the 75th percentile and the three students at the 100th percentile perceived the variable as a generalised number and did not concatenate or close any of the algebraic expressions.

Discussion and conclusion

Both the results of the written test and the interview support Kucheman's stages of understanding. Not only did the less able students, students at the 1st and 25th percentile, seemed to perceive the variable as representing a specific unknown but they also exhibited a need to close algebraic expressions. By contrast, the more able students did not need to close algebraic expressions and they perceived the variable as a generalised number.

The results also seem to indicate that care must be taken when conjecturing about students understanding from written responses. First, the framing of the question itself could limit the types of responses given. The use of appropriate prompts could help elicit students' full understanding of the concept of a variable. For example, as indicated by Question 3 in the written test, the inclusion of (a) and (b) helped students frame a response to (c), and for question 1 the rewording resulted in a greater percentage of students with similar algebraic experience reach correct solutions.

Second, the medium in which questions are posed needs also to be considered when reaching conclusions from students' responses. From an analysis of the results of the written algebra test it seemed that many students perceived the variable as a letter standing for an object. The results of the interview seemed to indicate that this assumption was too simplistic. None of the students interviewed believed that p was "shorthand for pear." All the students who selected p as standing for an object like a pear, had valid reasons for its inclusion and these reasons relied on p standing for a number of pears and not pear. While these results point tot he limitation of asking questions only in written format, further probing is needed to ascertain how the context of the problem can influence this common misconception (Clement, 1982). Also, for the

expressions $p+m=12$ the product component (=12) is not the only factor that limited students' thinking. It seemed that the placement of '+' before the variable also played a key role. Students at the 1st and 25th percentile believed that '+m' meant that the value of m must always be positive. This seems to indicate that some students are not capable of delineating between '+' as the operation of addition and '+' indicating a positive value. Both of these misunderstandings are difficult to identify in a written test format.

The results of this study seem to confirm generalities found in previous studies. First, the wording of questions can influence the type of response given. A slight change in how the question is framed can lead to a very different array of responses. Second, adding prompts, lead ins and explain components to questions appears to help students frame appropriate responses. The role of these components needs to be further explored. Third, the value of interviewing and listening to students explanations to how they solve problems can not be underestimated when gaining insights into students' understanding of algebraic concepts. Fourth, when teaching arithmetic and algebra there is a need to delineate between '+' as an operation and '+' as denoting a positive number. Recent research has already acknowledged this need for '-' but not for '+'. The results of this study also indicate that rewording of questions can significantly influence the responses given by students. Rewording of questions in previous areas of mathematical research needs to be carried out in order to both confirm and refute conclusions drawn.

TYPES OF RESEARCH IN MATHEMATICS EDUCATION

Dylan Wiliam
King's College London

Different approaches to research are described in terms of the different emphases accorded to the hermeneutic notions of text, context and reader. Knowledge-building in mathematics education is defined as a dual process of establishing warrants for particular beliefs, and eliminating plausible rival hypotheses, where 'plausibility' is established either by explicit reference to a theoretical frame, or implicitly within a discourse. These perspectives are then integrated by a classification based on whether the primary source of evidence is reason, observation, representation, dialectic, or ethical values. It is then argued that educational research, as well as building knowledge by the process identified above, requires subjecting the consequences of the research to the ethical judgements of the community.

Introduction

The community of PME is heterogeneous, and while there appears to be reasonable agreement about the purposes of research in the Psychology of Mathematics Education, there is much less agreement as to how that research should be conducted and disseminated and what is to count as evidence or knowledge (Lester, 1998). Supplementing the traditional paradigms of experimental psychology, recent work has borrowed heavily from ethnographic traditions of research, and more recently still, there has been an increasing interest in 'action research'—that is research carried out by teachers in their own classrooms for their own benefit. With this proliferation of paradigms, there is a danger that debates about the quality of research are clouded by differences in researchers' views about what counts as evidence rather than about the quality of the research. The purpose of this paper is to present a framework for thinking about research in mathematics education, with a view to clarifying the debate about the quality of that research.

Evidence and inference

The relationship between different approaches to research in mathematics education can be clarified by the use of some ideas from hermeneutics. Traditionally, it had been assumed that an utterance, picture, piece of writing etc (collectively referred to as *text*) has an absolute meaning. In hermeneutics, it is acknowledged that the same text has different meanings when presented in different contexts, and when presented to different readers. For example, when a student says that the work that she has been asked to do is "boring", in one context, and to a particular teacher, this might be an informed comment that the work was too repetitive, not sufficiently challenging, and unlikely to effect any meaningful learning. In another context, or to another person, "boring" might mean almost the opposite — work that is too challenging, or even threatening. The text (in this case "It's boring") will be interpreted differently in different contexts, and by different readers (eg teachers). These three key ideas — text, context and reader — are said to form the *hermeneutic circle*.

In educational research the 'text' is usually just 'data'. Sometimes the fact that the data has to be elicited is obvious, as when we sit down with someone and ask them some questions and tape-record their responses. At other times this elicitation process is less obvious. Observing and making notes on a teacher's actions does not feel like 'eliciting' evidence. It feels much more like the evidence presenting itself. However, it is important to realise that the things I choose to make notes about, and even the things that I observe (as opposed to those I see), depend on my personal theories about what is important. In other words, all data is, in some sense, elicited. This is true even in the physical sciences, where the physicist Werner von Heisenberg remarked that "What we learn about is not nature itself, but nature exposed to our methods of questioning" (quoted in Johnson, 1996 p. 147).

For some forms of evidence, the process of elicitation is the same as the process of recording the evidence. If I ask a school for copies of its policy documents in a particular area, all the evidence I elicit comes to me in permanent form. However, much of the evidence that is elicited is *ephemeral*, and only some of it gets recorded. I might be interviewing someone who is uncomfortable with the idea of speaking into a tape recorder, and so I have to rely on note-taking. Even if I do tape-record an interview, this will not record changes in the interviewee's posture which might suggest a different interpretation of what is being said from that which might be made without the visual evidence. The important point here is that it is very rare for all the evidence that is elicited to be recorded.

During the process of elicitation and recording, and afterwards, the evidence is *interpreted*. Research based on approaches derived from the physical sciences emphasises *text* at the expense of *context* and *reader*. The same educational experiment is assumed to yield substantially the same results were it to be repeated elsewhere (for example in another school), and that different people reading the results would be in substantial agreement about the meaning of the results. Other approaches will give more or less weight to the role played by *context* and *reader*. For example, an ethnography will place much greater weight on the *context* in which the evidence is generated than would be the case for more positivistic approaches to educational research, but would build in safeguards that different readers would share, as far as possible, the same interpretations. In contrast, a teacher researching in her own classroom might pay relatively little attention to the need for the meanings of her findings to be shared by others. For her, the meaning of the evidence in her own classroom might well be paramount.

In what sense, then, can the results of educational research be regarded as 'knowledge'? The traditional definition of knowledge is that it is simply 'justified true belief' (Griffiths, 1967). In other words, we can be said to know something if we believe it, if it is true, and if we have a justification for our belief. There are at least two difficulties with applying this definition in educational research.

The first is that even within a subject as precisely defined as mathematics or science, it is now acknowledged that there are severe difficulties in establishing what, exactly, constitutes a justification or a 'warrant' for belief (Kitcher, 1984). The

second is that these problems are compounded in the social sciences because the chain of inference might have to be probabilistic, rather than deterministic. In this case, our inference may be justified, but not true!

An alternative view of knowledge, based on Goldman's (1976) proposals for the basis of perceptual knowledge, offers a partial solution to the problem. The central feature is that knowing something is, in essence, the ability to eliminate other rival possibilities. For example, if a person (let us call her Chris) sees a book in a school, then we are likely to say that Chris knows it is a book. However, if we know (but Chris does not) that students at this school are expert in making replica books that, to all external appearances, look like books but are solid and cannot be opened, then with a justified-true-belief view of knowledge, we would say that Chris does not *know* it is a book, even if it happens to be one.

Goldman's solution to this dilemma is that Chris knows that the object she is looking at is a book if she can distinguish it from a relevant possible state of affairs in which it is not a book. In most cases, the possibility that the book-like object in front of Chris might not be a book is not a relevant state of affairs, and so we would say that Chris does know it is a book.

However, in our particular case there *is* a relevant alternative state of affairs—the book might be a dummy or it might be genuine. Since Chris cannot distinguish between these two possibilities, we would say that Chris does not know.

Within educational research, therefore, we can view the task of producing 'knowledge' as having two requirements. The first is establishing that the inferences that are made from the evidence are warranted. This is something at which most researchers are relatively good. The second requirement, honoured more in its breach than its observance, is establishing that the chosen interpretation is more warranted than plausible rival interpretations.

Such a process can never be complete—there are no 'off-the-peg' methods; only a never-ending process of marshalling evidence that the chosen interpretation is *a) supported by the available evidence, and b) more warranted than plausible rival interpretations*.

This solution to the problem of 'knowledge' in education is only partial, because it leaves open what counts as a *plausible* rival hypothesis. In practice, even in the physical sciences, this is decided by the consensus of a community of researchers. Sometimes what is and is not plausible is made absolutely explicit, in the form of a theoretical stance. In other words, a researcher might say "because I am working from this theoretical basis, I interpret these results in the following way, and I do not consider that alternative interpretation to be plausible". More often, communities of researchers operate within a shared discourse that rules out some alternative hypotheses, although these tend to be implicit and are often unrecognised.

To sum up, evidence is elicited, recorded in some form and interpreted (not necessarily in that order!). The interpretations are validated by the elimination of plausible rival interpretations of the evidence, and the definition of what counts as 'plausible' is determined by the discourse within which the validation takes place.

Meanings and consequences

The above description has dealt with the production of 'educational knowledge', which, although it acknowledges the role of context in interpreting text, still places substantial emphasis on the production of shared meanings within a community of researchers.

During the 1980s, this concern with sharing of meanings across readers was questioned in what is sometimes called *action research*. In action research, what is important is the potential of the research to transform practice in the individual school or even for the individual teacher. Even if the research has different meanings (or even if it is meaningless) for those in different contexts, this is not a problem, as long as it has meaning for the teacher. There is no doubt that action research has huge transformative potential for the individuals involved in the research, but many have argued that it cannot be classed as research per se, because the research makes no effort to produce meanings that are shared beyond the immediate context and readers.

My concern here is not, however, with whether action research is valid research or not, but to show how it can fit into a theoretical framework and to examine how it differs from other approaches to research.

In all research, there is a tension between the *meanings* and *consequences* of research. For example, it would not be unusual for a researcher to discover something about a teacher's practice (perhaps through interviews with students) that appeared to be preventing the students from learning effectively. The question is, then, should the researcher communicate this to the teacher? In the traditional research paradigm, the answer would be a resounding 'no'. Feedback by the researcher to the teacher might change the teacher's subsequent behaviour, thus rendering the results of the research much more difficult to interpret. At the other extreme, many advocates of action research would say that such important evidence should be fed back to the teacher, and if this changes what is being investigated, then so be it. Put crudely, in traditional *text*- and *context*-focused research, unfortunate (or non-existent!) *consequences* are frequently justified and legitimated by the need for shared *meanings*. In action research, weakness in the extent to which meanings of the research findings are shared are justified and legitimated by the consequences of the research.

A full consideration of the nature of educational research must, therefore, take account of the consequences as well as the meanings of the research. The role of consequences in the validation of research is made much more explicit in the classification of inquiry systems developed by Churchman, to which we now turn.

Inquiry systems

Different methods of inquiry were investigated by Churchman who regarded all kinds of inquiry as being classifiable into 5 broad categories, each of which he labelled with the name of a philosopher (Leibniz, Locke, Kant, Hegel, Singer) he felt best exemplified the stance involved in adopting the system, and in particular, what is to be regarded as *evidence*.

More detailed accounts of the systems can be found in the work of Churchman (1971) and his colleagues (Mitroff & Sagasti, 1973; Mitroff & Kilmann, 1978), and Messick (1989). However, it is perhaps easier to understand the framework when it is applied to a 'real' research question in mathematics education — should students be allowed unrestricted access to calculators when learning mathematics?

One approach to this problem is to use only rhetorical tools to attempt to establish the truth of the proposition. For example a report by the London Mathematical Society, the Institute of Mathematics and Its Applications and the Royal Statistical Society (1995) argues that "To gain a genuine understanding of any process it is necessary first to achieve a robust technical fluency with the relevant content" (p9).

This would be an example of what Churchman calls a *Leibnizian* inquiry system, in which certain fundamental assumptions are made, from which deductions are made by the use of formal reasoning rather than by using empirical data. In a Leibnizian system, reason and rationality are held to be the most important sources of evidence. Although there are occasions in educational research when such methods are appropriate, it is usually far more appropriate to use some sort of evidence from the situation under study (usually called empirical data) in the inquiry.

The most common use of data in inquiry in both the physical and social sciences is via what Churchman calls a *Lockean* inquiry system. In such an inquiry, evidence is derived principally from the observations of the physical world. Empirical data is collected, and then an attempt is made to build a theory that accounts for the data. This corresponds to what is sometimes called a 'naive inductivist' paradigm in the physical sciences, and is most appropriate for well-structured problems.

In the context of our investigation into the use of calculators, we might design an experiment in which students were tested on their mathematical attainment, randomly assigned to one of two groups: one given unrestricted access to calculators and one given no access to calculators, and then re-tested after some period of teaching. From the resulting data, we would then attempt to build a coherent account of what was going on (see, for example, Hembree and Dessart, 1986).

The major difficulty with a Lockean approach is that, because observations are regarded as evidence, it is necessary for all observers to agree on what they have observed. Because what we observe is based on the theories we have, different people will observe different things, even in the same classroom.

For less well-structured problems, or where different people are likely to disagree what precisely is the problem, a *Kantian* inquiry system is more appropriate. This involves the deliberate framing of multiple alternative perspectives, on both theory and data (thus subsuming Leibnizian and Lockean systems). One way of doing this is by building different theories on the basis of the same set of data. Alternatively, we could build two theories related to the problem, and then for each theory, generate appropriate data (different kinds of data might be collected for the two theories).

For the issue of access to calculators, this could involve development of two alternative theories. For example, we might examine the relative effectiveness of calculator use and non-calculator use in terms of achievement, or in terms of

BEST COPY AVAILABLE

attitudes towards mathematics and confidence. It is not immediately apparent where these two theories overlap and where they conflict, but by attempting to reconcile the alternative conceptualisations, new theories can develop.

This idea of reconciling two (or more) rival theories is more fully developed in a *Hegelian* inquiry system, where antithetical and mutually inconsistent theories are developed. Not content with building plausible theories, the Hegelian inquirer takes the most plausible theory, and then investigates what would have to be different about the world for the *exact opposite* of the most plausible theory itself to be plausible. The tension produced by confrontation between conflicting theories forces the assumptions of each theory to be questioned, thus possibly creating a synthesis of the rival theories at a higher level of abstraction.

An Hegelian approach to our inquiry into the use of calculators would involve researchers who have adopted an 'achievement' perspective on the use of calculators to think through what would have to be different about the world for the exact opposite of their theory to be true. Those who adopt the 'attitude' perspective would do the same, which might then result in sufficient clarification of the issues to make a synthesis of the two perspectives, at a higher level of abstraction, possible.

The differences between Lockean, Kantian and Hegelian inquiry systems were summed up as follows by Churchman:

> The Lockean inquirer displays the 'fundamental' data that all experts agree are accurate and relevant, and then builds a consistent story out of these. The Kantian inquirer displays the same story from different points of view, emphasising thereby that what is put into the story by the internal mode of representation is not given from the outside. But the Hegelian inquirer, using the same data, tells two stories, one supporting the most prominent policy on one side, the other supporting the most promising story on the other side (Churchman, 1971 p. 177).

However, the most important feature of Churchman's typology is that we can inquire about inquiry systems, questioning the values and ethical assumptions that these inquiry systems embody. This inquiry of inquiry systems is itself, of course, an inquiry system, termed *Singerian* by Churchman after the philosopher E A Singer (see Singer, 1957). Such an approach entails a constant questioning of the assumptions of inquiry systems. Tenets, no matter how fundamental they appear to be, are themselves to be challenged in order to cast a new light on the situation under investigation. This leads directly and naturally onto examination of the values and ethical considerations inherent in theory building.

In a Singerian inquiry, there is no solid foundation. Instead, everything is 'permanently tentative'; instead of asking what 'is', we ask what are the implications and consequences of different assumptions about what 'is taken to be':

> The 'is taken to be' is a self-imposed imperative of the community. Taken in the context of the whole Singerian theory of inquiry and progress, the imperative has the status of an ethical judgment. That is, the community judges that to accept its instruction is to bring about a suitable tactic or strategy [...]. The acceptance may lead to social actions outside of inquiry, or to new kinds of inquiry, or whatever. Part of the community's judgement is concerned with the *appropriateness of these actions from an ethical point of view*. Hence the linguistic puzzle which bothered some empiricists—how the inquiring system can pass linguistically from "is" statements to "ought" statements— is no puzzle at all in the Singerian inquirer: the inquiring system speaks exclusively in the "ought," the "is" being only a convenient *façon de parler* when one wants to

block out the uncertainty in the discourse. (Churchman, 1971 p. 202; my emphasis in fourth sentence).

The important point about adopting a Singerian perspective is that with such an inquiry system, one can never absolve oneself from the consequences of one's research. Educational research is a process of *modelling* educational processes, and the models are never right or wrong, merely more or less appropriate for a particular purpose.

A Singerian approach to calculator use would then look at all possible perspectives, but also at the ethical and value positions underlying such perspectives. Even if restricting access to calculators results in higher average achievement, who are the winners and losers, and what are the resulting costs to society? Such difficult questions can be avoided within Leibnizian, Lockean, Kantian and Hegelian inquiry systems, but must be confronted within a Singerian inquiry system.

Educational research can therefore be characterised as a never-ending process of assembling evidence that:

1) particular inferences are warranted on the basis of the available evidence;
2) such inferences are more warranted than plausible rival inferences;
3) the consequences of such inferences are ethically defensible.

Furthermore the basis for warrants, the other plausible interpretations, and the ethical bases for defending the consequences, are themselves constantly open to scrutiny and question.

Conclusion

In this paper, different approaches to educational inquiry have been characterised in terms of the hermeneutic notions of *text*, *context* and *reader*. Traditional 'positivistic' forms of research seek to produce texts (eg data, research findings etc.) whose meanings are shared by different readers, and across a variety of contexts. Other approaches (particularly those sometimes labelled 'qualitative') acknowledge the context-dependent nature of the research findings, but nevertheless seek to produce texts whose meanings are widely shared. However, research results that have widely shared meanings appear to be more difficult for teachers to 'make sense of' and to make use of in improving their practice.

The approach sometimes called 'action research' addresses this by not even trying to generalise meanings across readers—what matters is the meaning of the research findings for the teacher in her own classroom. This lack of generalizable meaning for action research is justified by its potential to transform the practice of the individual teacher. There appears, therefore, to be a trade-off between meanings and consequences. Put crudely, in action research, the lack of shared meanings are justified by the consequences, while in other kinds of research, the lack of consequences are justified by their more widely-shared meanings.

The tension between meanings and consequences was then further explored in terms of Churchman's five-fold classification of inquiry systems, based on what is taken to be the primary source of evidence:

Inquiry system	Source of evidence
Leibnizian	Reasoning
Lockean	Observation
Kantian	Representation
Hegelian	Dialectic
Singerian	Ethical values

Adopting a Singerian perspective, it was argued that educational research involved marshalling evidence that:

1) the interpretations made of the data were warranted;
2) the interpretations were more warranted than plausible rival interpretations;
3) the consequences of such interpretations were ethically defensible.

From the point of view of the individual researcher, the important message is that nothing that is written about the process of research relieves the individual researcher of the responsibility for the research she undertakes, and what happens as a result of that research.

A MATHEMATICS ANALOGUE OF CHOMSKY'S LANGUAGE ACQUISITION DEVICE?

Carl Winsløw
Department of Mathematics
Royal Danish School of Educational Studies

Abstract. The aim of this paper is to suggest a perspective on mathematical knowledge and its learning which is radically different from both Platonism (an old favorite of mathematicians) and constructivism (currently popular among educators,); in particular, to stress that the denial of one does not imply the other. The starting point is what Chomsky (1986) calls Plato's problem: *explain how we know so much, given that the evidence available to us is so sparse.* Some major theories related to this problem in the contexts of linguistics and cognitive psychology are discussed. In particular, I propose a mathematics analogue of Chomsky's language acquisition device, and discuss the relations between the two that emerge from the description of mathematics as a linguistic 'register' (Pimm, 1991; Winsløw, 1998).

1. Background: LAD, LASS and so on.

Plato's problem arises for Chomsky (1957, 1988) in the following way: it can be theoretically argued that natural language is too complex to be acquired from finite input alone (thus, the constructivist idea of an initial *tabula rasa* must be abandoned). The radical Chomskyan proposal to solve Plato's problem for language acquisition is the hypothesis of the *language acquisition device* (LAD): an innate[1] mental structure, common to all human beings, which takes, as input, primary linguistic data – a finite number of more or less 'correct' utterances in the language to be acquired – and produces a 'grammar' of this language, i.e. a system of rules which allows the learner to speak the language creatively – to 'perform' linguistically. The original LAD hypothesis (Chomsky, 1965) is very strong concerning the detailed 'mechanics' of the device; as a reconstruction, I have represented the whole mechanism in process-diagrammatic form in Fig. 1. For a detailed explanation, the reader should consult (Chomsky, 1965, §1.6-8); the basic idea is that, given the finite input, LAD chooses among an infinity of in-built 'possible grammars' one which is in optimal consistency with the input

The scientific status of LAD is, so far, unclear; at best, it is an unverified hypothesis about the innate language competence of the human mind, but as it is even quite unclear how it could be scientifically rejected, a Popperian critique might claim that *no substantially stronger claim to scientific status can be made for it than for Homer's collected stories from the Olympus* (Popper, 1963, §1). Of course, the point

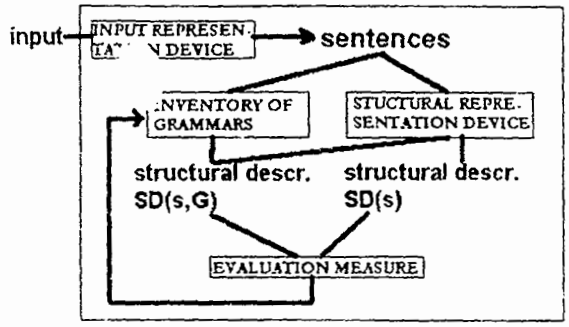

Figure 1: LAD

of bringing up the idea of a LAD here is not to reject it in this way (let alone that Popper's falsification criteria are widely acknowledged to be impracticable in any science). The aim is, first, to point out the LAD model as an outstanding example of an unverified hypothesis which has inspired many fruitful research efforts, in this case not only in linguistics, but also in educational psychology, as evidenced e.g. by (Bruner, 1983) and (Karmiloff-Smith, 1992). Secondly, and more importantly, alike hypotheses form the indispensable lifeblood of research regarding the mechanisms of cognition, where measurable evidence in a direct physical sense is still very sparse, in spite of recent progress (to which we return below). A parallel may be found e.g. in nineteenth century chemistry, which used notions such as valence and molecule as *convenient myths devised to help organize experience* (Chomsky, 1986, p. 7).

Later works on language acquisition have provided various auxiliary hypotheses and modulations, such as pointing out the necessity of taking into account the interaction between input and output in a language community setting, e.g. the language acquisition support system (LASS) discussed in (Bruner, 1983), or proposing domain-specific cognitive 'modules' as discussed (and questioned) in (Karmiloff-Smith, 1992). Recently, the notion of *metaphor* has been used as a central explanatory model for language related cognitive mechanisms, including natural language, e.g. in (Lakoff, 1987); the idea is also exemplified in the context of mathematics (Lakoff-Núñez, 1997).

Until fairly recently, the study of cognition had to be based solely on evidence of performance, with no possibility to gain direct evidence of cognitive structures[2]. The interest of theories (systems of hypotheses about cognitive structure) derived from analysis of performance is increased by current developments in cognitive neuroscience which suggest that measurable evidence for such theories may become available; see (Dehaene, 1997) for a leisurely introduction to this exciting area as it applies to mathematics. As in any experimental science, techniques to gain

evidence have to be complemented by theories suggesting what to look for; only explicit (and, at least initially, simple) theories will do here.

2. Linguistic aspects of mathematical knowledge.

The striking similarity between discourse in natural language and mathematical discourse (in the sense of (Winsløw, 1998)) has at least the following aspects, which form together a strong indication that Plato's problem arises for mathematical knowledge much in the same way as for language[3]:

- the complexity of the rules governing discourse,
- the extent to which consensus may be reached (within a community of discourse) about the rules,
- the implicit nature of the vast majority of those rules.

We already mentioned (in sec. 1) one sense of the first point in the case of natural language (even when considering only syntax), and Chomsky's argument is actually to demonstrate the possibility of embedding a non-finite state mathematical structure into English[4]. The third point is in fact an immediate corollary of the first, and poses Plato's problem exactly as for natural language. The second aspect is not theoretical but empirical in nature, but is theoretically essential to counterbalance the other two; without it, neither natural languages nor mathematics would represent useful means of communication. The paranthesis about consistency referring to a community is essential, though; it marks the difference between *languages* and *registers*, which we proceed to explain (see also Pimm, 1991). A *language* is a system of structured knowledge applicable to express human thoughts, while a *register* of language is a systematic way of using language in some specifiable setting[5]. Thus, the second aspect is about registers (within natural languages, and in mathematical discourse).

To penetrate deeper into the connection between natural language use and mathematical discourse, we shall study more closely how they interact. As suggested in (Winsløw, 1998) and further elaborated below, mathematical registers integrate natural language use with the use of certain symbolic languages:

1. Parts of the word and sentence inventory of natural language are *semantically defined or redefined* for use in the mathematical register.
2. Symbol strings may replace word strings in phrases of natural language, whose syntax remains otherwise unchanged. Replacement does, in this context, not mean that an ordinary meaningful phrase in verbal language is transformed into a phrase of the mathematical register by simply replacing some syntactic elements (e.g., a noun) by a symbol string, but rather that the phrase in the mathematical register can be *formally derived* from a syntactically correct (but possibly meaningless) phrase in verbal language by such a replacement[6]. Very specific rules can be given about how replacement takes place within a given mathematical register.
3. Finally, the symbolic inventory (producing symbol strings) has its own syntax, as explained in (Winsløw, 1998, Sec. 3.2). The basic concepts (called *universal*

BEST COPY AVAILABLE

syntactic features) here are those of *object*, *relation* and *operator*, and for syntactic relations among symbol strings the derived concept of *transformation*. The syntax of symbol strings (at a deeper level than the universal syntactic features, for instance, the construction of objects), and not least their *semantics*, can be given in detail only for very specific subregisters, as it is highly context dependent (cf. e.g. Woodrow, 1982).

The most important point here is the crucial *relation* between natural language and mathematics – the fact that mathematical knowledge, understood as knowledge of the mathematical register, is to a large extent *depending on* knowledge of natural language. The impact of childrens language background on their performance in mathematics learning contexts has indeed been the subject of numerous studies[7], and it has been shown beyond reasonable doubt that this influence is both strong and many-sided, even when discounting external factors that correlate with natural language capacities[8]. We need hypotheses – convenient myths – regarding the intrinsic source of those correlations. As was argued in this section, such a model of mathematics acquisition will have to relate to (or even contain) a model of language acquisition. One may consider the LAD as a simple yet significant model of the last sort, and we use it as a working hypothesis for natural language acquisition in the following.

3. Contours of a minimal MAD.

Our task now is to determine a minimal set of competencies for acquiring mathematical knowledge which are not themselves acquired, but which are part of the human cognition apparatus. It is obvious that minimality is most desirable, as we are not willing to settle with the easy but mystifying Platonic solution (claiming *all* mathematical knowledge to be 'built in'). On the other hand, as argued in sec. 2, if the overall aim is a model *accounting* for all mathematical knowledge – not just the chess-type parts – then this minimal set is not empty. In fact, language acquisition competencies are necessary but not sufficient. The existence and importance of such a minimal solution is a main point of this paper. Notice that *uniqueness* is neither implied nor claimed to be implied.

The discussion in Sec. 2 does suggest some elements of the cognitive faculties which the human capacity to learn and foster mathematical knowledge seems to necessitate. The most basic one is the ability to perceive symbolic language and to distinguish it from natural language. This it not in itself a faculty which is solely related to mathematics in a strong sense (like mathematical registers as considered here); the human use of symbolic inscription and signification is likely to be as old and broad in scope as natural languages. We may think of this as a supplementary feature belonging to the 'input representation device': the capacity to perceive and distinguish symbol type input in different surface forms (audile and visual). This faculty is related to 'mental imagery' as studied in cognitive

psychology (Paivio, 1971) and some of its effects are (in a more direct way) studied in iconography. Where the properly mathematical enters the scene is in the ability to represent and manipulate structures involving states and processes of symbolic entities. This faculty clearly pertains to structural description of represented symbol input, that is, it belongs to what is called the structural description device in Chomsky's LAD. It accounts for the universal syntactic features of mathematical knowledge: some symbols are perceived as distinguished *objects* which may be found in the state of *relation* to other objects, while other symbols represent processes by which objects are changed (*operators*); and finally that such processes induce new relations when related objects are changed by the same operator (the state structure is changed by what we call *transformation*). However, the concrete transformational rule relate different structural descriptions and hence it belongs to the domain of 'grammar', just as in the case of natural language. Assuming further the capacity of evaluating different transformational grammars of symbol language against structural descriptions of represented input, we have situated all the elements of a MAD (construed in analogy and even in addition to the LAD) required to account for the universal syntactic features of mathematical symbol language.

To accomplish our task set out at the beginning, we must reconsider the phenomena of (re)naming and replacement (point 1 and 2 in sec. 2) by which the mathematical register is brought together as a whole.

Naming, which effectuates semantic (re)definition, carries greater weight in mathematics than the mere assignment of lexical signifiers (Sfard, 1991). I believe it is important to distinguish two different naming procedures here, as suggested by the following examples.

(a) 'A function G from A to B is a subset of $A \times B$ such that for every $a \in A$ there is precisely one $b \in B$ such that $(a,b) \in G$.'

(b) 'Let G be a function.' (Equivalent: 'Let a function be given; call it G.')

The first kind assigns a name to a mathematical structure, and this relation name-structure becomes part of the 'lexicon' much as in the case of natural language. If we are, at a later point, told that a function is a non-commutative group, this leads to conflict. By contrast, the second kind of naming feeds a short-memory name-symbol lexicon which can easily be changed the same way by later namings. The last naming of a symbol prevails and must often be available in the lexicon *before* applying the syntactic parts of the structural representation device to the whole sentence (as in 'Let G be a function with $G' \geq 0$...'). Any revision of the structure-name lexicon must be based on the structured description of the whole sentence, as in the feeding of the natural language lexicon. To sum up: the structural representation device contains two semantic components handling two kinds of naming, one which feeds a symbol-name lexicon directly, and one which marks (parts of) the sentence as a naming of structure, which (via the evaluation measure) causes a relation name-structure to be

activated in the corresponding lexicon. Both lexicons are part of the grammar used in (and affected by) the structural description of a sentence.

The simplest way to accomodate the phenomenon of *replacement* at this final stage, seems to be twofold: an 'inverse replacement' component of the structural representation device, adding to the structural description a base phrase from natural language from which the sentence can be derived by lexical insertions; and an addition to the grammar, consisting of rules for replacement by symbol strings (just as rules of replacements are built into the grammar of natural language, cf. (Harris 1965, §2)).

The tentative model of a MAD developed above is summarised schematically in Fig. 2, which contains (and is built upon) Chomsky's LAD as interpreted in Fig. 1.

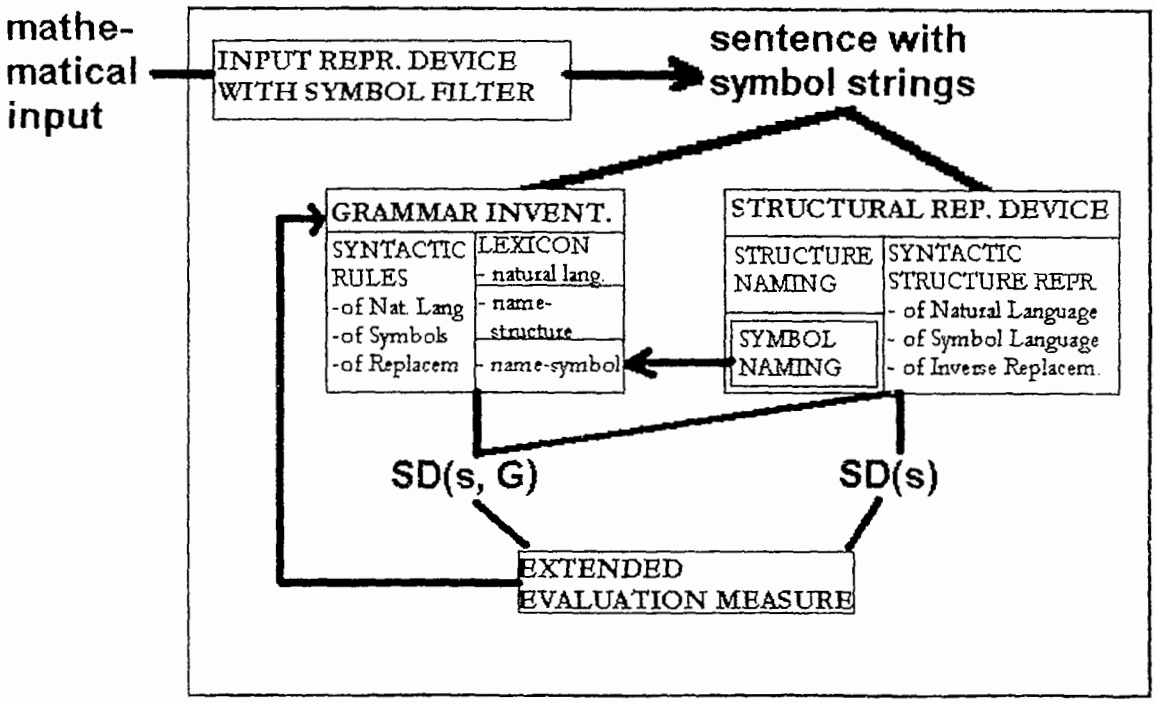

Figure 2: MAD

This picture only aims to reflect the 'acquisitionist' aspects of learning, but it should be clear that output (and hence participation in mathematical discourse) is not ignored because of this. On the contrary, the value of the evaluation measure (specific lexicons and syntactic rules) at any time reflects the linguistic type knowledge based on which the learner performs mathematically (or, as LAD is built in, using natural language alone). What cannot be accounted for by such a model is the actual

production of output. However, it is clear that in addition to linguistic type knowledge, a central item is *memory and associative use of it*.

Notes.

[1] Notice that this does *not* imply acceptance of Plato's idea world, but may be explained (as Chomsky does) as a product of evolution.
[2] As an early exception, Skemp (1987) noticed with enthousiasm what he saw as a neuropsychological confirmation of his analytically based theory of visual-geometrical thinking as opposed to verbal-algebraic thinking; Skemp's theory was published in 1971, and the relevant work in neuropsychology (due to Shannon) in 1980.
[3] This is in a way also the original setting, as described in Plato's dialogue *Menon.*
[4] In (Chomsky, 1957, n.3), it is also explicitly noted that *any formalized system of mathematics or logic will fail to constitute a finite state language.*
[5] The definition of concept of *register* goes back to (Halliday, McIntosh, Strevens, 1964; p. 87), although formulated in different wording and with a narrower definition of language than given here.
[6] In more technical terms: the *phrase structure* is the same, but in addition to usual lexical insertion, some elements of a phrase may be filled by symbol strings. One may think of the latter as 'replacing' a natural language string by the symbol string, although no such replacement actually takes place.
[7] A classical collection of such studies may be found in (Cocking and Mestre, 1988).
[8] That is, one has identified even purely *intrinsic* effects, in the sense of (Saxe, 1988).

DIVISION WITH FRACTIONS IS NOT DIVISION BUT MULTIPLICATION: on the Development from Fractions to Rational Numbers in terms of the Generalization Model Designed by Dörfler

Takeshi YAMAGUCHI
Fukuoka University of Education, Japan

Hideki IWASAKI
Hiroshima University, Japan

(Abstract) Division with fractions is the "capstone " of elementary school arithmetic and the "cornerstone " of algebra. It is a teaching material of calculation depending finally upon quantities and considering division as the special case of multiplication. Conceptual understanding of both the expression and algorithm on it is traditionally planed based on the proportional relation about two concrete quantities in the elementary school of Japan. Only simple procedure "invert and multiply", however, is confirmed as a result of teaching and learning for lack of "constructive abstraction" in the sense of Dörfler's generalization.

Most students cannot reach at the idea of division by way of schema of proportion, and moreover schema of share and measure known by students cannot induce and deduce division with fractions. We, therefore, propose here that schema of comparison is quite applicable for making the expression about it, and algebraic treatment learned by students is much relevant for understanding the algorithm of the expression. As a matter of fact, both of them were abstracted constructively in the classroom lesson of sixth grade(twelve years old). The educational significance mentioned at the opening paragraph was realized in this practice, and this teaching and learning process was more successful than the present treatment based on the proportional reasoning.

1. Conceptual Understanding of Division: separation of division with natural numbers and that with fractions

Conceptual understanding of division with fractions is traditionally and carefully taught on the base of proportional relation between two concrete quantities in the sixth grade of Japan. Proportional reasoning plays an important role there, and moreover in the transition from elementary mathematics to advanced mathematics as Lesh, Post, and Behr say as follows (1988, pp 93-94):

> *We view proportional reasoning as a pivotal concept. On the one hand, it is the capstone of children's elementary school arithmetic; on the other hand, it is the cornerstone of all that is to follow.*

What is firmly established in the sixth graders, however, is only the procedure "invert and multiply" concerning a divisor. Most of them cannot make a reason why division becomes multiplication suddenly in the case of fraction as well as they cannot often make a division expression to the word problem including fractions. Such an outstanding difference between the concept and procedure is due to the following fact the schema of share and measure concerning

divisions with natural numbers learned by students cannot be assimilated and accommodated to that of proportion on division with fractions. Constructive abstraction about this, therefore, is almost impossible on the presupposition of partitive and quotitive divisions because their characteristics are quite different from that of division with fractions except dividend(See Table 1) They are definitely division as it is, and cannot induce or deduce multiplication with the inverse of a divisor.

The idea of Lesh, Post, and Behr is theoretically right but is not practically right in the case of division with fractions as the national achievement survey showed in Japan. Many teachers also know this fact from their experience. The expression and algorithm of division with fractions, therefore, should not be induced and deduced over the proportional relation between two concrete quantities. The expression of it can easily get the meaning in the schema of comparison which is as fundamental as that of share and measure. The algorithm of it can be deduced from the calculation rule which students have already learned. This is our proposal and point.

Table 1. Characteristics of Partitive and Quatitive Division

	Partitive Division	Quatitive Division
Image	Sharing a quantity into equal parts	Measuring a quantity with some quantity
Meaning	To ask how much the unit is	To ask how many units there are.
Dividend	Rational number	Rational number
Divisor	Natural number	Rational number
Quotient	Rational number	Natural number
Remainder	No existence	Principally existence

2. The Result of the National Survey concerning Division with Fractions

The achievement survey, which was implemented by Ministry of Education in Japan, 1994 and had 16,000 samples in each grade fifth and sixth, shows that 27.2 % of students correctly answered the word problem mentioned at Table 2 to make an expression of division with fractions. On the other hand, 89.7 % of same students calculated the division expression with fractions $2/7 \div 3/4$ correctly. Furthermore in the same survey, 65.9 % of students in fifth grade correctly answered the word problem mentioned to make an expression of division with decimals which has the same mathematical structure as the case of fractions. There is much difference between division with fractions and that with decimals in making an expression

Both are typical problems for introducing division with decimals and fractions in each grade fifth and sixth of the elementary school. To make a division expression as well as to understand its algorithm in both cases are taught and learned on the base of proportional relation between two concrete quantities in the classroom lesson. Making a division expression first, the case of decimals and fractions are extrapolated into the case of natural numbers referring concrete quantities. Next its algorithm is explained using usually two number lines which

Table 2 Achievement tasks of division with fractions and decimals

(Problem for fifth graders) There is a steel pipe. Its weight is 4.2 kilogram to the length of 3.5 meter. How much weight is it for one meter steel pipe? Write an expression to get an answer.
(Problem for sixth graders) There is a water tank. Water is poured 5/6 liter per 2/3 minute into the tank. How much water is poured for one minute? Write an expression to get an answer.

represent proportional relation figuratively. Proportional reasoning, therefore, plays a fundamental roll to understand not only the division expressions but also their algorithm.

But there is big difference in the rate of correct answer between two problems although they have the same mathematical structure. According to the Dörfler's generalization, "constructive abstraction" and "intensional generalization" are well conducted in classroom lesson about division with decimals consequently speaking. On the other hand, division with fractions has a serious problem in the process of intensional generalization for understanding the algorithm even if it succeed in constructive abstraction for making the expression.

Division with decimals is division and not multiplication. It is a kind of extension of division with natural numbers. But division with fractions is not division but multiplication. This algebraic reconstruction cannot be overwhelmed only by proportional reasoning. We think that whether there is this transformation or not reflects the results of the national survey consequently, and this is the problem of "constructive abstraction" and "intensional generalization"

3. Analysis of Teaching and Learning of Division with Fractions from Dörfler's Generalization Model

(1)Critical Analysis of Division with Fractions Based on Schema of Proportion from Dörfler's Generalization Model

In the teaching and learning process of division with fractions, division is supposed to be integrated into the special case of multiplication with the extension of meaning of division. Therefore we can regard conceptual understanding of it as a kind of generalization process. In this sense, Dörfler's generalization model (1991) as shown in Fig.1 gives us some suggestions which clarify the reason of serious detachment between making the expression and understanding the algorithm about division with fractions.

In Dörfler's generalization model, the pre-stage of "symbols as objects" is called "constructive abstraction", the objective and method of activity are reflected upon first and the properties of elements of activities and the relation of elements are extracted as a result. Furthermore, the applicability of these properties and relation is considered in the "extensional generalization". After this stage, symbolical description of the invariants is detached from the original context and the symbol itself has become object of thinking This is to say "symbols as

objects", which connotes to proceed to "intensional generalization". It is a symbolic operation to multiply divisor and dividend or denominator and numerator of fraction by the same number on the assumption of "symbols as objects".

Conceptual understanding of calculation is composed of an expression and its algorithm. The expression is induced from a word problem using a number line and extrapolation particularly in the case of division with both decimals and fractions. After that their algorithms is deduced in terms of proportional reasoning.

Making an expression corresponds to constructive abstraction and understanding its algorithm to intensional generalization in the Dörfler's generalization. The algorithm of division with decimals is intensionally generalized into that of division with natural numbers through proportional relation between two quantities On the other hand, the algorithm of division with fractions is intensionally generalized into proportional relations, and transformed into multiplication. Most students suppose that they invent new algorithm "invert and multiply" from division. They, therefore, repeat constructive abstraction for understanding the algorithm although they arrived at "symbols as objects" through it

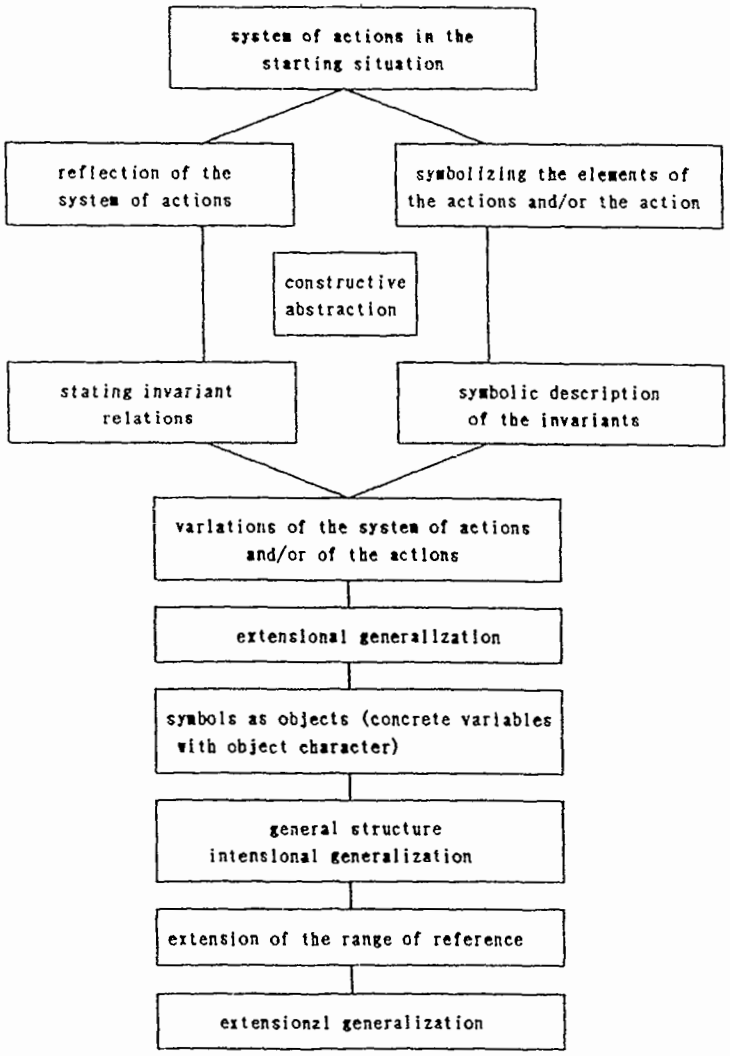

Fig.1 Dörfler's generalization model (1991,p.74)

The similar processes in the different meaning interfere mutually and restrain each other The process of making an expression consequently fades away from cognition and the procedure "invert and multiply" fades in it and is firmly established as a result. We think this is the reason why there is a big difference in the rate of correct answer of the national survey. In other word of the Dörfler's generalization, the division with decimals could have "constructive abstraction" but the division with fractions could not have "constructive abstraction". Then we should

1565

choose another schema and devise the teaching way other than the schema of proportion about division with fractions.

(2)Division with Fractions Based on Schema of Comparison as the Alternative Framework

In order to overcome this issue, we propose new instructional framework based on "schema of comparison". Schema of comparison has two mathematical aspects which are *difference* and *ratio* between two quantities. One typical word problems in the context of schema of ratio is "*There are the tape A and tape B. The length of tape A is 3/5 meter and that of B is 2/7 meter. How many times is tape A as long as tape B ?*". This kind of situation more easily induces the division expression than that of the proportional relation.

After making the expression, however, it is a significant issue that schema of comparison can not work in itself as the driving force which forms conceptual understanding of the procedure "invert and multiply". So students are requested to remind of some rules about fractions and division learned by them, and to figure out the algorithm as follows:

(A)
$$\frac{3}{5} \div \frac{2}{7}$$
$$= \left(\frac{3}{5} \times 35\right) \div \left(\frac{2}{7} \times 35\right)$$
$$= (3 \times 7) \div (2 \times 5) = \frac{3 \times 7}{2 \times 5}$$
$$= \frac{3}{5} \times \frac{7}{2}$$

(B)
$$\frac{3}{5} \div \frac{2}{7} = \frac{3 \times 14}{5 \times 14} \div \frac{2}{7}$$
$$= \frac{3 \times (14 \div 2)}{5 \times (14 \div 2)} = \frac{3 \times 7}{5 \times 2}$$
$$= \frac{3}{5} \times \frac{7}{2}$$

These ideas are not related to quantities directly but mathematical operation of fraction and calculation Furthermore these activities would contribute to build up new conceptual network among properties of fraction, rules about calculation, and cognitive schema of division depending on partitive or quatitive division, which is the essence of the "intensional generalization" in the sense of Dorfler's generalization.

4. Design and Evaluation of Teaching Practice Based on Schema of Comparison

(1)The Result of Pre-test of Division with Fractions

Prior to the teaching practice in this study, we conducted the pre-test of division with fractions Subjects in this pre-test were sixth graders at Ukiha Elementary School in Fukuoka, Japan. Problems in this pre-test are shown as below. Problem 1 is about division with fractions on the base of schema of proportion and Problem 2 is about that of comparison. We should note that sixth graders had already learned division with fraction before we gave them this test

---

1 We can paint 2/5 m^2 of the board per 3/4 *dl*. How much area of the board can we paint for 1 *dl* ?

2 The length of Kaori's tape is 2/3 meter and that of Shiho's tape is 5/7 meter How many times is Shiho's tape as long as Kaori's tape ? (Note: Kaori and Shiho are names of Japanese girls)

Results of this pre-test are shown in Table 3. Only four of sixth graders (14%) made correct expression in Problem 1, although they had already learned this subject matter. In addition to this, table 4 shows the number of students who made the expression of division in Problem 1 and 2 respectively. According to this table, we can see the tendency that the word problem based on schema of comparison is more closely related to division expression than that of proportion. As Problem 2 is briefly requested to find the value of ratio between two quantities, the schema of comparison is accessible to that of measure for quatitive division even if both divisor and dividend are fractions. This is one of reasons why this difference between division based on schema of proportion and that of comparison is caused. According to these two results, at least, we can suppose that making an expression based on schema of comparison is easier for sixth graders than that based on schema of proportion.

Table 3. Results of Pre-test (N = 28)

	Problem1 (Schema of Proportion)		Problem2 (Schema of Comparison)	
	The Number of Students	Method	The Number of Students	Method
Correct	4	2/5 ÷ 3/4 (4)	9	5/7 ÷ 2/3 (9)
Wrong	20	3/4 × 2/5 (8) 3/4 ÷ 2/5 (7) 4/4 × 2/5 (2) Others (3)	17	2/3 ÷ 5/7 (13) 5/7 × 2/3 (3) 5/7 − 2/3 = 3/4 (1)
No Response	4		2	

Table 4 The Number of students who made the expression of division

Problem	Schema	The number of students		
1	Proportion	11	Correct	4
			Wrong	7
2	Comparison	22	Correct	9
			Wrong	13

(2)Design and Evaluation of Teaching Practice Based on Schema of Comparison

Based on the results in the pre-test, we designed teaching practice of two lessons based on schema of comparison for sixth graders. The objective of this teaching practice was to verify empirically that students could make the expression of division with fractions based on schema of comparison and deduce the procedure "invert and multiply" logically, referring and using properties of fractions and rules about the calculation which students had already learned The class was, for necessity, divided into small groups of 6 to 7 members so that they felt it easy to make discussion We report here the brief sketch of sixth graders' activities below

At the beginning of this lesson, the following problem situation was presented by a teacher *"Hana has the tape whose length is 3/4 meter. Yuki has 2/5 meter. Compare the length of Hana's tape with that of Yuki's tape"*. At the earlier stage of this lesson, to this task, some students showed three types of method as follows

(a) $\frac{3}{4} - \frac{2}{5} = \frac{3\times5}{4\times5} - \frac{2\times4}{5\times4} = \frac{15}{20} - \frac{8}{20} = \frac{7}{20}$

Hana's tape was longer than Yuki's one by 7/20 meter.

(b) $\frac{3}{4} \div \frac{2}{5} = \frac{3}{4} \times \frac{5}{2} = \frac{15}{8}$

The length of Hana's tape was 15/8 times as long as Yuki's tape.

(c) $\frac{3}{4} : \frac{2}{5} = \frac{15}{20} : \frac{8}{20} = 15 : 8$

(The length of Hana's tape) : (The length of Yuki's tape) = 15 : 8

Most students could easily make an expression of division with fractions such as (b) or understand meaning of this expression by others' explanation.

After this, teachers asked students to explain the reason why we could calculate division with fractions by the algorithm of "invert and multiply" since they had already learned it. Students, however, felt much difficulty as we anticipated it because the proportion schema could not be driven for the explanation and the comparison schema could not either generate the algorithm of multiplication with the inverse of divisor in itself. Then a teacher need to inform of some mathematical knowledge known by students. The teacher helped them to reconfirm the property of fractions such as "*The value of fraction is constant when both denominator and numerator are multiplied by the same number.*" and to make sure of rules about division such as "*The quotient of division is constant when both divisor and dividend are multiplied by the same number.*" (for example, "0.6 ÷ 0.2 = 6 ÷ 2"). There happened to be a student who explained the way of calculation by the idea of transformation of division with fractions into that with decimals as follows.

$$\frac{3}{4} \div \frac{2}{5} = (3\div4)\div(2\div5) = 0.75 \div 0.4 = 75 \div 40 = \frac{75}{40}$$

Though this idea itself did not produce the algorithm "invert and multiply" at all, students could apply another meaning of fractions such as "a/b = a ÷ b".

Then a teacher gave students a word of advice to multiply both divisor and dividend by any other numbers than 100. Following this advice, one students wrote the following explanation on the blackboard and explained in detail.

$$\frac{3}{4} \div \frac{2}{5} = (\frac{3}{4}\times20)\div(\frac{2}{5}\times20) = (3\times5)\div(2\times4) = \frac{3\times5}{2\times4} = \frac{3\times5}{4\times2} = \frac{3}{4}\times\frac{5}{2}$$

Some opinions about this explanation were exchanged among students in the class as follows

S1 Why is the multiplier twenty in this expression ?

S2 It is the reason why twenty is the least common multiple of four and five.

S3 Why is the expression " $(\frac{3}{4}\times20) : (\frac{2}{5}\times20)$ " transformed into the expression "(3 × 5) ÷ (2 × 4)" ?

S4 The reduction of four and twenty or that of five and twenty produce this transformation of the expression

BEST COPY AVAILABLE

S3 I don't understand your explanation.

S4 We can reduce twenty to five in the fraction $\frac{3\times 20}{4}$ like this (reducing twenty to five) and get the expression "3 × 5"

S5 I think that the fraction " $\frac{3\times 5}{2\times 4}$ " will be transformed into the expression " $\frac{3}{2}\times\frac{5}{4}$ " by this manner Is it OK ?

S6 Because we can change "2 × 4" into "4 × 2", we can get the algorithm " $\frac{3}{4}\times\frac{5}{2}$ ".

Students in the class: All right. I can understand the meaning of the procedure "invert and multiply".

As this protocol shows, students in this class deduced the algorithm of division with fractions logically for themselves, referring properties of fractions and rules about division, and negotiated the meaning of it through the social interaction among students in the class. These exchanges of ideas represents the process of building up new network by means of combining prior cognitive schema of division with properties of fractions and rules about division.

5. By Way of Conclusion

We consider division with fractions as the transitional teaching material from arithmetic to algebra. According to Lesh et al., proportional reasoning is supposed to play a role of bridge between them. And division with fractions is carefully taught in sixth grade in Japan in terms of proportional reasoning. But the conceptual understanding of it is not taken place but only the procedure "invert and multiply" is firmly remained as shown in the national survey. Therefore it is our research concern of this paper to overcome this difficulty on the instruction of division with fractions by setting up new instructional framework based on schema of comparison as the alternative instructional framework.

As a result, in the teaching practice in this paper, we have confirmed that sixth graders easily made an expression of division based on schema of comparison, and that most of them can deduce the procedure "invert and multiply" logically and understand conceptual meaning of this algorithm sufficiently, referring properties of fractions and rules about division.

In the present practice of division with fractions, proportion schema does not work substantially as the bridge. On the other hand, comparison schema facilitates to cope algebraically with the division expression because the expression is well established by comparison schema but can not be calculated in terms of it. In this sense, division with fractions realizes its teaching objective mentioned at the head of this section This is our proposal and main finding in this paper.

TEACHING MATHEMATICAL MODELING WITH A COMPUTER ALGEBRA SYSTEM

Nurit Zehavi and Giora Mann

Weizmann Institute of Science, Israel Levinsky College of Education, Israel

Abstract

Here we present an approach to studying mathematical models using a Computer Algebra System (CAS). Pupils (ages 13-14, n = 141) were introduced to the mathematical model of the classical problem "How long did Diophantus live" They examined the model by solving problems, manipulating the parameters, and inventing similar story problems; and found that the model is more than an equation and that the implicit restrictions are an integral part of the model. The interaction of pupils with the computer disclosed some of the cognitive processes involved in the modeling activities and caused teachers to reflect on their methods of teaching.

Introduction

Probably all generations of pupils, who studied algebra, were introduced to the famous problem from the Greek Anthology, "How long did Diophantus live". It is known that Diophantus (about 250 AD) solved arithmetical problems, not equations, but he was interested in *exact* rational solutions. Therefore, his title as the father of algebra is a matter of historiographical study (Boyer, 1968, pp. 196-216). Father of algebra or not, his place in algebraic textbooks is secure.

Algebraic word problems are notoriously difficult to solve for most pupils. The challenge for educators is to somehow overcome the difficulties. We describe here a few attempts that are relevant to our approach. Stacy and MacGregor (1995) used different verbal descriptions of the same problem to encourage pupils to form mental representations. Many pupils, as they worked, extended their mental models to encompass additional features of the mathematical structure. Hoz et al. (1997) studied in depth the role of structural and semantic factors in the solution of speed problems. They recommend that teachers use similar/isomorphic problems in order to clarify the inference of the relations embedded in the structure of the problems. Inspired by cognitive science, educators attempted to use computers to enhance word problem solving. One such system, *Animate* (Nathan, 1992) creates animations of the story problem derived from the algebraic equations constructed by the pupils. Experiments with the system indicated that the animated simulations of the problem provided

experiential feedback for error detection and correction (Nathan, 1998). In this paper we approach mathematical modeling using a Computer Algebra System.

The appearance of Computer Algebra Systems (CAS) on personal computers in the mid-eighties opened the way to new teaching strategies and curricular developments. Research on the use of CAS in mathematics education is relatively new. Most of the work in this area concentrated on the student-knowledge-technology triangle, realizing that computer algebra software does not answer questions; rather it reacts to an action and produces something that needs to be interpreted. Therefore it is essential to teach pupils how to make the most effective use of the output of the software (Hunter et al., 1995). It is commonly believed that a CAS, by freeing students from syntactic manipulation, allows them to concentrate on semantic or conceptual aspects of algebraic reasoning. Pozzi (1994) studied this in a qualitative case study with students of ages 16-17. He has pointed out that students, who do not fully comprehend a CAS output, will develop informal and possibly erroneous ideas of what the computer is doing. Pozzi has concluded that using a CAS may necessitate a closer conceptual understanding of the algebraic manipulations. With a CAS executing the procedures efficiently, we can now reflect on relationships that connect the formal notation and the procedures for performing mathematical tasks (Zehavi, 1996, 1997). The implication of studies on learning with a symbolic manipulator, is that the teacher plays a far more complex role while teaching in this new environment (Heid, 1996). This was the motivation for Drouhard (1997) to generalize the *didactic triangle* (student-knowledge-teacher) by defining the *double didactic pyramid* with two new vertices, the CAS and the group. He challenges researchers to pursue studies in mathematics education that investigate the construction of knowledge in CAS environment.

The MathComp project

The MathComp (mathematics on computers) project was initiated in 1996 in the Science Teaching Department at the Weizmann Institute of Science with the aim of integrating CAS into teaching, to improve the learning of mathematics with the following goals.

Student goals:

1. Creating a network of relations between concepts and the procedures leading to them. This became possible because CAS frees the student from the tedious work involved in carrying out the procedures;
2. Enriching the mathematical language used by students while they "do" mathematics;
3. Developing independent and critical thinking especially while using CAS;
4. Using technology to stimulate and motivate students to do mathematics.

Teacher goals:

1. Using technology to increase teachers' awareness of the cognitive aspects of learning and to design tools to deal with these aspects;
2. Challenging rethinking of curricular and didactical aspects of mathematics learning and teaching;
3. Developing independence and creativity when incorporating CAS into the professional lives of mathematics teachers.

These goals seem adequate to any technology-based educational project. Indeed, what really matters are the ways to achieve these goals. We decided to develop *mathematical learning units with computer algebra* to be worked out in a computer lab. The units accompany the syllabus for junior high school mathematics. Each of the units that have been developed includes a variety of tasks aimed at improving skills, understanding concepts, and investigating problems. These tasks create a network of mathematical connections, which in turn, give deeper meaning to the subject at hand and open windows for new mathematical experiences.

The basic assumption in the design of the MathComp units is that for the time being, pupils do algebra with paper and pencil in class, and use CAS in the lab to broaden learning opportunities and to promote mathematical understanding. This assumption is affected by practical circumstances, as well as, by the current state of CAS in education. The topics that are dealt with in the units were selected by considering the potential use of *Derive* (by Soft Warehouse) to achieve new didactic opportunities, new learning strategies, and new curricular relations. It is our hope that the units will act as a stimulus for teachers developing their own tasks. Here we bring a unit for Grade 8 "Equations and problems". We explain the rationale of this unit and the formative development process of the tasks. An exploratory study in four classes that worked on the unit using the CAS software *Derive* is described, and the conclusions of the study are discussed.

Equations and problems: A learning unit with *Derive*

The unit "Equations and problems" deals with building a model (equation) for a 'story' problem. It is clear that CAS cannot translate a story into an equation - so how can a CAS support modeling activities? Our idea was to choose story problems that do not fall into the common schemas (e.g., velocity problems, mixture problems) for which teachers and their pupils 'pretend' to have algorithms for solving the problems. The old puzzle about the *School of Pythagoras* (Problem 1) seemed suitable for our needs. This problem also includes fractions, which are both intimidating and difficult to calculate for pupils, but not for CAS. The idea was that pupils will interact with the software by using the *solve* command and other commands for feedback and for debugging their models. After solving the problem, we do not proceed immediately to another problem; rather, we challenge the pupils to invent similar word problems of

1512

their own. The main goal of such an activity is to shed light on the equation itself as an object for exploring, and not as just a tool for finding an answer to the puzzle. The design of similar problems forces the designer to realize that there are implicit restrictions in the model, in addition to the equation itself.

Problem 1: Pythagoras' school

Pythagoras, who lived in the sixth century BC, ran a school. He was once asked how many students are in his school. After thinking for a while, he said:

1/2 of the students do mathematics.

1/4 of the students deal with science.

1/7 of them are silently exercising their mind.

And in addition to all the above we have three girls.

How many students were in Pythagoras' school?

We have observed that pupils are motivated to play "teacher" and to express themselves by inventing problems close to their heart. Naturally, some girls expressed their disagreement with the "three girls" item. However, in the first experiments we realized that they write whatever comes to their heads, sometimes without writing the algebraic model. Those who set equations and applied the solve command often got 'unreasonable' solutions (e.g., a negative solution for the equation $x/2 + x/3 + x/4 + 5 = x$). We therefore need to prepare them to reflect on their stories/models. Hence we added tutorials for making explicit the implicit restrictions of the model. For example: (a) "Pythagoras' secretary reported that 1/2 of the students do math, 1/3 do science, 1/6 think in silence, and there are also 3 girls". The model that describes this story simplifies to $x + 3 = x$, which evidently has no solution; (b) How do we change the problem so that the number of students in the school will be 280 instead of 28? The second example (which, in fact was suggested by a pupil) leads to the relation between the number of girls in the school and the total number of students.

The unit includes a built-in assessment tool based on the famous story about Diophantus (Problem 2). The model is similar to the previous one, only a little more complex. Both models simplify to an equation of the form $25/28 \cdot x$ + "number" = x. Again, pupils are encouraged to write their own story. (Note that we modified the authentic story, in which a son was born and later died, because we realized that the context of students' stories was affected by the tragic fact.)

Problem 2: Diophantus' life

A puzzle, similar to the following, was written on the grave of Diophantus:

Diophantus spent 1/6 of his life as a child, 1/12 as a young man, and more 1/7 of his life as bachelor.

Five years after he got married he left his hometown.

He returned to his hometown 4 years before his death.

Diophantus stayed away from his hometown ½ of his life.

How long did Diophantus live?

Exploratory study

An exploratory study was carried out in four Grade 8 classes (n = 141) of average and above ability. The students worked on three *Derive*-based units in which they became familiar with the following computer procedures: substituting numbers in expressions, solving (in)equalities, and performing operations on both sides of an (in)equality (using the *F4* key). Then they were asked to solve Problem 1 and to explain how they used *Derive*. We show three lines from a *Derive* file created during one pupil's work:

$$\#7 \quad x - \frac{x}{2} + \frac{x}{4} + \frac{x}{7} = 3 \qquad \textit{User}$$

$$\#8 \quad \frac{25x}{28} = 3 \qquad \textit{Simp(\#7)}$$

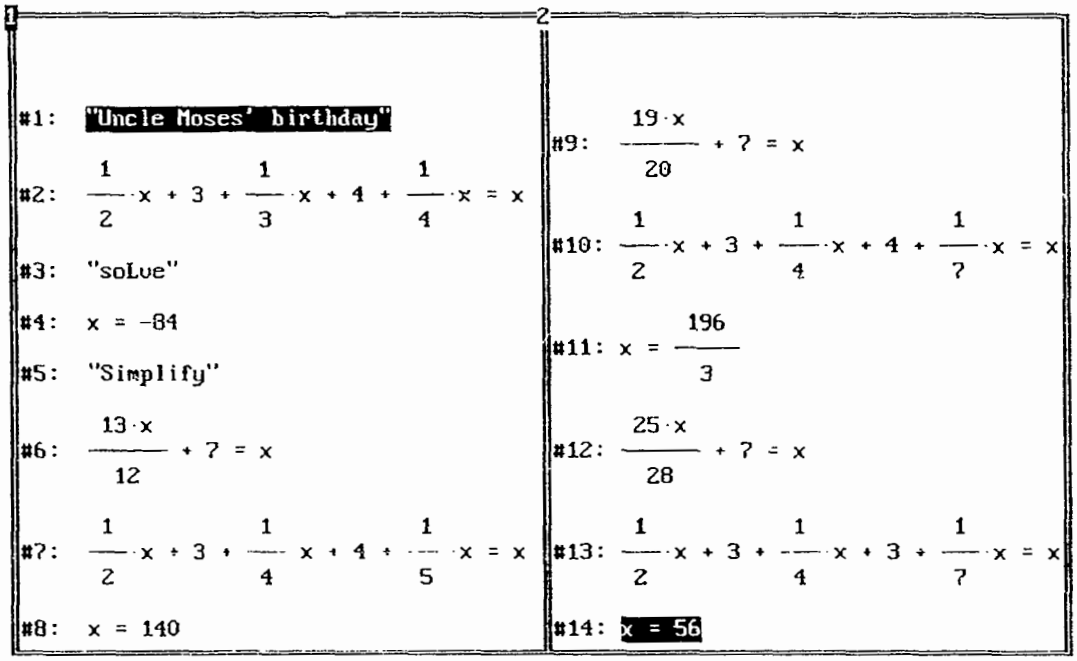
$$\#9 \quad x = \frac{84}{25} \qquad \textit{Solve(\#8)}$$

In the following lines the student modified the equation until he got the correct one. All four teachers were impressed by the fact that after about 10 minutes, all the pupils managed to get the correct answer, "28 students", with only a little help from the teacher and their classmates. This was not so when students in other classes worked on the problem with paper and pencil.

In Table 1 we summarize students' work on Problem 1 based on what students wrote in their worksheets and on *Derive* files that were created during their work. In row 1 we see two equations that represent the two basic types of equations that students came up with. The first is a straightforward translation of the story, and the second is

the result of some data processing that pupils did in their heads. (It is not surprising that the pupils who constructed the second model could later find more easily than the others that we get the solution, x = 280, if we change the number of girls from 3 to 30). In the last row we have the percentages of pupils who concluded their answers, without being explicitly asked, with the calculation of the number of students engaged in various activities of the story.

Table 1: Distribution of solutions to Problem 1



Solution to Problem 1: School of Pythagoras		Class A n = 38	Class B n = 33	Class C n = 36	Class D n = 34
EQ	$\frac{x}{2}+\frac{x}{4}+\frac{x}{7}+3=x$	84%	100%	75%	60%
	$x-x(\frac{1}{2}+\frac{1}{4}+\frac{1}{7})=3$	16%	0%	25%	40%
PROCEDURES	soLve, (Simplify)	35%	45%	30%	73%
	Simplify, soLve	60%	15%	40%	18%
	F4 - Operations on both sides , Simplify, (soLve)	5%	40%	30%	9%
Calculation		5%	3%	33%	20%

We discussed with the four teachers the distribution in each class and the differences between the classes. Each teacher described his didactical strategies, techniques, and goals in teaching algebra in the class. Together we came up with the conclusion that pupils' work on the problem with *Derive* reflect their previous experience. The teachers could make specific inferences to their teaching.

Another source of insight to the teachers was the story problems that students wrote that followed Problem 2. The number of complete story problems (i.e. story, equation and reasonable solution) in each class varied from 33% to 61%. To illustrate a typical story and model formulated we show in Table 2 a *Derive* file related to the story of Uncle Moses who challenged his friends, on his birthday, with the puzzle: *How old am I?* The file illustrates, somewhat transparently, the monitoring, evaluating, and planning processes that were part of pupils' reasoning. We can see that he used the *solve* command for monitoring the model, and the *simplify* command for evaluating the expressions. It seems that in his planning he referred to the fact that the sum of the fractions should be less than 1(see line #7), but the role of the "number" in

determining the solution was not yet clear to him (see the trial and error in lines #10 - #12). Based on the findings of the study, we are currently revising the unit. We are considering including of a parametric form of the model, which can easily be manipulated by the software, to enhance the understanding of the structure of model.

Table 2: Modeling the story of Uncle Moses' birthday

Conclusion

In designing learning units in a CAS environment we have at least three concerns: (a) What is the balance between student interaction with the system and student reflection? (b) Does the complexity of the system simplify the parts that cause the student the most trouble? (c) How do conceptual and procedural knowledge interact when the CAS is performing the procedures?

In this study we have found that the use of technology does not replace reflection on the part of the student, but rather enhances it. When a pupil is using CAS to solve a word problem and immediately gets a solution, he is free to check if the solution does not make sense. In such a case he knows that the source of the trouble is the model/equation and not the algebraic manipulations. He may reflect on the way he constructed the model and try to resolve the problem. This is a big advantage over the conventional way of teaching, where pupils do not have the immediate control over

BEST COPY AVAILABLE

their work, and therefore they have to wait until the teacher reacts to their solution before they start to reflect, if at all.

The weight we placed on the model emphasizes the fact that usually the complete model of a word problem includes, in addition to the equation(s), some implicit restrictions. Because the pupils were asked to play the role of the teacher by inventing their own story problems, they realized the importance of those implicit restrictions. Thus, the design of the unit leads in a natural way to parametric equations, which we plan to investigate further. Our experience so far indicates that the use of CAS in this unit and in others creates networks of relationships between conceptual and procedural knowledge that facilitate mathematical understanding.

BOYS, MATHEMATICS AND CLASSROOM INTERACTIONS: THE CONSTRUCTION OF MASCULINITY IN WORKING-CLASS MATHEMATICS CLASSROOMS.

Robyn Zevenbergen
Griffith University

This paper explores the interactions between teacher and students in attempting to understand the ways these contribute to the construction of masculinity with the primary school setting. Research suggests that not all boys or girls are winners in mathematics, but rather, it is important to consider the intersection between gender and other variables such as ethnicity, rurality, class and poverty. This paper examines the intersection of gender and social class – namely boys and working class. It analyses a transcript taken from a series of videotaped lessons during the last year of primary school (12-13 year old).

A considerable amount of research has investigated aspects of mathematics and mathematics education which have resulted, or have the potential to result in, the marginalisation of girls in and through mathematics. Such research has been very powerful in changing the status and outcomes for girls and women in the study of mathematics. However, as has become increasingly evident across Australia and internationally, there is a recognition of the polarisation of the performance of boys. In part, such foci are a result of a backlash against many of the political and economic reforms sweeping the world. Traditional male roles have come under challenge within the economic and workplace reforms of the post-Keynesian reforms. Such changes have seriously challenged the role and place of men in society, and just as women's movements had taken up the challenge in the 60s for girls, men's movements are now taking up the challenge for boys' education.

Boys simultaneously have a clear at a disadvantage and advantage in the study of mathematics. In the 1999 Year 12 results for Queensland, boys dominated both the top and lowest 10 percentile in results. Similar results have been noted in other state-wide testing regimes. However, as Teese, Davies, Charlton, and Polesel (1995) have noted that it is not gender alone that compounds success, but also socio-economic privilege, rurality and culture. In Australian schools, in both literacy and numeracy, Aboriginal girls outperform Aboriginal boys, but as a group, they score considerably lower than other Australian students (Gilbert & Gilbert, 1998; Zevenbergen, 1996); and those living in remote areas do not perform as well as those in urban areas (Gilbert & Gilbert, 1998; Lamb, 1997). Similar patterns occur for working-class students who do not do as well as their middle-class peers, but in study of mathematics, middle-class girls are likely to score as well as their middle-class male peers, whereas working-class girls are less likely to score as well as their working-class male peers (Teese et al, 1995).

1518

In examining the teaching of mathematics from feminist standpoints, studies of questioning in mathematics classrooms have shown similar results where boys are asked significantly more questions than girls, (Leder, 1990) boys are asked more challenging questions whereas girls are more likely to be asked closed questions; girls tend to be more focused on writing and presentation whereas boys are concerned and rewarded for experimentation (Forgasz & Leder, 1995, Walkerdine, 1989). Whereas this literature arose from the needs to recognise the girls in mathematics, it also is useful in documenting potential areas for boys' education. Just as the gender identity literature has alerted educationalists and the wider society to the restricted versions of masculinity open to boys, so too does the literature on girls and mathematics. The options open to boys, while may be more empowering, they are only empowering for a restricted number of boys.

Studies of classroom interactions have demonstrated a regularity in the interactions which become *taken-for-granted* to constitute what becomes part of a mathematics culture. The culture of the mathematics classroom has been well documented and had often been described by teachers and students within restricted frameworks. Teachers' widely-held beliefs that they are responsible for teaching students specified procedures in order to solve mathematical problems (Goodland, 1983; Stodolosky, 1988) facilitates the development of traditional forms of classroom cultures which are so familiarly recalled by students. Most often it is described as teacher directed, students undertaking routine exercises and pencil-and-paper testing procedures (Leder & Forgasz, 1992). With a greater emphasis on inquiry modes of pedagogy, mathematics classrooms which have adopted these approaches have been placed under scrutiny. Bauersfeld, Krummheuer and Voigt, (1989) along with Wood (1994) note that the changes in the epistemological approach adopted by the teacher produces changes in the patterns of interactions within the reformed classroom.

"Triadic dialogue" (Lemke, 1992) has been documented as one of the most frequently occurring interactions within the classroom and is not unique to any particular curriculum area. This form of interaction consists of three key parts: the teacher initiates a question to which the answer is usually known by the teachers; the student responds; and the teacher then evaluates the response (Sinclair & Coulthard, 1976; Mehan, 1982). Such interactions serve the purpose of controlling the interactions as well as the content of the lessons. Lemke (1990) argues that the rules for interacting are not explicitly taught and hence students come to learn them through participation in the interactions. However, Lemke also notes that the patterns of interaction are not consistent across the three phases of a lesson. Triadic Dialogue is common in the introductory phase of a lesson where the teacher attempts to keep tight control of the content and students. Hence a significant amount of power resides with the teacher. Similar observations are made of the concluding phase of the lesson. However, during the work phase of the lesson, the patterns of power are somewhat more equal and students can express their lack of understanding. This phase of the lesson adopts patterns of interactions that are somewhat more equal

between teacher and students. The role of teachers' questions are critical in controlling the interactions with classrooms. As Lemke (1990) has shown through Triadic Dialogue, questions are used to control the flow of the lesson, the content to be covered, the behaviour of students and to provide progressive evaluation of student learning and lesson implementation.

Wood (1994) contends that many of these interaction types found in mathematics classrooms do not require the students to be working mathematically to participate. In her work with inquiry classrooms, she contends that the questions asked are substantially different in form where the answer is often unknown; and seeking further information and/or encouraging reflective thinking from the students (p.152). Extending the notion of interaction to include extended interactions, two key forms of interactions have been identified as potentially contributing to mathematical understanding. Funnel interactions (Bauersfeld, 1988; Voigt, 1985) are those where the students "narrowing of a joint activity to produce a predetermined solution procedure by teacher...[by] providing students with leading questions" (Wood, 1994, p. 155). Focussing patterns of interactions occur when the teacher uses carefully worded questions to guide the students to the more critical components of the task. In so doing the teacher poses problems to the students so as to ensure that the interaction is focused on the student and that she/he assumes responsibility for the resolution of the problem.

These studies have been useful in identifying micro and macro patterns in classroom interactions, but they do not address gendered aspects of the interactions. Such studies are valuable in identifying key aspects of the hidden components of the classroom culture which may be instructional in understanding the ways in which masculinity is exercised in mathematics classrooms.

Studies of classroom talk of who talks, for how long, with what forms of questions and about what, show that boys dominate the linguistic space usually within masculinist and often aggressive ways. However, as Gilbert and Gilbert (1998) are quick to recognise, it is not all boys who are advantaged by such interactions. Just as narrow readings of femininity constrained girls education, so too can the narrow versions of masculinity constrain boys education. This project critically examines the interactions within a mathematics classroom in order to understand the ways in which masculinity is being constructed in and through mathematic for working-class boys.

The Study

The study was conducted in a working-class school in a major regional centre of Australia. The school was selected on the basis of its nationally computed disadvantage index. The class "self-selected" with the teacher volunteering to participate when the school was approached to participate in the study. The class was in the last year of primary school (12-13 year olds), mixed gender with approximately equal representation of boys and girls. There were approximately 30 students in the class. The teacher adopted an interactive approach to teaching mathematics in which debate and discussion were actively encouraged. The project involved the

videotaping of weekly mathematics lessons for one school term (11 weeks). All videotapes were transcribed and analysed. For the purposes of this paper, the analysis was conducted on the introductory phases of the mathematics lessons and the ways in which interactions were gendered.

The lesson to be discussed in this paper is one which is focused on co-ordinates. The lesson begins with the teacher sketching a very crude map of Australia on the board over which a 3 x 2 grid is drawn with the y-axis labelled A and B, the x-axis as 1-3. The teacher uses this grid work to revise co-ordinates before setting the students to the task in which they have a series of co-ordinates which they must plot and then produce a sketch. Students are able to discuss and help each other with the task during the work phase. The conclusion of the lesson is very brief with teacher and students discussing their drawings, any areas of difficulty – including the incorrect co-ordinate provided in the activity sheet.

The following is a short segment from the introductory phase

1. T: This is a very rough map, making it as clear as mud. OK. Got that. 123AB. Can you look up here please?
2. B: Do we have to do it?
3. T: Just look at this. Just look at it. OK. Right, this mud map is a mud map of Australia. Here is our little map of Australia. Tasmania down here.
4. B: Where's New Zealand?
5. [T draws in New Zealand]
6. B: It's not a very good one!
7. T: The other island over here .... Near enough, OK.
8. B: Yeah rub off New Zealand
9. T: If we were looking up a particular place on this map, you would use the grid reference and the grid reference is the numbers and letters. Can anybody tell me the grid reference for let's see..... Tasmania? What is the grid reference for Tasmania?
10. B: B2
11. T: Put your hand up please. Rebecca?
12. G: B2
13. T: Yes. So ...B2. And what if you wanted to go from Tasmania to say... Perth. What is the grid reference for where you would find Perth? Tate?
14. B: B1
15. T: Right, Thank you. Now it would look this. So you would say from B2 to B1. Now it's pretty unclear exactly [referring to map], I mean it could be from here to here because we're not exactly certain. Who can tell me what it would be if you want to draw or show someone from Tasmania to Darwin?
16. B: [calling out] I don't know where Darwin is.
17. T: Guess if you don't know exactly.....Yes, what do you think it will be?
18. B: A1.

19. B: Yeah
20. T No, we want to go from ...to
21. B: B2 to A1
22. T: Right B2 to A1....thank you.

The introduction continues on as the teacher and students plot a few more cities and draw the connecting lines between two points. The interactions continue in a very similar fashion, with no girl being asked a question until the work phase where one seeks clarification of the task.

All lessons analysed produced similar results, confirming earlier research on the girls and mathematics. Boys were asked substantially more questions that girls, frequently in excess of 80% of the questions. In some cases, very few, if any questions were asked to the girls in the introductory phase of the lessons. In 3 lessons, no girls were asked any questions in the introductory phases. These outcomes convey very subtle message to boys and girls about the nature of mathematics and mathematics teaching. From a feminist standpoint, this could be seen to be very disempowering for girls while being very empowering for boys. However, such a position does not consider how *some* boys (and girls) are being marginalised from the study of mathematics. In considering the social-class variable, these interactions are very disempowering for girls and arguably could be a significant factor in the marginalisation of working-class girls in and through mathematics. As noted, this group is one of the most-disadvantaged groups in Australian education. However, as it will be shown, the interactions can equally be disempowering for the working-class boys.

In considering the Triadic Dialogue identified by Lemke (1990), it is clear that such a strategy is useful in controlling the classroom and content of the lesson. At the end of line 13, where the teacher asks Tate where is Perth, to which the boy answers correctly, the teacher then evaluates the response, acknowledges that it is correct and then is able to move on to the next step of the lesson content. In contrast, in interactions 9 to 13, the teacher asks the question, but admonishes the student for calling out and then asks another student (a girl) to respond. From this interaction, it can be seen that when a student violates the taken-for-granted rules of the classroom (in this instance, it is improper to call out) the response is ignored and the student's response is rendered invisible and another response is called for. Using this simple Triadic Dialogue, the teacher is able to keep the lesson flowing effectively both in terms of the mathematical content where the students are being asked to identify co-ordinates for different locations (eg B1) and the tracks between two co-ordinates (eg from B2 to A1). Simultaneously, the interactional pattern is useful in controlling the social norms of the classroom – rules such as putting hands up to give answers, sitting in seats, not writing during instructions and so forth are often made explicit. However, as Lemke (1990), the patterns of interaction are never made explicit, they must be learned through participation.

Although not apparent in this extract from the transcript, this lesson and others contained interactions that supported notions of funnel interactions and focussing interactions. Such extracts support the notion that such interactions facilitate a stronger mathematical understanding to be developed. In contrast, the interactions in this extract support only minimal mathematical working. They tend to be low level and more at the level of revision and/or consolidation.

What is worthy of discussion is the ways in which gender, vis-à-vis masculinity, is being constructed for this group of boys. As noted in the introductory sections, working-class boys do not perform as well in mathematics as middle-class boys and middle-class girls (Teese et al, 1995). In line 2, the first challenge from the floor is made when a boy asks whether he has to do this work. The unspoken rules of classroom behaviour is that there is little or no leeway in participation. There may be coersive means by which the students may resist participation, but these are most frequently left unspoken. After seven years of formal schooling most students know this rule. In this interaction, the boy openly challenges the teacher as to whether participation is compulsory. The teacher's response indicates the type of participation that he is expecting.

In the fourth line a student (from New Zealand) challenges the teacher and asks where New Zealand is to which the teacher responds by drawing New Zealand on the map. Another male student interjects that New Zealand should be removed from the board. This friendly banter was common in the classroom but it was almost always instigated by a boy. The verbal challenges and rebuffs made by the boys can be seen to be masculine ways of interacting and reinforced in the public domain of the introductory phase. The challenges being drawn out through the interaction are among the boys and are not overt challenges to the teacher.

In line 16, a boy calls out, but unlike like 10, is not punished. Given that the top western quarter of Australia lies in the quadrant A1, then the location of Darwin is not really an issue. In this case, the student knew the location of Darwin, but was making overtures about the poor drawing of Australia. The boy has challenged the teacher's control of the lesson through this transgression, but has been able to ward off any retribution from the teacher. The transgression has been successful, and the boy's reputation was left in tact.

The disruptive behaviour in classrooms is often for the purposes of attention seeking. Frequently such behaviour was generated by the boys to gain approval from their peer group. Interviews with students at the end of the project confirmed that the most popular students were those who had strong profiles in the classroom. The profiles were not often associated with academic performance, but rather the social aspects of classroom antics. For example, one student thought that Daniel was the "best kid in the class because he could muck around a bit, you know, give the teacher a bit of a hard time. He made us laugh." Such comments indicate that status within the peer group for boys is often achieved through transgressing the social norms of the classroom.

Disruptive behaviour can be a seen as exciting in that it pushes the boundaries, exerts a sense of independence and challenges authority. In some cases, the pushing of boundaries may be valid when the lessons are boring, slow or repititive, but in other cases it may not be so legitimate. By displaying disruptive behaviour, the boys challenge the teacher's authority and in so doing, can be seen to be engaging in risk-taking behaviour. In some cases, the boys were successful in transgressing the social norms of classroom behaviour, in other instances they were not. When unsuccessful, they risk humiliation among their peers. Overall, disruptive behaviour is a key component of boys' school culture. In the playground, the events can be relived and celebrated with laughter and backslapping, cementing the bonds of boyhood and camaraderie. Boys' behaviour is closely linked to their public persona and their need to establish themselves in the public arena in a way which they feel is acceptable. For the boys in this classroom, this often was seen to take on quite masculinised ways of working and resisting the school mathematics culture. In so doing, they were effectively and progressively excluding themselves from mathematical content and knowledge.

In another study (Zevenbergen, 1995), it was found that such disruptive behaviour was not as evident in middle-class mathematics classrooms. Boys and girls complied with the Triadic Dialogue so that both social and mathematical norms were unchallenged. In these classrooms, students were exposed to far greater mathematical content and language than their middle-class peers, suggesting an area for the potential differences between class and gender.

Conclusions

Boys' education has alerted researchers to the unique aspects of boys' schooling. The study of interactions in mathematics classrooms provides scope for understanding how the classroom context contributes to the personal development of how students come to understand and construct themselves as learners of mathematics. How students construct and are constructed by classroom dynamics is an area worthy of in-depth investigation. As has been shown here, the interactions within a working-class classroom offer restricted outcomes for learning mathematics. Potentially the interactions ,restricted in the content, are constrained by the transgressions posed by students. Such transgressions appear to be male dominated both quantitatively and qualitatively. In many cases, the boys are positioning themselves within practices which reflect their emerging senses of masculinity. The challenges posed by the boys tend to disrupt the flow and content of the mathematics lessons. To this end, both the working-class boys and girls are potentially exposed to a restricted offerings of mathematical understanding. As a consequence of such actions, it is suggested that emerging sense of the masculine self, may contribute to the marginalisation of working-class boys and girls in the study of mathematics
