AUTHOR	Zaslavsky, Orit, Ed.
TITLE	Proceedings of the Conference of the International Group for the Psychology of Mathematics Education (23rd, Haifa, Israel, July 25-30, 1999). Volumes 1-4.
INSTITUTION	International Group for the Psychology of Mathematics Education.
ISSN	ISSN-0771-100X
PUB DATE	1999-00-00
NOTE	1526p.
PUB TYPE	Collected Works - Proceedings (021)
EDRS PRICE	MF12/PC62 Plus Postage.
DESCRIPTORS	Cognitive Processes; Cultural Influences; Educational Technology; Elementary Secondary Education; Evaluation; Foreign Countries; Higher Education; *Mathematics Curriculum; *Mathematics Education; Mathematics Instruction; Number Concepts; Problem Solving; Professional Development; Social Influences; *Teacher Education; Visualization

ABSTRACT

This conference proceedings contains 135 research reports, 73 short oral reports, 30 poster session reports, 4 plenary addresses, 3 research forums, 6 project groups, and 5 discussion group reports. Only the research reports, research forums, and plenary addresses are full reports; the others are generally one-page abstracts. The first volume includes: (1) "Where in shared knowledge is the individual knowledge hidden?" (R. Hershkowitz); (2) "Professional development, classroom practices, and students' mathematics learning. A cultural perspective" (G. B. Saxe); (3) "One theoretical perspective in undergraduate mathematics education research" (B. Czarnocha, E. Dubinsky, V. Prabhu, and D. Vidakovic); (4) "Cultural aspects in the learning of mathematics" (N. Presmeg and P. Clarckson); (5) "Developing skills of advanced mathematical thinking" (P. E. Kahn). The second volume includes: (1) "Teacher profile in the geometry curriculum based on the Van Hiele theory" (M. D. Afonso, M. Camacho, and M. M. Socas); (2) "Pupils' images of teachers' representations" (C. Bills and E. Gray); (3) "What kind of mathematical knowledge supports teaching for 'conceptual understanding'? Preservice teachers and the solving of equations" (D. Chazan, C. Larriva, and D. Sandow); (4) "Argumentative aspects of proving: Analysis of some undergraduate mathematics students' performances" (N. Douek); (5) "A numeracy assessment framework for the international life skills survey" (I. Gal). The third volume includes: (1) "'What Can We All Say?' Dynamic geometry in a whole-class zone of proximal development" (J. Gardiner, B. Hudson, and H. Povey); (2) "Pedagogy and the role of context in the development of an instrumental disposition towards mathematics (S. Goodchild); (3) "Alternative assessment for student teachers in a geometry and teaching of geometry course" (B-S. Ilany and N. Shmueli); (4) "Learning pre-calculus with complex calculators: Mediation and instrumental genesis" (J. B. Lagrange); (5) "This patient should be dead! Or: How can the study of mathematics in work advance our understanding of mathematical meaning-making in general?" (R. Noss, C. Hoyles, and S. Pozzi). The fourth volume includes: (1) "The research of ideas of probability in the elementary level of education" (A.-M. Ojeda); (2) "Monitoring of dynamics of students' intellectual growth in MPI-Project" (S. Rososhek); (3) "Conceptual understanding of conventional signs: A study

Reproductions supplied by EDRS are the best that can be made
from the original document.

without manipulatives" (C. Silveira); (4) "Does the understanding of variable evolve through schooling?" (M. Trigueros and S. Ursini); (5) "Boys, mathematics and classroom interactions: The construction of masculinity in working-class mathematics classrooms" (R. Zevenbergen). (ASK)

Reproductions supplied by EDRS are the best that can be made

PREFACE

It is an honor and pleasure for me to chair the 23rd PME conference in Haifa. This conference has a special meaning to all of us. It marks a year since Efraim Fischbein, the founder president of PME, left us. In his plenary address at the 20th anniversary of PME, Efraim Fischbein expressed his hope that every year we will meet and pass the *message of goodwill, of cooperation, of love for mathematics and reason, the love for our students coping with the difficulties and fascination of learning mathematics.* We share this hope and look forward to a meeting that - in addition to its scientific merit - conveys this message.

The papers in the four volumes of the proceedings are grouped according to types of presentations: Plenary Addresses, Plenary Panel, Research Forums, Project Groups, Discussion Groups, Short Oral Communications, Posters, and Research Reports. The plenary addresses and the research forum papers appear according to the order of presentation. The Groups are sequenced according to their numbers. For the other types of presentations, within each group, papers are sequenced alphabetically by the name of the first author, with the name(s) of the presenting author(s) underlined.

There are two cross-references to help readers identify papers of interest to them:

- by research domain, according to the first author (p. 1-xxvii)
- by author, in the list of authors (p. 1-369).

I wish to extend my appreciation to all the people who took part in the production of these proceedings. I am particularly indebted to Joop van Dormolen, Lea Keinan, and Doron Zur for their dedication, cooperation and endless amount of work devoted to the preparation of the proceedings.

This conference received support from many sources, without which we could not have organized it to meet PME standards. We are grateful to the sponsors, especially to the hosting institute, the Technion – Israel Institute of Technology, for the support and facilities provided to the conference organizers.

Last, but not least, many thanks to the members of the Program Committee and the Local Organizing Committee for sharing with me so willingly the responsibilities involved in this enterprise.

Orit Zaslavsky
Haifa, July 1999

TABLE OF CONTENTS

VOLUME 1

Preface 1-iii
Table of contents 1-v

Introduction

The International Group for the Psychology of Mathematics Education 1-xxix
Proceedings of previous PME conferences 1-xxxi
The review process of PME23 1-xxxiii
List of PME23 reviewers 1-xxxiv
Index of presentations by research domains 1-xxxvii

A Tribute to Efraim Fischbein

Tall, D. 1-3
Efraim Fischbein, 1920-1998, Founder President of PME
A Tribute

Plenary Addresses

Hershkowitz, R. 1-9
Where in shared knowledge is the individual knowledge hidden?

Saxe, G. B. 1-25
Professional development, classroom practices, and students' mathematics learning: A cultural perspective

Steinbring, H. 1-40
Reconstructing the mathematical in social discourse - aspects of an epistemology-based interaction research

Ruthven, K. 1-56
Constructing a calculator-aware number curriculum: The challenges of systematic design and systemic reform

Plenary Panel

Sfard, A., Nesher, P., Lerman, S. & Forman, E. 1-75
Doing research in mathematics education in time of paradigm wars

BEST COPY AVAILABLE

Research Forums

Theme 1: ***Learning and teaching undergraduate mathematics***
Coordinators: A. Selden and J. Selden

Czarnocha, B., Dubinsky, E., Prabhu, V., & Vidakovic, D. 1-95
One theoretical perspective in undergraduate mathematics education research

Tall, D. (reactor) 1-111
Reflections on APOS theory in elementary and advanced mathematical thinking

Sierpinska, A., Trgalová, J., Hillel, J., & Dreyfus, T. 1-119
Teaching and learning linear algebra with Cabri

Leron, U. (reactor) 1-135
Finding the student's voice vs. meeting the instructor's expectations

Theme 2: ***Becoming a mathematics teacher-educator***
Coordinator: T. J. Cooney

Zaslavsky, O. & Leikin, R. 1-143
Interweaving the training of mathematics teacher-educators and the professional development of mathematics teachers

Krainer, K. (reactor) 1-159
Promoting reflection and networking as an intervention strategy in professional development programs for mathematics teachers and mathematics teacher educators

Tzur, R. 1-169
Becoming a mathematics teacher-educator: Conceptualizing the terrain through self-reflective analysis

Jaworski, B. (reactor) 1-185
What does it mean to promote development in teaching?

Theme 3: ***Visual thinking in mathematics education***
Coordinator: N. Presmeg

Yerushalmy, M., Shternberg, B. & Gilead, S. 1-197
Visualization as a vehicle for meaningful problem solving in algebra

Parzysz, B.. (reactor) 1-212
Visualization and modeling in problem solving: From algebra to geometry and back

Owens, K. 1-220
The role of visualization in young students' learning

Gray, E. (reactor) 1-235
Spatial strategies and visualization

Project Groups

PG1: *Algebra: Epistemology, cognition and new technologies* 1-245
Coordinators: J.-P. Drouhard, A. Bell & S. Ursini

PG2: *Classroom research* 1-246
Coordinators: S. Goodchild & R. Shane

PG3: *Cultural aspects in the learning of mathematics* 1-247
Coordinators: N. Presmeg & P. Clarckson

PG4: *Research on mathematics teacher development* 1-248
Coordinators: A. Peter-Koop, R. Möller & V. M. Santos-Wagner

PG5: *Social aspects of mathematics education* 1-249
Coordinators: J. Boaler & P. Valero

PG6: *The teaching and learning of stochastics* 1-250
Coordinators: J. M. Truran, K. M. Truran, D. Ben-Zvi & C. Batanero

Discussion Groups

DG1: *Exploring different ways of working with videotapes in research and inservice work* 1-253
Coordinators: J. A. Mousley, C. Breen & H. Frederick

DG2: *Learning and teaching elementary number theory* 1-254
Coordinators: R. Zazkis & S. Campbell

DG3: *Mathematics in working practice* 1-255
Coordinators: R. Noss, C. Hoyles & R. Straesser

DG4: *Teachers' and pupils' mathematics-related beliefs* 1-256
Coordinators: E. Pehkonen & F. Furinghetti

DG5: *Understanding of multiplicative concepts* 1-257
Coordinators: T. Watabane, J. Anghileri & A. Pesci

Short Oral Communications

Arvold, B. 1-261
Becoming a mathematics teacher educator: Reflections and analysis

Barallobres, G. & Panizza, M. 1-262
Two aspects of the mathematical rationality. Functions of the counterexample

Bazzini, L. 1-263
From natural language to symbolic expression: Students' difficulties in the process of naming

Berger, M. 1-264
A relational analysis of a mathematical learning episode

Bershadsky, I. & Zaslavsky, O. 1-265
The effect of dragging in a dynamic geometry environment on students' strategies solving locus problems

Blanton, M. L. 1-266
Using the undergraduate mathematics classroom to challenge prospective secondary teachers' notions of mathematical discourse

Brender, M., Dickman, N., Heller, R., Marku, L., Shmukler, A., Ziskin, C. & Zaslavsky, O. 1-267
Mathematics and literature: Learning mathematics in a folk-tale context

Cabrita, I. & Alves de Oliveira, A. 1-268
Acquisition of the model of proportionality supported by hypermedia document

Cha, I. & Wilson, M. 1-269
Prospective secondary mathematics teachers' conceptions of function: Mathematical and pedagogical understandings

Crisan, C. 1-270
Mathematics teachers' use of the new technology

Day, C. 1-271
An activity approach to dynamic assessment

Drouhard, J.-P. & Sackur, C. 1-272
The "Cesame" Project: Mathematical discussions and aspects of knowledge

Edwards, L. D. & Zazkis, R. 1-273
What do students do with conjectures? Pre-service teachers' responses to a generalization task

Ezer, H., Patkin, D. & Millet, S. 1-274
Literacy-in-mathematics perception of mathematics educators: From literacy-in-mathematics to mathematics literacy

Fakir Mohammad, R. 1-275
Teacher Development: A self-inquiry approach

Frant, J. B. & Rabello de Castro, M. 1 276
Meaning production for function: Parallel axes

Fuglestad, A. B. 1-277
Computers and the teachers' role in mathematics learning environment. Some episodes from the classroom

Graven, M. 1-278
What do mathematics senior phase teachers understand about the new outcomes based curriculum 2005?

Hardy, M. D. 1-279
When obstacles seem too big

Hazzan, O. 1-280
Attitudes of prospective high school mathematics teachers towards integrating information technologies in their future teaching

Huhtala, S. 1-281
Student's own mathematics as an explanation for errors in drug calculations

Huillet, D. & Mutemba, B. 1-282
Institutional relation to a mathematical concept: The case of limits of functions in Mozambique

Hungwe, G. 1-283
The process of acceptance of the realistic mathematics curriculum by teachers in Harare

Ilany, B., Binyamin-Paul, I., Ben-Yehuda, M., Gafny, R. & Horin, N. 1-284
The effects of the exposure to the "math is next" database on teachers' methods in teaching mathematics to young children

Kahn, P. E. 1-285
Developing skills of advanced mathematical thinking

Kaldrimidou, M., Sakonidis, H. & Tzekaki, M. 1-286
Communicative interactive processes in primary versus secondary mathematics classroom

Khoury, Y. & Francis, N. 1-287
Diagnose and Treat - Pupils with mathematics difficulties in middle schools

Klein, R. & Tirosh, D. 1-288
Relationship between PCK and lesson plans: Does improvement in teachers' PCK affect their lesson plans?

Kot, L. Kiro, S. & Arcavi, A. 1-289
Mistaken conjectures as a trigger to develop basic probabilistic reasoning

Koyama, M. 1-290
Research on the validity of "Two-Axes Process Model" of understanding mathematics

Kramarski, B. 1-291
Interaction between knowledge and contexts on ability to solve problems: The role of different learning conditions

Kratzin, C. 1-292
Constructions of new mathematical knowledge in different learning environments

Krupanandan, D. 1-293
Mathematics assessment in a new curriculum model in South Africa

Lozinskaia, R. 1-294
The language of mathematics as the object for special study

Markovits, Z. 1-295
Average, teachers and students

Merenluoto, K. 1-296
Problems of conceptual change on the enlargements of the number concept

Merri, M. & Vannier, M.-P. 1-297
Tutorial interactions and didactics of mathematics: Recognition of fractions in primary school and vocational education

Mesquita, A. L. 1-298
On developing tridimensional space at school

Mkhize, D. 1-299
Cooperative groupwork - a vehicle for democracy in black South African mathematics classrooms?

Mochon, S. & Rojano, T. 1-300
Teaching math with technologies: A national project in Mexico

Mousley, J. A. 1-301
Models of mathematics understanding

Nakahara, T. 1-302
Multi-world paradigm in mathematical learning

Nasser, L. & Tinoco, L. 1-303
Helping to develop the ability of argumentation in mathematics

Ninomiya, H. 1-304
A study on the function of transactional writing: A function model of socio-mathematical skill in mathematics education

Nortvedt, G. A. 1-305
Difficulties in calculating the volume of three-dimensional arrays of cubes

Nyabanyaba, T. 1-306
"Everyday" contexts in school mathematics

Piteira, G. C. 1-307
Mathematical activity in the classroom: Geometric dynamic environment as a window for learning

Rabello de Castro, M. & Frant, J. B. 1-308
A social representation approach to investigate learning

Rasslan, S. 1-309
Definitions for the concept of maximum / minimum of a function

Reiss, K. 1-310
Spatial ability and declarative knowledge in a geometry problem solving context

Riives, K. 1-311
On application of elements of communication theory in classroom practice

Robinson, N. & Adin, N. 1-312
"Written conversation forms" as promoters of teachers' change

Ron, G. & Zaslavsky, O. 1-313
Is a counter-example always enough to refute a mathematical statement?

Rossouw, L. & Smith, E. 1-314
Teachers ' view on mathematics teaching and their practices

San, L. W. & Gwambe, R. 1-315
Triangular relationship institution-teachers-secondary school pupils: The case of inequalities

Schroeder, T. L., Donovan II, J. E., Schaeffer, C. M. & Reisch, C. P. 1-316
Tasks for assessing rational understanding of functions based on the operational/structural distinction

Sela, H., Zaslavsky, O. & Leron, U. 1-317
Re-thinking the notion of slope under change of scale

Shama, G. & Layman, J. 1-318
Mathematical modeling by pre-service teachers in a physics course

Shane, R. 1-319
Models for teacher enhancement in mathematics education: A two-year program in the Beduin schools

Stehlíková, N. & Henjy, M. 1-320
The teacher – the decisive agent in the quality of teaching

Steinberg, R. 1-321
Teachers in a process of change: Reforming mathematics by building on children 's thinking

Tabach, M. 1-322
Emphasizing multiple representations in algebraic activities

Taizi, N. 1-323
Generalizing with Excel at the beginning of learning algebra

Tarlow, L. & Dann, E. 1-324
Modeling Fibonacci: Two unifix cube problems

Thomas, N. 1-325
Children's number concepts: Implications for teacher education

Tirosh, C. 1-326
Universal Theorems: A paradigmatic model of mathematical theorems

Tomazos, D. & Hall, C. A. 1-327
What counts as evidence: Uncovering the foundations of failure in mathematics learning

Tsamir, P. & Almog, N. 1-328
"No Answer" as a problematic response: The case of inequalities

Winbourne, P. 1-329
Mathematical becoming: The place of mathematics in the unfolding stories of learners' identities

Yamaguti, K. 1-330
Visualization of solutions of a quadratic equation

Zamir, S. & Zaslavsky, O. 1-331
Understanding the connections between the graph of a function and the graph of its derivative

Zazkis, R. 1-332
Confronting and modifying students' intuitive rules in number theory

Zeichner O., Kramarski, B. & Mevarech, Z. 1-333
Improving students' mathematical thinking: The role of different interactions in a computer environment

Poster Presentations

Albert, J. 1-337
Motivating teachers to use alternative assessment

Amir, Y. & Gottlib, O. 1-338
Mathematical sense-making strategies of non-academically oriented students

Asman, D. & Markovits, Z. 1-339
Teachers' beliefs and use of non-routine problems in mathematics teaching

Campos, Y. & Navarro De Mendicuti, T. 1-340
Learning mathematics by projects using web page

Carlson, M. P. 1-341
A study of second semester calculus students' notion of covariation

Chang, C.-K. 1-342
Learning constructivist teaching by doing: A course for in-service teachers

Chen, I.-E. & Lin, F.-L. 1-343
The complementary roles of idea initiator and inquirer in mathematics conjecturing activity

Climent, N., Contreras, L. C. & Carrillo, J. 1-344
The heterogeneous character of the student teachers thought

Cockburn, A. D. 1-345
Authentic learning in mathematics: A real possibility or an academic's fantasy?

De Bock, D., Verschaffel, L. & Claes, K. 1-346
Does the authenticity of the context affects the tendency towards improper proportional reasoning?

Elliot, S., Hudson, B. & O'Reilly, D. 1-347
Visualisation and the influence of graphical calculators

Even, R., Bar-Zohar, H., Gottlib, O., Hirshfeld, N., Robinson, N. & Shamash, J. 1-348

Hanna, G. & Jahnke, H. N. 3-73
Using arguments from physics to promote understanding of mathematical proofs

Har-Zvi, S. H., Mevarech, Z. R. & Rahmani, L. 3-81
Generating adequate mathematical questions according to type of problems

Heirdsfield, A. M., Cooper, T. J., Mulligan, J. & Irons, C. J. 3-89
Children's mental multiplication and division strategies

Hoskonen, K. 3-97
A good pupil's beliefs about mathematics learning assessed by repertory grid methodology

Hoyles C. & Healy, L. 3-105
Linking informal argumentation with formal proof through computer-integrated teaching experiments

Ilany, B.-S. & Shmueli, N. 3-113
Alternative assessment for student teachers in a Geometry and Teaching of Geometry course

Jaworski, B., Nardi, E. & Hegedus, S. 3-121
Characterizing undergraduate mathematics teaching

Kendal, M. & Stacey, K. 3-129
CAS, calculus and classrooms

Kent, P. & Stevenson, I. 3-137
"Calculus in Context": A study of undergraduate chemistry students' perception of integration

Keret, Y. 3-145
Change processes in adult proportional reasoning: Student teachers and primary mathematics teachers, after exposure to 'Ratio and Proportion' study unit

Klapsinou, A. & Gray, E. 3-153
The intricate balance between abstract and concrete in linear algebra

Koirala, H. P. 3-161
Teaching mathematics using everyday contexts: What if academic mathematics is lost?

Kutscher, B. 3-169
Learning mathematics in heterogeneous as opposed to homogeneous classes: Attitudes of students of high, intermediate and low mathematical competence

Kynigos, C. & Argyris, M. 3-177
Two teachers' beliefs and practices with computer based exploratory mathematics in the classroom

Kyriakides, L. 3-185
Baseline assessment and school improvement: Research on attainment and progress in mathematics

Lagrange, J. B. 3-193
Learning pre-calculus with complex calculators: Mediation and instrumental genesis

Latner, L. & Movshovitz-Hadar, N. 3-201
Storing a 3-D image in the working memory

Lawrie, C. 3-209
Exploring Van Hiele levels of understanding using a Rasch analysis

Leder, G. C. & Forgasz, H. J. 3-217
Returning to university: Mathematics and the mature age student

Leu, Y.-C. 3-225
Elementary school teachers' understanding of knowledge of students' cognition in fractions

Leu, Y.-C., Wu, Y.-Y. & Wu, C.-J. 3-233
A Buddhistic value in an elementary mathematics classroom

Lin, P.-J. & Tsai, W.-H. 3-241
Children's cultural activities and their participation

Magajna, Z. 3-249
Making sense of informally learnt advanced mathematical concepts

Malara, N. A. 3-257
An aspect of a long-term research on algebra: The solution of verbal problems

Mariotti, M. A. & Maracci, M. 3-265
Conjecturing and proving in problem solving situations

Markopoulos, C. & Potari, D. 3-273
Forming relationships in three-dimensional geometry though dynamic environments

McGowen, M. & Tall, D. 3-281
Concept maps & schematic diagrams as devices for documenting the growth of mathematical knowledge

Mendonça Domite, M. do C. 3-289
Reinforcing beliefs on modeling: In-service teacher education

Möller, R. D. 3-297
The development of elementary school children's ideas of prices

Murray, H., Olivier, A. & de Beer, T. 3-305
Reteaching fractions for understanding

Musicant, B. 3-313
Operations on "open-phrases" and "open-sentences" expressions – Is it the same?

Nardi, E. 3-321
Using semi-structured interviewing to trigger university mathematics tutors' reflections on their teaching practices

Newstead, K. & Olivier, A. 3-329
Addressing students' conceptions of common fractions

Nisbet, S. & Warren, E. 3-337
The effects of a diagnostic assessment system on the teaching of mathematics in the primary school

Noda, A. M., Hernández, J. & Socas, M. M. 3-345
Study of justifications made by students at the "preparation stage" of badly defined problems

Noss, R., Hoyles C. & Pozzi, S. 3-353
This patient should be dead! or: How can the study of mathematics in work advance our understanding of mathematical meaning-making in general?

VOLUME 4

Research Reports (continued from Volume 3)

Ojeda, A.-M. 4-1
The research of ideas of probability in the elementary level of education

Patronis, T. 4-9
An analysis of individual students' views of mathematics and its uses: The influence of academic teaching and other social contexts

Pawley, D. 4-17
To Check or Not To Check? Does teaching a checking method reduce the incidence of the multiplicative reversal error?

Pegg, J. & Baker, P. 4-25
An exploration of the interface between Van Hiele's levels 1 and 2: Initial findings

Pehkonen, E. & Vaulamo, J. 4-33
Pupils in lower secondary school solving open-ended problems in mathematics

Pehkonen, L. 4-41
Gender differences in primary pupils' mathematical argumentation

Peled, I., Levenberg, L., Mekhmandarov, I., Meron, R. & Ulitsin, A. 4-49
Obstacles in applying a mathematical model: The case of the multiplicative structure

Boys, mathematics and classroom interactions: The construction of masculinity in working-class mathematics classrooms

INTRODUCTION

THE INTERNATIONAL GROUP FOR THE PSYCHOLOGY OF MATHEMATICS EDUCATION (PME)

History and Aims of PME

PME came into existence at the Third International Congress on Mathematics Education (ICME3) held in Karlsruhe, Germany in 1976. Its past presidents have been Efraim Fischbein (Israel), Richard R. Skemp (UK), Gérard Vergnaud (France), Kevin F. Collis (Australia), Pearla Nesher (Israel), Nicolas Balacheff (France), Kathleen Hart (UK), Carolyn Kieran (Canada) and Stephen Lerman (UK).

The major goals of the Group are:

- To promote international contacts and the exchange of scientific information in the psychology of mathematics education;
- To promote and stimulate interdisciplinary research in the aforesaid area with the cooperation of psychologists, mathematicians and mathematics educators;
- To further a deeper understanding into the psychological aspects of teaching and learning mathematics and the implications thereof.

PME Membership and other Information

Membership is open to people involved in active research consistent with the Group's goals, or professionally interested in the results of such research. Membership is on an annual basis and requires payment of the membership fees (US$30 or the equivalent in local currency) per year (January to December). For participants of PME 23 Conference, the membership fee is included in the Conference Deposit. Others are requested to contact their Regional Contact, or the Executive Secretary.
More information about PME as an association can be obtained trough its home page at: http://members.tripod.com/~IGPME (case sensitive) or through the Executive Secretary.

Honorary Members of PME

Hans Freudenthal (The Netherlands, deceased)
Efraim Fischbein (Israel, deceased)

Present Officers of PME

President:	Gilah Leder (Australia)
Vice-president:	Judith Mousley (Australia)
Secretary:	João Filipe Matos (Portugal)
Treasurer:	Gard Brekke (Norway)

Members of the International Committee

Janet Ainley (UK)
Abraham Arcavi (Israel)
Chris Breen (South Africa)
Gard Brekke (Norway)
Jan Draisma (Mozambique)
Toshiakira Fujii (Japan)
Gilah Leder (Australia)
Nicolina Antonia Malara (Italy)
João Filipe Matos (Portugal)
Ana Mesquita (France)
Judith Mousley (Australia)
Rafael Núñez (Switzerland)
Alwyn Olivier (South Africa)
Norma Presmeg (USA)
Marja van den Heuvel (The Netherlands)
Vicki Zack (Canada)
Orit Zaslavsky (Israel)

Executive Secretary: Joop van Dormolen

Members of PME23 Program Committee

Orit Zaslavsky (Technion, Israel) (Chair)
Janet Ainley (Warwick University, UK)
Abraham Arcavi (Weizmann Institute, Israel)
David Ben-Chaim (Oranim College, Israel)
Tommy Dreyfus (Holon Center for Technological Education, Israel)
Toshiakira Fujii (University of Yamanashi, Japan)
Gilah Leder (LaTrobe University, Australia)
Irit Peled (Haifa University, Israel)
Dina Tirosh (Tel-Aviv University, Israel)
Joop van Dormolen (Technion, Israel)

Members of PME23 Local Organizing Committee

Orit Zaslavsky (Chair)
Dan Aharoni
Abraham Arcavi
Tamar Brenner (Conference Secretariat)
David Ben Chaim
Ruhama Even
Lea Keinan
Roza Leikin
Uri Leron
Carel Mayer (Conference Secretariat)
Nitsa Movshovitz-Hadar
Shakre Rasslan
Ziva Shaham
Joop van Dormolen
Karni Yalin
Michal Yerushalmy

PROCEEDINGS OF PREVIOUS PME CONFERENCES

Copies of some previous PME Conferences are still available for sale. For information, see the PME home page at http:/members.tripod.com/~IGPME/procee.html (case sensitive!) or contact the Executive Secretary Joop van Dormolen, Rehov Harofeh 48A, 34367 Haifa, Israel; email: joop@tx.technion.ac.il; fax: +972 4 8258071.

All proceedings, except PME 1, are included in ERIC. Below is a list of the proceedings with their corresponding ERIC codes.

PME International

THE REVIEW PROCESS OF PME23

Research Forum

Four themes had been suggested by the Program Committee as research forum themes for PME23: *Learning and Teaching Undergraduate Mathematics; Becoming a Mathematics Teacher educator; Visual Thinking in Mathematics;* and *Assessment, Learning and Mathematics.* The Program Committee received 12 research forum proposals for these themes (4 for the first theme, 3 for each of the second and third themes, and 2 for the latter). For each theme, all the proposals were reviewed and ranked by three reputable scholars with expertise in the respective fields. The Program Committee considered and generally accepted the research forum coordinators' evaluations of the reviews and their ranking of the proposals. Consequently, 2 proposals were selected for each of the first three themes. The two proposals of the latter theme did not seem to provide a rich and wide enough scope of the field, thus, it was decided to cancel this forum.

Research Reports

The Program Committee received 202 research report proposals. Each proposal was sent for blind review to three reviewers. As a rule, proposals with at least two recommendations for acceptance were accepted. The reviews of proposals with only one recommendation for acceptance were carefully read by at least two members of the Program Committee. When necessary, the Program Committee members read the full proposal and formally reviewed it. Proposals with 3 recommendations for rejection were not considered for presentation as research reports. Altogether, 136 research report proposals were accepted. When appropriate, authors of proposals that were not accepted as research reports were invited to re-submit their work -- some in the form of a short oral communication and some as a poster presentation.

Early Bird Proposals

The Program Committee received 21 early bird research report proposals. Each proposal was sent to 3 reviewers who were asked to suggest ways to improve the proposal for resubmission as a research report. Of the early bird proposals 18 were re-submitted as research reports and one re-submitted as a short oral. Altogether, of the 21 early bird proposals 16 were finally accepted as research reports and 3 were accepted as short oral communications.

Short Oral Communications and Poster Presentations

The Program Committee received 72 short oral communication proposals and 17 poster proposals. Each proposal was reviewed by at least two Program Committee members. Altogether, 59 short oral proposals and 12 poster proposals were accepted. There were cases in which the program committee did not accept a proposal in the form that it was intended but invited the author(s) to present it in a different form.

A TRIBUTE TO EFRAIM FISCHBEIN

Efraim Fischbein, 1920-1998, Founder President of PME
A Tribute

David Tall

The 23rd meeting of the International Group for the Psychology of Learning Mathematics in Israel is touchingly the first in which we cannot be joined by our Founder President, Professor Efraim Fischbein, who left us on July 22nd 1998. It is a time of sadness, yes, but it is also a time for celebrating the achievements of this gentle man who is responsible for the existence of our organisation. In particular, it is to him that we owe our focus on the *psychology* of learning mathematics.

Efraim Fischbein was born in Bucharest on January 20th, 1920. He was a precocious child who learned to read Hebrew from the old testament at the age of three. He spent his formative years in Romania where he had to cope with the hardship of living in a rising fascist state. When World War II broke out he was forced into hard labour with other Jewish youths. His sight was seriously damaged and at the end of the war he prepared for his university examinations by listening to the reading of friends and conversation with his fellow students. He graduated at the Bucharest University in 1947 with an MA in Psychology and the qualification to teach mathematics in high school.

His first activity was to travel to Transylvania to care for a hundred orphans who were survivors of death camps. In 1948 he returned to Bucharest as a high school teacher and then, in parallel, as a lecturer in developmental psychology at the university. His long association with the University of Bucharest culminated as head of the Department of Educational Psychology from 1959 to 1975.

He was a prolific author of articles and books during this time, including the first original Romanian text-book on Psychology (*How do we know the world*, 1958). His monograph *The Figural Concepts: the nature of geometric entities and their development in children* was published in 1963 and accepted for his PhD. Other titles published in Romanian include: *The Man, Master of His Habits* (1955), *Concept and Image in Mathematics Thinking* (1965), *The Art of Thinking* (1968), *Hazard and Probability in Children's Thinking* (1974).

He caught the eye of the international mathematics community and was invited to address the first International Congress in Mathematics Education in 1969. His outstanding presentation on "Enseignement mathémathique et développement intellectuel" and his rising eminence led to his invitation to chair the Working Group on the Psychology of Mathematics Education at the second ICME conference in 1972 This highly successful working group continued under his chairmanship at the third Congress in

Karlsruhe in 1976 where the participants voted to continue with conferences every year as "The International Group for the Psychology of Mathematics Education". Efraim Fischbein was elected its founder president and served in this role from 1976 to 1980. Meanwhile he was appointed Professor of Psychology and founder chairman of the School of Education in Tel-Aviv University in 1975. He remained here for the rest of his life, with many visiting positions abroad, at Nottingham, UK, Montréal, Canada, Pisa, Italy, Georgia, USA, Heidelberg, Germany, and Granada & Valencia in Spain.

He continued to publish prolifically throughout his working life, including books in English on *The Intuitive Source of Probabilistic Thinking* (1975) and *Intuition in Science and Mathematics* (1987). His articles are a model of carefully designed research methodology and generative theory. Although well-versed in the methods of psychology, he was critical of its limited application to mathematics and saw that the psychology of mathematics education must develop its own theoretical perspectives.

His greatest creation is surely the organisation to which we belong. Following the decision to meet annually at Karlsruhe in 1976, the first meeting occurred the following year at Utrecht, organised by Hans Freudenthal. At Osnabrüch in 1978 the organisation was formally constituted under the title "International Group for the Psychology of Mathematics Education", subsequently shortened from IGPME to PME.

I remember vividly the talk he gave at PME in 1978, for it was to change my whole professional life. He presented his empirical and theoretical ideas on individual conceptions of infinity. His slim, wiry frame resonated with vigour and emotion as he passionately advocated the theoretical implications of his empirical findings. His enthusiasm had a profound effect on me personally. My own, previously solitary studies in undergraduate thinking suddenly began to take their place in the wider picture that he painted. It inspired me to make the study of limits and infinity—and broader research in undergraduate mathematics—as the focal point of my studies at that time. By 1985 a growing interest in this area led to the formation of the Advanced Mathematical Thinking group. Thus it was that Efraim's interest in the psychology of school mathematics permeated through to mathematics education at all levels.

He had a salutary wisdom that challenged those who professed to wear Emperor's clothes. I remember explaining to him that I could "see" an infinitesimal as a graph that tended to zero. He challenged me forcefully, saying: "*Show* me an infinitesimal". I was taken aback. I could not do it. Though I could formulate the formal mathematical framework, I had never analysed what it was that made the ideas work cognitively. It took a perceptive genius to ask the right question that cause a new theory to blossom. In my own case, this question from Fischbein spurred the journey of a life-time as I struggled to understand the relationship between conceptions to *think* about mathematics and processes that allow us to *do* it.

It is a salutary thought that he continued in vigour in his sixties and seventies, producing books and research articles of great quality at a time when many others have taken a well-earned retirement. At almost every conference of PME it has been my

privilege and delight to take my turn amongst his many friends and colleagues who sought his wisdom and advice.

His research has a subtle balance between theory and empirical evidence that has always been the hallmark of his scholarship. It is these qualities which should continue to mark our present and future work in PME.

His work on primary and secondary intuitions, on children's probabilistic thinking, on the complex meaning of infinite concepts and on intuition in both mathematics and science have been seminal. They provide us with fundamental notions on which we can continue to build into the future. While we lament his passing, we therefore rightly celebrate his achievement and his legacy:—the gift of "PME" which draws us together every year to pursue our continuing quest to understand the subtleties of psychological studies in mathematics education.

Farewell dear friend, our journeys continue in your footsteps.

WHERE IN SHARED KNOWLEDGE IS THE INDIVIDUAL KNOWLEDGE HIDDEN?

Rina Hershkowitz
The Weizmann Institute of Science, Israel

In more and more research and development projects, it is rightly assumed that "multiple interaction learning environments" (among students, between students and teacher, with the tool or with the task, etc.) are desirable for a meaningful construction of knowledge. It is then natural that social interaction within the classroom community is currently the object of intensive investigation. However, the individual as the one who uses the constructed knowledge, and shares it with others in various communities, has been neglected in these investigations. The relationships between construction of shared knowledge within a community and the individual construction of knowledge, are discussed and exemplified. Related issues concerning research paradigms and methodologies are also raised.

Background

Coming from the field of curriculum development, I view research questions from within a very comprehensive setting, which includes:

(1) Design considerations before starting the actual development and research work;

(2) Implementation of activities in a few classrooms, accompanied with observations of learning and teaching practices;

(3) Analysis of the data collected in order to redesign sequences of activities towards the creation of a complete curriculum (compatible with an official syllabus);

(4) Dissemination of the curricular aims and "spirit" on a national scale;

(5) Initiation of a new cycle of curriculum development (i.e. back to (1)).

About 6 years ago, we began a new cycle of such a curriculum development and research program at the Weizmann Institute, the CompuMath Project -- learning mathematics with computerized tools. Like others (e.g., Balacheff, & Kaput, 1996; Roth & Bowen, 1995), I believed that "multiple interaction learning environments", in the form of activities among students and/or between students and teacher through the

mediation of (computerized) tools, are desirable for a meaningful construction of individual student knowledge. Computerized tools were chosen and used because of their amplifying and reorganization capabilities, as mediators in meaningful learning of mathematics (Dörfler, 1993; Kaput, 1992; Pea, 1985). Activities were designed as multi-phased open-ended problem situations. For a detailed description of the CompuMath project, see Hershkowitz and Schwarz (1999). Experienced teachers, who usually belonged to the project team, first implemented activities in a few classrooms.

We were carried away by the overwhelming and surprising processes we observed in these classrooms, which differed from what we had observed in the last two decades of development and research. We confess that our excitement was not only due to the new activities and environment we created, but also because we decided to see the reality through new lenses. The need to describe, understand, explain (to ourselves as well as to others) and analyze what was going on in the classroom, naturally pushed us closer to the concerns of socio-cultural psychology. Like many others (e.f. Perret-Clermont, 1993; Yackel & Cobb, 1996), we felt the shortcomings of the cognitive theories, methodologies and tools we had at our disposal to describe and interpret learning and teaching processes in the classroom. We needed different kinds of units of analysis by which we would be able to describe meaningfully learning practices (Kuutti, 1996) and an appropriate "zoom of the lens" (Lerman, 1998) to observe, document, analyze and explain.

The research, which is an integral part of our work, is mostly from an interactionist perspective: the construction of knowledge is analyzed while students are investigating problem situations in different contexts. For example, we studied pairs of students in peer work during classroom activity or in an interview situation (Hadas & Hershkowitz, 1998, 1999), collaboration of a small group of students to solve a problem followed by a whole classroom discussion (Hershkowitz & Schwarz, 1997; 1999; Schwarz & Hershkowitz, 1995), or individual students interacting with a researcher during an interview at the end of a course (Dolev, 1997; Hershkowitz, Schwarz & Dreyfus, submitted).

The dilemma I would like to raise and discuss here arose and took hold during the research I have already done, and becomes clearer as I plan my further research program. My research is embedded in comprehensive socio-cultural paradigms of current cognitive research, therefore the controversies and questions I would like to discuss, are in a way derived from, and relevant to, these kinds of research as a whole.

The dilemma focuses on the individual construction of knowledge within the different "ensembles" of which he or she is part. (I prefer to use the term "ensemble" rather than the general term "community". This term, defined by Granot (1998), designates "the smallest group of individuals who directly interact with one another during developmental processes related to a specific activity context"). It raises questions about the difficulties in "zooming with our lens" on the individual's development as

he/she participates in the collective construction of shared cognition, in an ensemble (a couple of students or a small group), or in the whole classroom community.

In the following I will attempt to detail the dilemma through considerations and questions related to theory, research and methodology. The different questions will emerge from, and be demonstrated by, the presentation and analysis of a few examples.

Theoretical Considerations

Following Vygotsky, I consider the psychological development and learning of the individual as participation in the social activity of his/her own community. For Vygotsky the relationships between the two poles – the individual and the social -- are asymmetrical. In an article in which he argued and criticized Piaget's theory of the child's speech and thought, he expressed his principle concerning the development of thinking:

> In our conception, the true direction of the development of thinking is not from the individual to the socialized, but from the social to the individual (Vygotsky, 1986. p. 36).

Vygotsky's research concerning the ways in which social communicative speech becomes "inner speech" -- a mental function of the individual, was the basis of the above theoretical claim, as well as additional theoretical claims of his colleagues and successors. The influence of these theories on socio-cognitive research in the last decade is expressed in more symmetrical perspectives.

For example, in a chapter entitled "The zone of proximal development: Where culture and cognition create each other", Cole (1985) expresses what he calls "culturally grounded theory of cognition", and explains the incorporation of the "activity" as a unit in which the study of "both systems of social relations and of internal (cognitive) activity" can be done (p. 159). Cobb, (1998) in his plenary lecture, claimed that the relationships, between the two perspectives, are reflexive, in the sense that one does not exist without the other. This means that the psychological perspective implies that "one analyzes individual students' reasoning as they participate in the practices of the classroom community" and the social perspective implies that "communal practices are continually generated by, and do not exist apart from the activities of the participating individuals" (p. 44).

Pontecorvo (1993) in her opening paper to the special issue of Cognition and Instruction, which aimed "to identify and describe the socio-cognitive mechanisms through which thinking and learning are developed in different types of socially interactive settings" (p. 192-193), summarizes some "general presuppositions" common to research in such settings:

1. The attempt to look at the interactive situation from the *Participant's perspective* which is expressed in questioning "the meaning that participants attribute to the interactional setting".

2. The assumption that "there is a continuous interchange between the *interactional event* and the *context*, where the context is considered as the "cultural frame that surrounds the specific interactional event and provides resources for its enactment and interpretation".

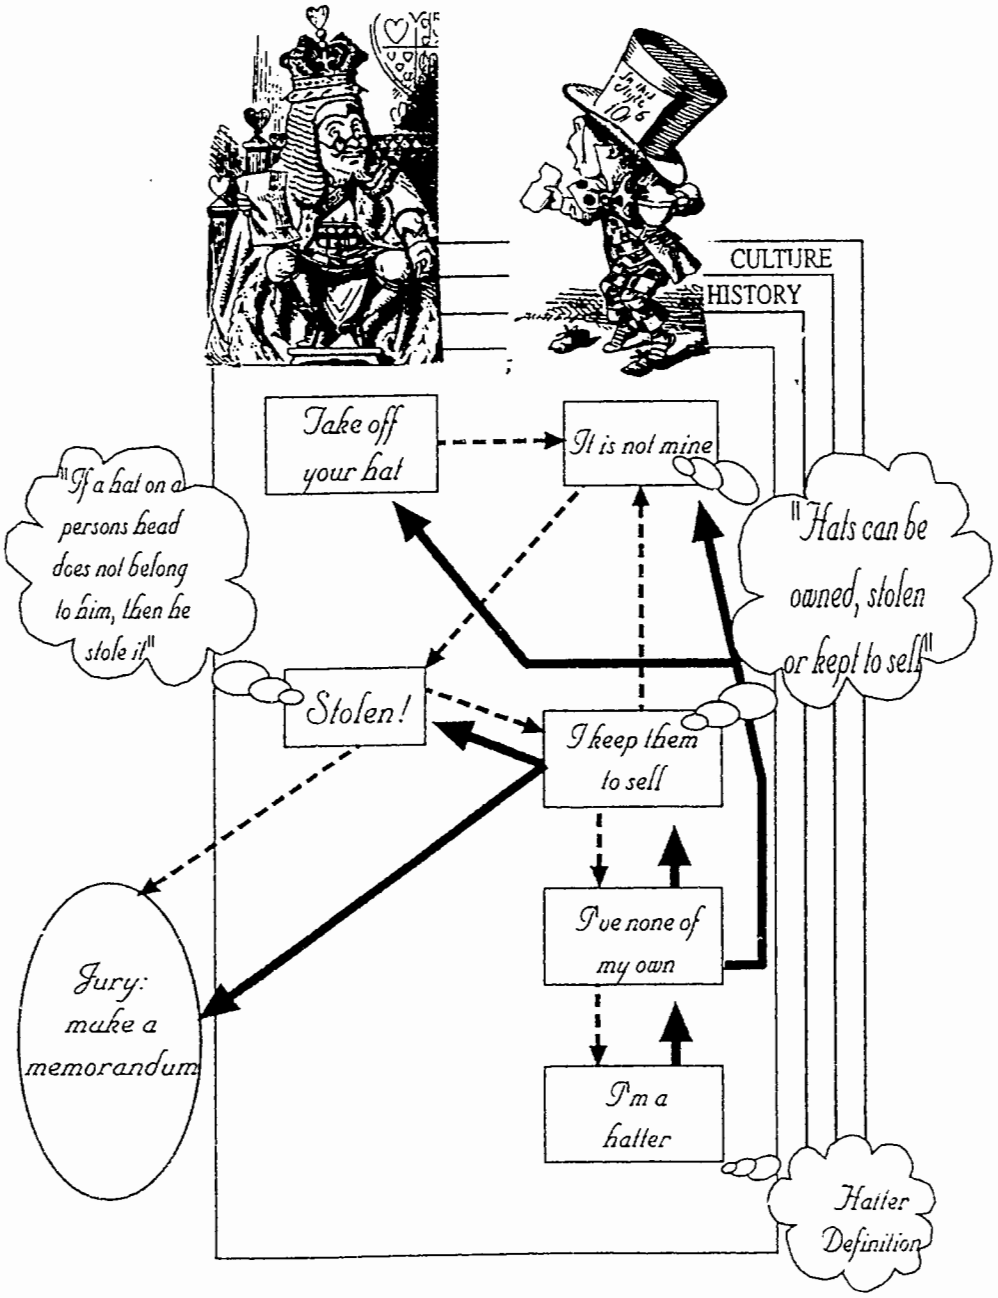
3. The relevant role-played by the *Other* - who is assumed to be "an active co-participant in speech and in action, who gives support for acting, understanding, and reasoning through both agreement and opposition".

The above three points represent a modern perspective of socio-cognitive studies (see, for example, some studies in the above special issue of Cognition and Instruction, 1993, as well as some of our papers mentioned above). These studies focus mostly on the *interaction* or the *interactional event* itself. The individual student is mostly an anonymous participant (even when he/she is named) in classroom episodes, which are selected and analyzed with the intention of highlighting the social context in which some cognitive processes take place. But, as "short stories" of quite complex situations, these episodes do not have the potential to focus on one student's cognitive changes while participating in such episodes. Cobb, in a joint paper on "learning mathematics through conversation" (Sfard, Nesher, Streefland, Cobb & Mason, 1988), criticizes the kind of instruction done in order "to shape classroom discourse", where "the issue of whether students might be learning any mathematics that is worth knowing is not a focus of investigation" (p. 46).

I would like to stress that, on the one hand, I consider the interactional processes and the "shared construction of knowledge" within the classroom community, that may be grasped at least partially in such episodes, as very important, and justifies the heavy research that has been done lately. On the other hand, I cannot ignore the fact that, in the end, the individual is the smallest autonomist "unit" that can carry his/her constructed knowledge to different communities even simultaneously (the pair, the small group, the whole classroom community), and share it with other individuals in various communities during a lifetime. One way is to investigate the individual actual knowledge at the end of an interactive learning process (Perret-Clermount, 1993; Schwartz & Hershkowitz, in press). But, this will tell us mainly about "end-products", and very little about the interactive processes of constructing this knowledge. The individual's work takes place in the work of teams, so I believe that we need, in addition, to investigate the developmental processes of his/her knowledge while participating in team work. These teams tend to have a short life, meaning that the individual belongs to numerous teams in different communities in her/his productive years. In a study on collaborative problem solving, Granot (1998) showed that ensembles formed, separated, and reformed naturally among participants within the

same class activity. In this sense learning can be seen as "a changing membership of communities of practice" (Lave & Wenger, 1991, p. 54). And therefore, as noted by Pontecorvo (1993), the question of the "types of knowledge or of socio-cognitive tools that can be accessed, built, and changed through collective discourse can be subsequently used in other settings, including individual problem solving, writing tasks, and answers to an interview", becomes very important.

The Dilemma through Empirical and Methodological Eyes



As can be concluded from the above, a central goal in empirical studies of socio-cognitive development is an empirical investigation of the individual development (learning) within the socio-cultural context of which he or she is part. I would like to use Lerman's metaphor (1998) about the zoom of a lens, and to raise the following question: If we put our lens on a socio-cognitive activity, can we, at the same time, zoom on the individual, and if yes, what we might see? I would like to discuss this issue through a presentation and analysis of some examples. The first example is borrowed from "Alice's Adventures in Wonderland" (Carroll, 1865/1965). The second stems from the investigative work done by Michal Tabach, a member of our team. The other two, which will be discussed briefly, derive from two studies that have already been completed and reported (Hershkowitz & Schwarz, 1999, and Hershkowitz, Schwarz, & Dreyfus, submitted).

The King and the Hatter Example

I have chosen a short dialogue between the king and the hatter from Lewis Carroll's book, as a parable to demonstrate the complexity of describing and interpreting individual cognitive behavior (in this case, without any evidence of learning or cognitive change) in an interactive situation. This episode is taken from the beginning of the trial in chapter 11 (see the following figure). The sharpness of Carroll's logic, the brevity of the episode, and the fact that there are only two "players", make it easy to follow and analyze the argumentation between the two figures.

I use different sets of arrows to show different kinds of links between the utterances of the king and the hatter. If we read along the arrows of the first set (dotted lines), we have the parts of the episode in their chronological order. In the second set (bold lines), I have tried to demonstrate the logical structure which underlies these utterances. For example "I keep them to sell", said the hatter *to contradict* the king's claim: "Stolen!", as well as *to explain* his utterance "It is not mine" to the public at the trial, including the jury, etc. We focus here on arguments of *contradiction, explanation,* etc., which are relations between an utterance and previous utterances or gestures. Therefore, the

arrows, in the second chain, are mostly in the opposite direction to the arrows in the first.

(From Lewis Carroll, Illustration John Tenniel)

1 - 14 BEST COPY AVAILABLE

The main frame is embedded in a sequence of other frames: First, our immediate interpretation (as notes within "clouds") of this episode and the roles of the two players in it. For example, for the king, a hat on a person's head can be interpreted as either belonging to this person, or stolen. The "hatter definition", given by the hatter himself, includes a third possibility: a hat can be kept by a person "to sell". This way of presentation and analysis of interactive episodes, which we will call "the hatter method", is quite close to other analysis methods used in various studies on interaction (e. g., Resnick, Salmon, Zeitz, Wathen, & Holowchak, 1993).

If we wanted to come closer to these two figures, and be able to grasp their different character and their different ways of behavior and thinking, we would need to know more about the contextual frames of the king and the hatter - their history, culture, etc. This could be discovered, at least partially, from other episodes in which the king and the hatter interact with other figures. Fortunately, Lewis Carroll was kind to us and left us the whole *book* on Alice's adventures.

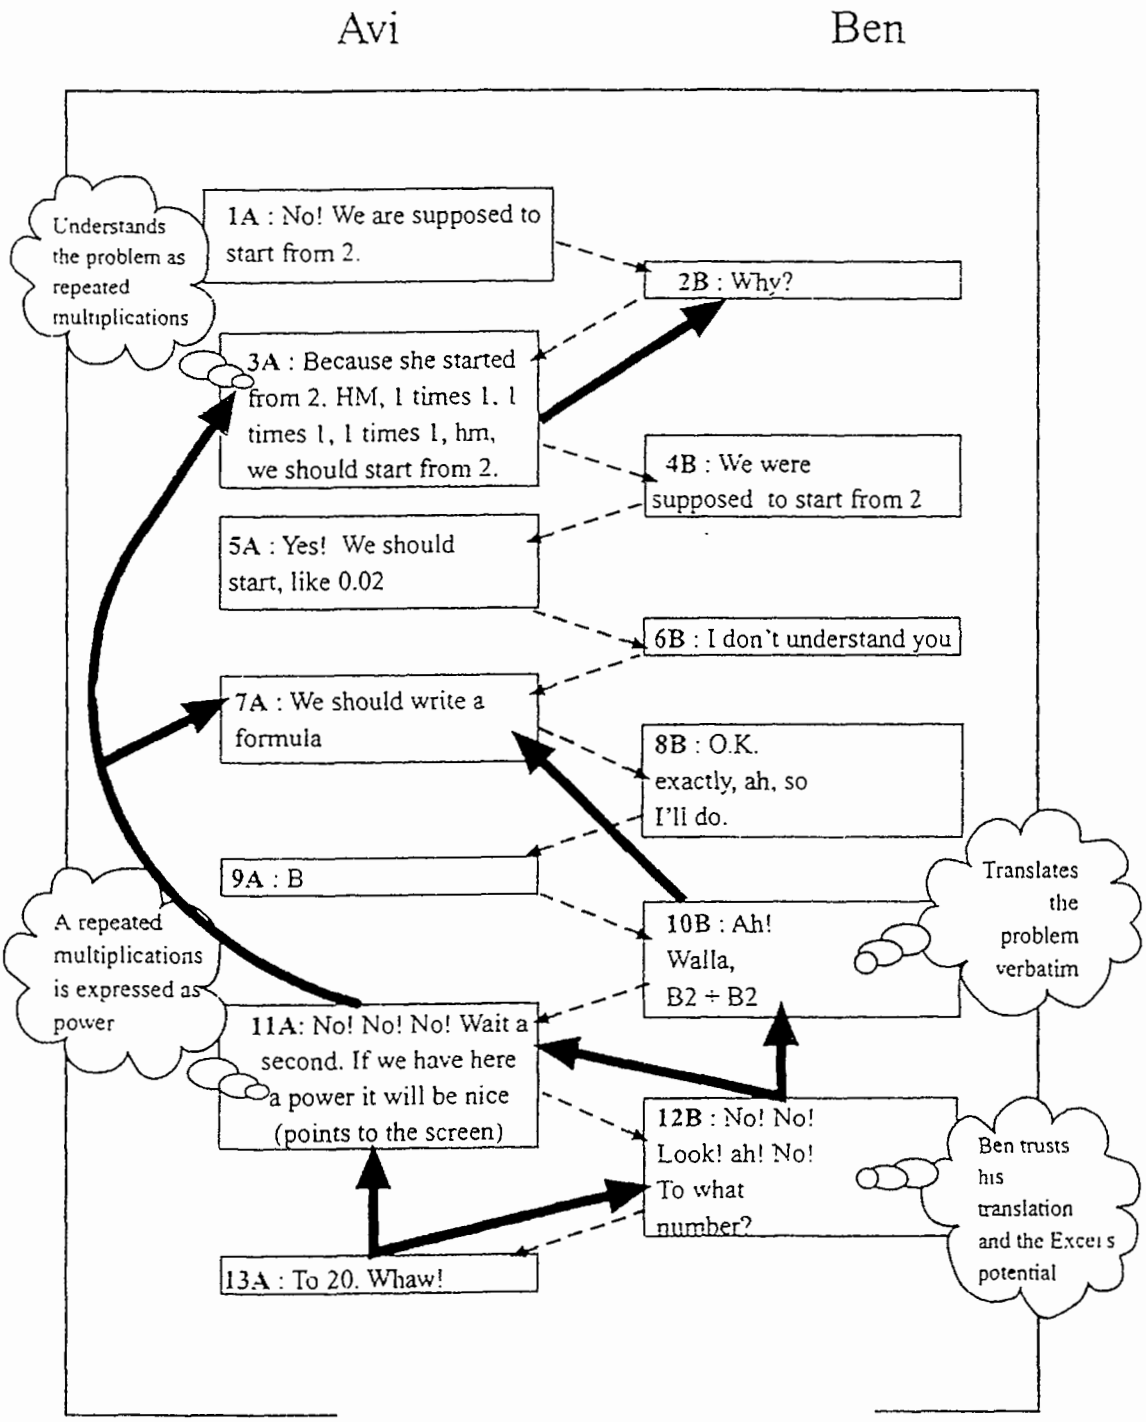
If we leave our fable, and come back to learning situations in an interactive environment, we have to face questions such as: What kind of *book* do we need in order to be able to trace the development of an individual in interactive situations? Do we have proper methodologies with the help of which this *book* can be written and interpreted? Do we have proper psychological tools to follow and analyze the individual cognitive behavior, while observing it? It is more realistic to relate to the above questions in the context of a real classroom situation.

The example of the pocket-money activity

The pocket-money activity is part of the year-long algebra course for seventh graders, which we have developed in the CompuMath project. The course consists of a sequence of multiphase problem situations and the use of a multi-representational tool (a spreadsheet). In the "pocket-money" activity, which was given about two months after the beginning of the year, students first investigated the weekly pocket-money savings of three children governed by different linear rules. After a few days, a new rule was proposed:

==========

Sharon receives pocket-money each week as follows: At the end of the first week she received 2ag (0.02 shekel). Each week she receives a sum equal to what she already has in her pocket. Sharon does not spend any money.



==========

Students were asked to hypothesize the rate of growth of Sharon's savings as compared to other children's savings, before obtaining the exact data from the generalized rule found through the mediation of the spreadsheet (Excel). The

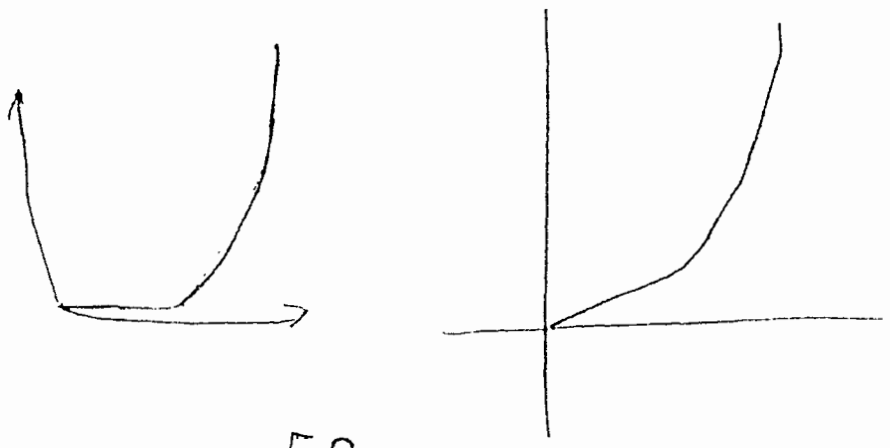
investigation was done in peer collaboration. It had two steps. First students were asked to hypothesize numerically the growth of Sharon's savings. After a "symbolic negotiation" with the Excel program (in order to write the savings rule in Excel symbols) and dragging down to get the weekly totals of Sharon's savings, they could compare the totals with their hypothesis. In a second step, they were asked to hypothesize the shape of the graph of Sharon's saving from the numerical data they had. Finally, after a "graphic negotiation" with the tool, they were asked to compare the graph they sketched with the graph they drew by the tool. Michal Tabach, investigated the construction of knowledge of few pairs of students working on such activities through the year. As a silent observer, she documented the work of two boys, Avi and Ben, on the above activity.

The figure on the next page is a presentation and analysis of one episode, in which the two students are involved in the "symbolic negotiation" with the Excel program to obtain the numerical data of the weekly sums of money.

In the analysis of this episode I have used "the hatter method" — two sets of arrows in the main frame, and interpretations "around" it. The chronological set of arrows seems to indicate a symmetric interaction between the two; each utterance is immediately followed by an utterance by the interlocutor. A deeper analysis, expressed by the second set of arrows (in bold), and the interpretations inserted outside the main frame, presents a more complicated situation. The episode starts from Avi's claim: 1A: "We are supposed to start from 2". It is impossible to know whether he meant that the amount of money in the first week is 2 ag., or that the savings column has to start from B2, or something else. He then explains to Ben (who asks "why?" (2B)) his idea (3A): "1 times 1, 1 times 1, we should start from 2". We interpreted this (see the "balloon" interpretations) as first evidence that Avi sees the growth, at least implicitly, as "repeated doubling", and if expressed as a power with "base" 1, there is no growth. From here until the end of this episode, the discourse between the boys does not seem to evidence a significant cognitive interaction. Avi ignores Ben's need for understanding (expressed in 6B), and continues telling him what should be done (7A). The two, work on the formula to be inserted in the weekly savings column, along separate lines – as expressed by the fact that most of the bold arrows connect utterances said by the same boy. Avi (11A) looks for a formula based on a power operation, while Ben immediately translates the saving rule "verbatim" into Excel symbols — B2 + B2 (10B), drags to obtain the whole picture numerically, and shows it to Avi (12B). The two boys share the surprise caused by the numerical representation of the exponential growth.

Avi
Ben
Understands the problem as repeated multiplications
1A : No! We are supposed to start from 2.
2B : Why?
3A : Because she started from 2. HM, 1 times 1. 1 times 1, 1 times 1, hm, we should start from 2.
4B : We were supposed to start from 2
5A : Yes! We should start, like 0.02
6B : I don't understand you
7A : We should write a formula
8B : O.K. exactly, ah, so I'll do.
9A : B
10B : Ah! Walla, B2 ÷ B2
Translates the problem verbatim
A repeated multiplications is expressed as power
11A: No! No! No! Wait a second. If we have here a power it will be nice (points to the screen)
12B : No! No! Look! ah! No! To what number?
Ben trusts his translation and the Excel's potential
13A : To 20. Whaw!

Many things can be learned and many questions can be asked on this episode:



- We have some information on the kind of interaction between the two boys, and what each of them contributed (did not contribute) to the "interactive/non-interactive" character of their work in this episode. Kieran & Dreyfus (1998), who analyzed types of interaction between two boys solving problems together, observed that moments when one boy participates in the "universe of thought" (Trognon, 1993, p. 341) of the other, were quite rare. The episode above is similar, in the sense that the universes of thought of Avi and Ben intersect only towards the end, where they realize together the rate of growth.

- It seems that both of them constructed some knowledge. Is this knowledge "shared"? NO! Because each of them has his own pace, and YES! Because both of them got some feeling of exponential growth, through the same activity in the same time.

- We can also explain the mediation role of the spreadsheet, where a combination of a "local symbolization" -- B2 + B2 -- and the dragging operation, provide Ben with a sort of a global rule of the growth, and because it is so simple and so fast, it has a convincing potential that attracts both students.

But, there is not much information on the individual construction of knowledge. Does Avi grasp a more mathematical construct of an exponential growth? If yes, how come that Ben was the first one to put his hands on the numerical data which express this growth? And does this numerical representation of the exponential growth prevent Avi from further development of an exponential construct? We can make some hypotheses and interpretations inspired by what was observed, but cannot be considered as resulting from the observations. Fortunately, in this activity, we have more data on the actions of the boys, which give us one more clue: --Students were asked to hypothesize the growth graph, and each boy proposed his own graph (see the following figure).

Avi **Ben**

Ben's graph looks like a half of parabola, whereas Avi's graph is close to the exponential. While sketching his graph, Avi added verbally: "at the beginning it grows slowly and slowly and then it grows faster and faster".

But we still do not know much about whether each one of them constructed knowledge about the exponential change, and if this knowledge was consolidated, in the sense that each boy could use it as an artifact in further construction of knowledge. To be able to answer this experimentally means *to write a book* for each boy working on further activities, in different ensembles or individually. Suppose we do just that, and that we had more data, do we have a proper methodology to analyze it? Is a methodology like that used in the hatter model useful when we pass from one episode in one activity, into a sequence of episodes in sequence of activities? How can we follow the individual when we have more than two participants in small group teamwork, or in a whole class interactive discourse? I shall try to come closer to the last question in the third example.

Where in the "Overseas Activity" is the individual knowledge hidden?

In a study on reflective processes in an interactive mathematics classroom (Hershkowitz & Schwarz, 1999), we followed a group of four girls through the phases of the Overseas Activity. A class of 40 students worked first individually during a preparatory phase (phase 0). Then they collaborated to investigate and solve a problem in small groups (phase 1), and subsequently wrote group reports (phase 2). Finally they engaged in a teacher led discussion, in which different groups verbally reflected on the processes they underwent, as well as on their learning styles (phase 3). I went back to the protocols of our target group, while investigating and solving the problem (phase 1), and while reporting to the class community their investigating processes (phase 3), and to the analysis and interpretations we did of these protocols. We claimed there that "we juxtapose the cognitive-individual and the discursive-interactional perspectives, without suggesting priority for either" (p. 78). Looking back, through the dilemma eyes, it might be concluded that the cognitive-individual perspective meant for us the presentation and explanation of the girls' cognitive contribution as individuals to the "shared cognitive process" of the group. This process was expressed in actions aimed to obtain the most appropriate hypothesis about the right solution, and at the end to elaborate the solution itself. This time I tried to go in the opposite direction, from the social to the individual. I tried to re-analyze the data by zooming on one individual girl, and to see what can be said about the contribution of the group interactive discourse to her learning. I found only a few clues and identified the following difficulties:

- As in the previous example, I felt that one episode (which in this case was quite long) is too narrow. We need a kind of *book* with more chapters on this girl, before and after this episode. Can we *write* such a book for one girl? For all four?

- The documentation of this episode was meant to show the whole group investigation process, so the camera changed its focus from one dominant participant to the other, and the documentation of each individual was incomplete. In spite of our desire to see both directions within the same activity, it seems that we have to document and analyze data in two different ways within the same situation.

- I have not (yet!) found a proper methodology to analyze and interpret *one girl's cognition* within the interactive discourse of the four girls. The "hatter method", or other similar methods, become very heavy when applied to four participants, even in only one episode.

- We can learn about the cognitive development of the group through verbal utterances and gestures. The individual development is dependent or expressed in cognitive mental functions which, by their nature, are more hidden. It seems that research should be done on "translating" these mental functions to actions that can be observed, analyzed and interpreted. At this point we can rely and come back, in a way, to the research and theoretical work done in classic cognitive research. The question whether this kind of research can be incorporated in investigations done within the "interactionist perspective", and in what ways, becomes quite crucial. I discuss this briefly in the next example.

Investigating Abstraction in Context

We undertook a sequence of studies (of which only the first one has recently been completed) to investigate the mental activity of abstraction as embedded in its socio-cultural mathematical context. In this first study (Hershkowitz, Schwarz & Dreyfus, submitted), which is based on an interview of a Grade 9 student, we elaborated a special approach to abstraction, as an activity of reorganizing previously constructed structures into a new structure (see the introduction to the paper). Thus, the interview was designed to enable and to observe the emergence of new knowledge constructed out of already acquired knowledge. In the analysis of the interview we accounted for the available tools (a grapher and a calculator), the social dimension of the interaction between interviewer and student and the history of the student. This analysis led us to propose a model for the genesis of abstraction on experimental grounds. At the center of the model, we identified three epistemic actions, which are dynamically nested in each other within the flow of the student's actions. The action of *Constructing* a new mathematical construct, in which actions of *Recognizing* and *Building with* already constructed knowledge, are nested. *Constructing* is an action of reorganization of knowledge to a new construct. By *Recognizing* we meant the action in which the student makes use of a construct or structure which has been constructed earlier.

Building with is an action performed by the student to combine structural elements in order to achieve a given goal.

We also suggested a longitudinal dimension to the above model, which takes into consideration the history, as well as future activity, as part of the proposed model. This means that artifacts that result from earlier constructions mediate the three epistemic actions, and the *Constructing* action leads to artifacts available for later epistemic actions. This longitudinal part of the proposed model, especially the use of outcomes of the epistemic actions in further activities, has been hypothesized only and needs experimental confirmation. At this point, we feel that a further experimental study of abstraction depends on the existence of a *book* containing the (hi)stories of students along their engagement in activities in different groups during the year.

Concluding Remarks

Through the examples considered, I have tried to discuss our ability and maturity to trace the development of individuals while participating in interactive processes in classroom activities. I described the topic as a dilemma, because it either raises questions for which we have mostly "wishful thinking" answers, rather than experimental answers, or questions for which answers go in contradicting directions.

Research from an interactionist perspective seems to be developing dynamically, from investigations of the interactive processes of learning per-se and the contributions of the individuals participating to these processes, towards the investigation of the contribution of the interactions within the ensemble to each individual. I have tried to indicate some limitations and difficulties of the latter direction of research as illustrated by the examples, which were taken from studies I share with my colleagues in the CompuMath project.

I have tried to show that, as the number of the participants in the ensemble grows, it becomes more complicated to focus on the individual. There is a need for different kinds of documentation within the same episode, and more longitudinal methods of documentation, where the individual is observed in different contexts. The analysis of these kinds of longitudinal data raises the need for new methodology. The question whether longitudinal description and analysis may distort the analysis of the single episode has also to be taken into consideration.

In addition, the analysis of the intra-cognitive processes within the inter-cognitive processes raises the need to investigate the individual's mental cognitive functions. In such investigations the accumulated research findings, which we inherited from classic cognitive research, should be incorporated into the global frame of research and theory, enlarged, and continued.

Acknowledgement

I would like to thank Joel Hillel for first challenging me with the above dilemma. Many thanks to Abraham Arcavi, Baruch Schwarz, Tommy Dreyfus, Joop vanDormolen and Maxim Bruckheimer for their comments on an earlier drafts.

PROFESSIONAL DEVELOPMENT, CLASSROOM PRACTICES, AND STUDENTS' MATHEMATICS LEARNING: A CULTURAL PERSPECTIVE

Geoffrey B. Saxe

University of California, Berkeley

Abstract

I present two studies designed to illuminate ways that ongoing reform efforts in mathematics education are becoming interwoven with teachers' classroom practices and children's developing mathematics. The first study examines patterns of K-12 mathematics teachers' changing assessment practices. The second examines the classroom practices of upper elementary teachers participating in two professional development programs, each designed to support implementation of a reform-oriented curriculum. Both studies show the utility of a focus on practice for understanding teachers' professional development and students' developing mathematical understandings in the context of ongoing reforms.

My purpose in this paper is to sketch a cultural-developmental framework for the analysis of conceptual change (broadly defined), using two recent studies to illustrate the framework. In the first study, I present an analysis of the shifting assessment practices of K-12 teachers in the context of ongoing reforms in mathematics education. In the second, I present an analysis of upper elementary classroom practices in our era of reform, with a particular focus on students' developing understanding of fractions linked to classroom practices.

A CULTURAL-DEVELOPMENTAL APPROACH TO THE ANALYSIS OF LEARNING IN PRACTICES

The research approach provides a cultural-developmental frame for the analysis of learning in practices. The orientation is cultural insofar as practices are analyzed as recurrent socially organized activities that permeate daily life. A key assumption is that there is a reflexive relation between individual activities and practices – individuals' activities are constitutive of

practices and at the same time practices give form and social meaning to individuals' activities. The orientation is developmental insofar as the focus is on cognitive developments that emerge in individuals' efforts to structure and accomplish goals in practices. At core of the developmental perspective is a concern with the interplay in development between *cultural forms* –artifacts that have emerged over social history (such as forms of assessment) – and *cognitive functions*, the purposes for which forms are used (such as to gain insight into student understanding).

Study 1: Teachers' Shifting Assessment Practices[1]

The field of mathematics education has experienced waves of reform throughout its history, and each wave has been marked by challenges to teachers (Tyack & Cuban, 1995). In the recent climate of reform, particular value is placed on problem solving and conceptual understanding, a marked departure from the more traditional focus on accuracy and procedural skills (California State Department of Education, 1992; NCTM, 1989, 1993). New mathematics curriculum has been developed to engage students in problem solving, and new methods of assessment have been developed to evaluate the ways that students interpret problems and construct strategies for their solution. Mathematics teachers are pressed to implement these new approaches or to adapt their existing practices to fit the reform recommendations. We know that they are challenged, but to date we understand little of the pathways by which they develop competence with the new forms and functions of practice.

The purpose of the first study was to explore how mathematics teachers' assessment practices shift over time in relation to the presses to change. The practice of assessment is conceptualized broadly (see Figure 1). Assessment practices involve multiple stakeholder groups, including students, teachers, parents, principals who vary in their relation to students' performances. Stakeholders have different relations to the performances that are the targets of assessment – as represented by the double arrows between

[1] Maryl Gearhart, Megan Franke, Sharon Howard, and Michele Crockett were collaborators in this study

each stakeholder group and student performance. Stakeholders may communicate with one another about assessments as represented by the double arrows between groups. Further, assessment also involves the production of multiple artifacts, including primary artifacts (students' class work that may involve solutions to exercises and open ended problems), evaluations of those artifacts (number correct, scores, rubric levels), secondary artifacts, including composite scores (e.g., report cards, portfolio evaluations), and "high stakes" scores (e.g., SAT, CTBS scores). Such artifacts are often the foci of stakeholder reflection, evaluation, and communication.

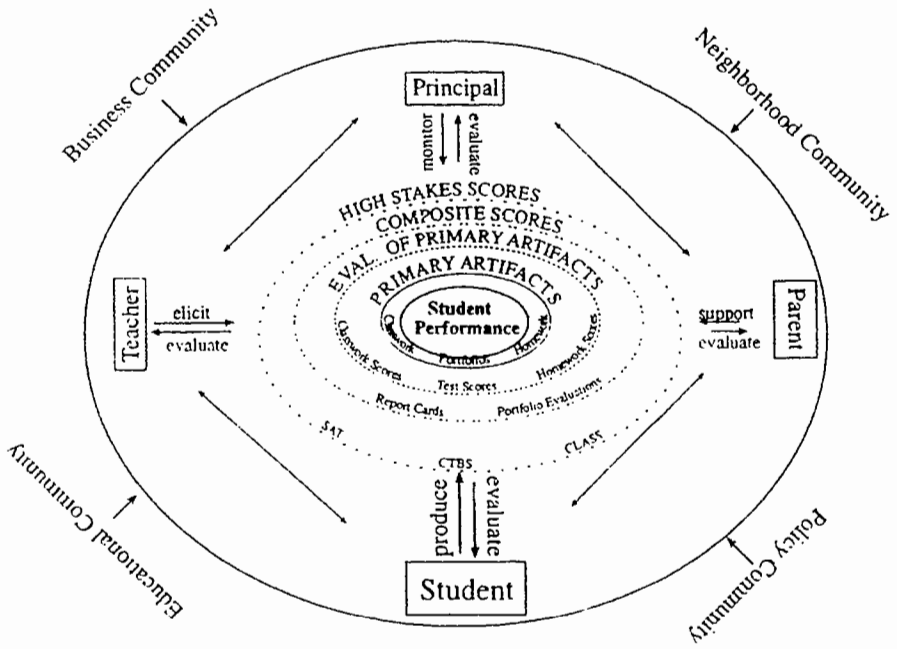

Figure 1: A sketch of stakeholder groups and principal artifacts in typical assessment practices.

I limit my focus in this talk to teachers' engagement with three forms of assessment and the functions that these forms serve in their practices. These included forms for eliciting student performances in class work such as exercises or open-ended problems as well as forms for evaluating student performances such as rubrics. While exercises are associated with traditional practices, open-ended problems and rubrics are associated with reform

BEST COPY AVAILABLE

practices. A focus on shifts over time in both teachers' differential frequency of use of these assessment forms and the different functions that these forms serve in assessment activities provides a window into the changing practices of teachers in this era of reform.[2]

Methods

In the first phase of the study, colleagues and I fielded surveys to two cohorts of K-12 teachers participating in a voluntary long-term professional development program (N=59). To capture the patterns of change, we asked the teachers to report on the frequency with which they were currently using the three assessment forms. In addition, to gain insight into trajectories of change. Therefore, we asked teachers to compare their current uses with their uses in the past and their anticipated uses in the future of the targeted forms.

We conducted a second phase of the study to shed light on the functions that these forms of assessment were serving in teachers' practices. We interviewed teachers, eliciting narrative descriptions of how they used targeted forms, the purposes that they served in their assessment practices, and whether and /or in what way these purposes might be changing.

Frequency of Use of Assessment Forms and Shifts in Use over Time

We analyzed the frequency with which teachers used particular assessment forms and the shifts in frequency (and projected frequency) over time. Our findings point to changing patterns of use linked to the current climate of reform and presses for change.

Though all teachers reported that they were implementing reforms, most reported using exercises frequently for purposes of assessment. Indeed, 75% of the teachers reported using exercises at least 2-3 times a week for assessment. The same was not true for open-ended problems and rubrics: Teachers reported using open-ended problems at more moderate

[2] The way stakeholders pressures are manifest in teachers practices is also critical to understanding shifting forms and functions of assessment, but will not be discussed in this paper due to time and space constraints.

levels, the majority reporting at least weekly use. The variability in use of rubrics was quite pronounced. Indeed, 50% of the sample reported uses of rubrics in the range between rare (once or twice a year) and relatively frequently (weekly).

By comparing teachers' reported uses of assessment forms last year, this year, and next year, we were able to identify patterns of change. For exercises, most teachers reported little change in frequency of use. Indeed, more than 75% of the teachers reported stable (and high) use over past through prospective practice. In contrast to the results for exercises, most teachers showed shifts towards greater frequency of use for open-ended problems and rubrics. Between 60% and 70% of the teachers' profiles indicated increases in frequency of use either from past to current and current to projected practice.

Shifts in Functions of Assessment

Our interviews were designed to explore continuities and discontinuities in functions of assessment forms in practices. In assessment practices, continuity is manifested in a teacher's decision to continue using either an 'old' assessment form over time, or, a new form to serve an 'old' function. Discontinuity is manifested in a teacher's decision to use a new assessment form, or, to use an 'old' form for a new function. Core to our approach is the assumption that continuity and discontinuity are inherently related to one another in the process of development -- continuity preserves the coherence or integrity of practice while discontinuity allows for adjustment to presses and organizational change.

We explored shifts in the purposes for which teachers used exercises, open-ended problems, and rubrics with 12 teachers. We documented several patterns of development. None of the patterns represents a radical re-organization of practice. Rather, for each pattern, shifts over time were marked by both continuity and discontinuity.

One pattern captures the ways that teachers may implement a new form of assessment in a way that served 'old' functions. For example, some

teachers used a 'new' form of assessment, open-ended problems, in ways that served instructional function. They engaged children with the open-ended problems to provide them the opportunity to invent strategies; for this pattern, they did not examine students' responses to open-ended problems to gain insight into the character of their mathematical thinking, a function linked to student inquiry promoted by reform documents.

A second pattern captures the ways that new forms of assessment may be implemented in pro forma ways. Some teachers used rubrics developed by others that focused on the completeness of students' written explanations. Teachers exemplifying this pattern did not revise such rubrics to capture students' mathematics.

A third pattern illustrates the ways that teachers may fashion or re-fashion forms of assessment in order to assess students' mathematical thinking, the function of assessment recommended by reform. Some teachers re-purposed an 'old' form of assessment, such as an exercise, to serve a new function, supplementing the old form as necessary with new forms (written explanations) that support the new function. In addition, some appropriated a colleague's rubric for evaluating students' responses to the open-ended problems, re-designing it to suit their curriculum and their goals for her students' mathematical learning.

A fourth pattern illustrates how teachers' concerns for efficiency may work against the quality of their assessments. Some teachers were considering strategies for more frequent and more rapid rubric scoring. Some as yet had no specific strategy for increasing the speed of scoring; at least one was considering replacing her analytic rubric with a holistic approach, expressing worries about tradeoffs between frequency of scoring and quality of the evaluation.

This study provides a preliminary frame for analyzing the dynamics of change in the professional development of teachers. A key notion here is that in order to understand why 'change takes time,' we need to identify developmental patterns in the ways that teachers construct goals in their

practices, goals that interweave the presses upon them, the resources available to them, and their current knowledge and patterns of practice.

Study 2: Relations between Teachers' Shifting Classroom Practices and Student Learning in the Domain of Fractions[3]

In the second study, colleagues and I produced an analysis of teachers' changing classroom practices linked to ongoing reforms and the relation of such change to student learning. To this end, we observed 23 upper elementary teachers implementing units on fractions, and assessed the learning of their students. We sampled teachers who were committed to traditional instructional approaches as well as teachers who were committed to reform. The latter group was implementing a new unit on fractions [Seeing Fractions (Corwin, Russell, & Tierney, 1990)].[4] In analyzing the relation between classroom practices and student learning, we compared the progress of two groups of students – those who began instruction with a rudimentary understanding of fractions vs. those without a rudimentary understanding of fractions. We assumed that these two groups of children might be forming different goals related to fractions in classroom practices. Further, we assumed that children's progress would be related to the extent to which classroom practices were aligned with reform frameworks. Thus, our focus was the relation between (a) the alignment of classroom practices with reform principles (b) students' prior knowledge and (c) the developing mathematics of each of these two groups of students.

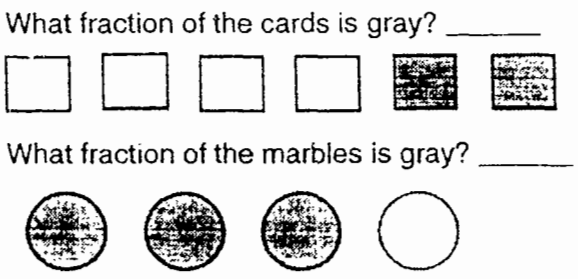
Analyzing and Rating Classroom Practices

To evaluate the extent to which classroom practices were aligned with reform principles, we developed rating scales and applied them both to videotape and fieldnote records of whole class lessons (cf. Gearhart, Saxe, Ching, Fall, Nasir, Schlackman, Bennett, Rhine, & Sloan. (in press)). The scales were used to evaluate core instructional principles espoused in reform

---

[3] Maryl Gearhart and Michael Seltzer were collaborators in this study

[4] Teachers implementing the reform curriculum were participating in one of two professional development programs colleagues and I organized.



documents – (a) the degree to which classroom practices elicit and build upon students' thinking (Integrated Assessment) and (b) the extent to which conceptual issues are addressed in treatments of problem solving (Conceptual Issues). To apply the Integrated Assessment scale, raters were instructed to attend to teacher questioning and public problem solving and the ways that these did or did not elicit and address students' mathematical understandings. To apply the Conceptual Issues scale, raters focused on the ways that methods for solving fractions problems were linked to core fractions concepts — part-whole relations, part-part relations, and equivalence relations. Parallel scales were developed for videotape and for fieldnotes, resulting in four scales in all. We then aggregated these measures in order to produce a single index of alignment.

Assessing Students' Rudimentary Understanding of Fractions

To partition students into those who demonstrated a rudimentary understanding of fractions and those who did not, we coded students' performance on an additional set of elementary items that were included as part of the pretest. These additional items were elementary fractions problems depicted in Figure 2, one subset involving discontinuous quantity (items in Figure 2A) and the other subset involved a continuous quantity (items in Figure 2B). Consistency of adequate performance on at least one subset was required for children to be regarded as displaying a rudimentary understanding of fractions (see Methods section).

For each picture below, write a fraction to show what part is gray:

Analyzing Shifts in Students' Problem Solving and Computation with Fractions as a Function of Instruction

Our assessments of student achievement in the domain of fractions were designed to measure both students' computational skills and their competence with problem solving. The distinction between computation and problem solving is captured in similar ways by other researchers using such constructs as procedural versus conceptual knowledge (Greeno, Riley, & Gelman, 1984; Hiebert & Lefevre, 1986), the syntax versus semantics of mathematics (Resnick, 1982), and skills versus principles (Gelman & Gallistel, 1978). We recognized that the distinction between computation and problem solving would become problematic when we operationalized it as distinctive sets of items. Indeed, a child might solve what we regarded as a computation task using an invented problem solving strategy, or might solve what we classify as a problem using a memorized procedure. Nonetheless, the items that we constructed provided a heuristically useful way to measure students' skills with fractions and problem solving with fractions. The computation items could be solved using routine algorithmic procedures or commonly memorized facts. The problem solving items could not easily be solved by standard computational approaches, and were more likely to require insight into the concepts underlying representations of fractions. In addition to the face validity of the distinction, we validated the distinction between computations and problem solving through confirmatory factor analytic techniques (Saxe & Gearhart, 1998).

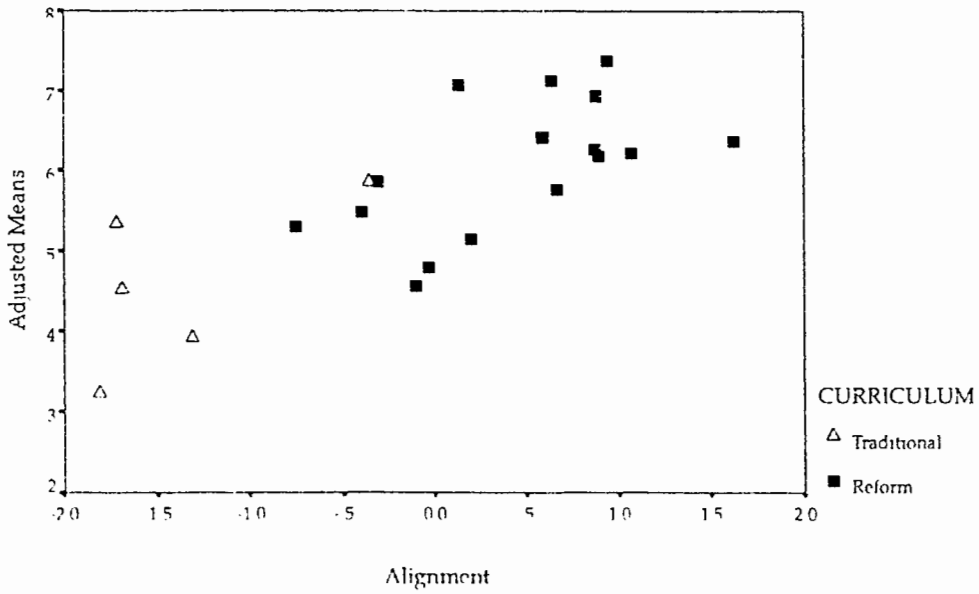
Expected Relations between Practice and Achievement

We expected students' performances on the problem solving and computation scales to vary as a function of students' prior understandings and alignment of classroom practices with reform principles. For the problem solving scale, we expected that students without rudimentary understandings of fractions would be at risk for not learning from instruction if there were little classroom support for children's conceptual engagement

with the subject matter (as indexed by a low level of support on our classroom alignment ratings). These students should be prone to interpret classroom activities involving fractions (e.g., representational forms presented in lessons, small group work) in whole number terms. Thus, classroom activities at lower levels of support should either be very confusing or systematically misunderstood in terms of whole numbers. However, if these students participated in classroom practices involving fractions that were geared for building on their understandings (as indexed by at least a moderate level of support on our classroom alignment ratings), we might expect to see growth in students fractions concepts, and even greater growth at high levels of support.

In contrast, we expected that students with rudimentary understandings at the start of instruction would show a different profile of learning as a function of alignment. These students should be more able to make sense of representational forms presented in lessons in terms of part-whole relations even if engagement with fractions concepts was not a focus of instruction (i.e., at low levels of alignment). Further, with greater support for conceptual engagement (increasing levels of alignment on our scale), we expected that these students would show greater gains in their understandings.

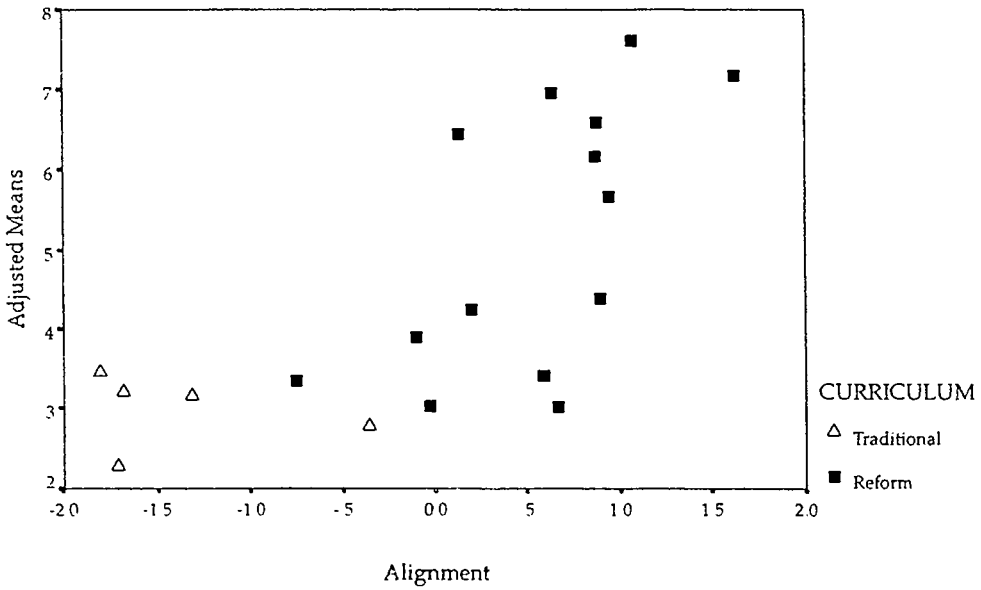
For the computation scale, we did not expect to find the same pattern of relations between alignment of practices with reform principles and student performance. Indeed, there is little reason to expect that reform practices would influence directly students' developing competence with computation tasks that are often readily solved through memorization of routine facts and algorithms. Thus, we expected at best a weak relation between alignment of whole class lessons with reform principles and students' computation achievement, regardless of students' prior understanding of fractions.



Relations between Alignment and Problem Solving Scale

Figures 3 and 4 contain plots of posttest performances on the problem solving scale as a function of our measure of the alignment of classroom

practices with reform principles (standard scores). The posttest means are statistically adjusted for language background and pretest performance. Visual inspection of the plots for students with and without a rudimentary understanding reveals that both slopes show a positive relation between posttest performance and classroom alignment. However, the character of the slopes differs.



For students with a rudimentary understanding, the relation between posttest performance and our measure of alignment appears linear (Figure 3). Our HLM analyses confirm this. For every unit increase in the classroom practice scale (a 1-4 point scale), there is a .87 increase in classroom posttest performance (a 13-point scale); the t statistic shows that the effect is significant (t(19)=4.91, p=.0000). We interpret this pattern as evidence that these students' rudimentary understandings of fractions allowed them to make sense of fraction problems in part-whole terms even when classroom practices were relatively inconsistent with the principles of reform.

Figure 3. Adjusted classroom posttest means on the problem solving scale for students with rudimentary understanding as a function of classroom alignment measure.

For students without a rudimentary understanding, the relation between posttest performance and our measure of alignment does not appear linear (Figure 4). Indeed, for classrooms in which alignment with reform principles was below the mean, the plot appears to show no relation between posttest performance and alignment. In contrast, for classrooms in which alignment with reform principles was above the mean, the plot appears to show a linear relation between alignment and posttest performance. To confirm the visual analysis of the plot in Figure 5, we fit a two-relation HLM to the data. Our model allows for the possibility that the relationship between class mean posttest scores and classroom practices may differ for those classes in which alignment is below average and those classes in which alignment is above average. The results of our HLM analyses supported the "two-relation" model. When alignment of classroom practices with reform principles is below average, we find no relation between posttest score and alignment ($t(16)=.81$, $p=.433$). In contrast, when alignment is above average, we find a significant effect. For every point increase in classroom alignment, there is an expected posttest score increase of 2.07 points ($t(16)=2.48$, $p=.025$). This is a significant relation that is almost five times the magnitude of the estimated effect for the relation for below average alignment classrooms. We interpret this finding as evidence that, in classrooms judged low on alignment (whether using traditional or reform curricula), students without a rudimentary understanding had little basis on which to structure mathematical goals in other than whole number or procedural terms. In contrast, at higher levels of alignment, posttest scores for students without rudimentary understandings were related to alignment, and, indeed, those scores increased sharply. We interpret this pattern as evidence of a threshold of support needed by such children. With such support, students may become engaged with mathematical goals involving fractions, leading to gains in their understanding of fractions.

Figure 4. Adjusted classroom posttest means on the problem solving scale for students without rudimentary understanding as a function of classroom alignment measure.

Together, the considerations above point to the importance of the coordinated analysis of students' rudimentary understandings, curriculum, and classroom practices in student achievement on the problem solving scale.

Relations between Alignment and Computation

In contrast to the problem solving items, the slopes for students with a rudimentary understanding and without a rudimentary understanding reveal no relation between posttest performance and alignment of classroom practice with reform principles. Our HLM analyses show that for students with a rudimentary understanding, the estimated effect was -.26 ($t(19)=-.70$, $p=.49$), and for students without a rudimentary understanding, the estimated effect was also -.26 ($t(19)=-.57$, $p=.58$).

The lack of relation between student performance on the computation scale and alignment of classroom practice with reform principles was expected. In the short term, neither support for students' conceptual engagement with mathematics nor efforts to build on student understanding are likely to enhance students' memorization of arithmetical procedures. Although some students may be able to extend their developing

understandings of fractions to computational items, it may well be that rehearsal of computational procedures under direct instructional methods is more successful in enhancing computational skills. This latter conjecture was beyond the purpose and scope of our analyses.

CONCLUDING REMARKS

Investigating relations between the shifting organization of classroom practices and student learning related to reform efforts is a complex analytic task. The cultural-developmental framework that I've sketched provides an initial foothold into this complex arena of study. Through a focus on practice and the way individuals' are structuring and accomplishing goals in classroom life, we gain insight into historical change in practice and shifts in patterns of learning and development. My hope is that greater understanding of the relations between development and practice will provide new insights about how to usefully support the professional development of teachers and mathematical understandings of students.

Reconstructing the Mathematical in Social Discourse – Aspects of an Epistemology-Based Interaction Research

Heinz Steinbring, Universität Dortmund, Germany

Abstract. *Mathematical knowledge depends on human thinking and social interaction. Neither symbols nor contexts alone provide the objective basic substance for mathematical existence. Mathematical knowledge is created by (mental and interactive) interpretation of signs with regard to possible reference contexts. With this theoretical perspective on knowledge in mind, mathematical interaction research is faced by a complementary difficulty: The object of research – mathematical communication – as well as its observation and scientific analysis are both "sign-interpreting-processes" that are constituted in social interaction. The analysing reconstruction of mathematical discourses requires the revelation of possible interactive interpretations of communicated signs and in this way the analysis reflects its "own" understanding of mathematical knowledge as a result of a social construction processes. This article presents crucial components of the epistemology-based research of mathematical interaction by using exemplary teaching episodes from an ongoing research project on "Social and epistemological constraints of constructing new knowledge in the mathematics classroom".*

1. Introduction

The social construction of new mathematical knowledge in teaching and learning processes depends on two important conditions: The special character of instructional communication and the specific epistemological nature of mathematical knowledge. In mathematics teaching at the primary level new knowledge cannot be constructed in a formal manner by a kind of preview technique, i.e. using algebra or formulas, but this construction is linked with the children's situated contexts of learning and of experience in a characteristic way. The young students have to learn – and they are able to do so by their personal means – to see the general in the particular. To better understand this problem is an important inquiry of the research project "Social and epistemological constraints of constructing new knowledge in the mathematics classroom" (funded by the German Research Society, DFG; see Steinbring et al. 1998). How are students of elementary grades able to grasp the new, general mathematical knowledge with their own conceptions and to describe it with their own words? And what factors support or hinder this generalising interactive knowledge construction?

2. What is the Specific Nature of Mathematical Concepts?

Mathematical concepts and mathematical knowledge are not given a priori in the "external" reality, neither as concrete, material objects, nor as independently existing (platonic) ideas. For the individual cognitive agent mathematical concepts are "mental objects" (Changeux & Connes 1995; Dehaene 1997); in the course of communication mathematical concepts are constituted as "social facts" (Searle 1997) or as "cultural

objects" (Hersh 1997). From an evolutionary point of view mathematical concepts develop as cognitive and as social theoretical knowledge objects in confrontation with the material and social environment.

In contrast to objects constructed by humans as for instance a chair, a table, a knife or a screw-driver one cannot deduce the meaning of social facts, as for instance money, time or the number concept neither from their form nor from their material. There are no direct insights into the corresponding mathematical object when inspecting the "material" or the functional form of number signs as $\sqrt{2}$, -3.17 or π. The meaning of these theoretical, social respectively mental objects has to be constructed by the individual in interaction with experience based and abstract referential contexts. In a general way, mathematical concepts can be conceived as "symbolised, operational relations" between their formal codings and certain socially intended interpretation.

Mathematical knowledge can be looked at in two complementary ways: On the one side, each mathematical knowledge domain represents a consistent structural wickerwork, in which all elements are linked in an equivalent logical manner. On the other side, new concepts posing new questions and problems can be constructed in every mathematical knowledge structure, concepts that are not yet imbedded in the actual logical structure, and in this way producing new insights.

This distinction between the *logical structure* and the *mathematical objects* is in accordance with the distinction made in philosophy between a subjective ontology of reality and the subject independent structure of the world. "... the ontology of the world is created by the cognitive agent, the structure of the world depends on the mind-independent external reality. In this way, the experiential world can be seen as both created and mind-independent at once. As there cannot be a structure without an ontology, it is the cognitive agent's act of creating an ontology that endows external reality with a structure" (Indurkhya 1994, p. 106).

The "logical coherence" and consequently the "unique generativity" of mathematical knowledge often is taken as an irrefutable "proof" for the objective existence of mathematical knowledge independent of any cognitive agent (Changeux & Connes 1995, p. 12); but also this property – a specific, epistemological mechanism for the autopoietic development of mathematical knowledge – needs the cognitive as well as the social environment of the cognitive agent for its unfolding.

3. The Epistemological and Communicative Function of Signs

3.1 The Epistemological Dimension

The peculiar interrelation between "Signs / Symbols" and "Objects / Reference contexts" is central for the description and analysis of mathematical teaching as a specific culture. This relation also represents a basic item of the epistemologically based interaction analysis. All mathematical knowledge needs certain *systems of signs or symbols* for grasping and coding the knowledge in question. These signs themselves do not have an isolated meaning; their meaning must be constructed by the learning child. In a general

sense, to endow mathematical signs with meaning, one needs an adequate *reference context*. Meanings of mathematical concepts emerge in the interplay between sign/symbol systems and objects/reference contexts (Steinbring 1993; or Maier & Steinbring 1998).

The interrelation between coding signs of knowledge and reference contexts can be structured in the *epistemological triangle* (cf. Steinbring 1989; 1991; 1998). The links between the corners in this epistemological triangle are not defined explicitly and invariably, they rather form a mutually supported and balanced system. In the course of further developing knowledge the interpretation of signs systems and their accompanying reference contexts will be modified and generalised.

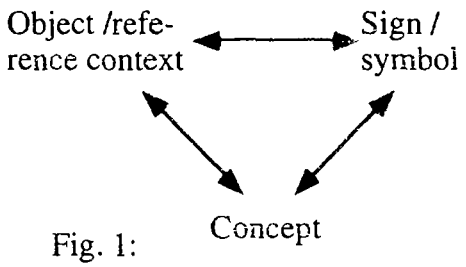

Fig. 1:
The epistemological triangle

Similar triangular schemes have been introduced in the philosophy of mathematics, in linguistics and the philosophy of language for analysing the semiotic problem of the relation between symbol and referent (Frege 1969; Ogden & Richards 1923).

Mathematical concepts are constructed as symbolic relational structures and are coded by means of *signs and symbols*, that can be combined logically in mathematical operations. With regard to the analysis of conditions for the construction of new mathematical knowledge in classroom interaction, mathematical signs and symbols are the central connecting links between the epistemological and the communicative dimension of interactive construction processes; on the one hand, signs and symbols are the *carriers of mathematical knowledge*, and on the other hand, they contain at the same time the *information of the mathematical communication*.

3.2 The Communicative Dimension

The sociologist Niklas Luhmann characterises »communication« as the constitutive concept of sociology: "... when communication shall come about, ... an autopoietic system has to be activated, that is a social system, that reproduces communications by communications and makes nothing else but this" (Luhmann 1996, p. 279).

The concept of "autopoietic system" has been introduced by Maturana and Varela (cf. i. e. 1987); it characterises self-referential systems, that exist and develop autonomously on the basis of this self-referential relation. These systems consist of components that are permanentiy re-produced within the system for its maintenance. With the concept of "autopoietic system" not only biologic processes are investigated but it is also applied to social and psychic processes.

What is the essential difference between a social and a psychic process? The psychic process is based on consciousness and the social system is based on communication. ' A social system cannot think, a psychological system cannot communicate. Nevertheless, from a causal view there are immense, highly complex interdependencies" (Luhmann

1997, p. 28). How these interdependencies can be understood? "Communication systems and psychic systems (or consciousness) form two clearly separated autopoietic domains; ... But these two kinds of systems are linked in a special narrow relation and they form reciprocally a »portion of necessary environment«: Without the participation of consciousness systems there is no communication, and without the participation of communication there is no development of consciousness" (Baraldi, Corsi & Esposito 1997, p. 86).

Language is a central "linking mean" between communication and consciousness. Within language one has to distinguish between »sound« and »sense«; accordingly within written language one has to distinguish between »sign« (more exactly »signifier«) and »sense«. This distinction between sign and intended meaning is the starting point – the take off (Luhmann, 1997, p. 208) – for the autopoiesis of communicative systems.

For the analysis of the conditions of the auto-poiesis Luhmann refers among others to the work of de Saussure, who made the following distinction between signifier (signifiant), signified (signifié) and sign (signe). Luhmann writes: "Signs are also forms, that means marked distinctions. They distinguish, following Saussure, the signified (signifiant) from the signifier (signifié). In the form of the sign, that means in the relation between signifier and signified, there are referents: The signifier signifies the signified. But the form itself (and only this should be named sign) has no reference; it functions only as a distinction, and that only when it is actually used as such" (Luhmann 1997, p. 208f.).

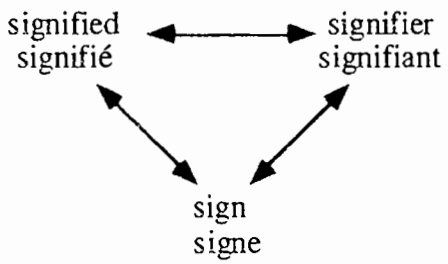

Fig. 2: The semiotic triangle

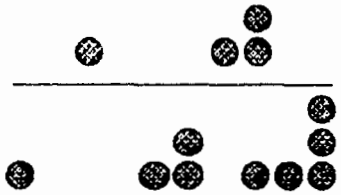
How the autopoiesis of the social, of communication, is possible? According to Luhmann, in the course of interaction or in the communication system the participants provide with their "conveyances" (or communicative actions) mutually "signifiers" which may signify certain "information" (signifieds). "Decisive might be..., that speaking (and this imitating gestures) elucidates an intention of the speaker, hence forces a distinction between information and conveyance with likewise linguistic means" (Luhmann 1997, p. 85).

The conveyor only can convey a signifier, but the signified intended by the conveyor, which alone could lead to an understandable sign, remains open and relatively uncertain; in principle, it can be constructed only by the receiver of the conveyance, in a way that he himself articulates a new signified. Luhmann explains this in the following way: "We do not start with the speech action, which will happen only when one expects, that it is expected and understood, but we start with the situation of the receiver of the conveyance, hence the person who observes the conveyor and who ascribes to him the conveyance, but not the information. The receiver of the conveyance has to observe the conveyance as the designation of an information, hence both together as a sign (as a

form of the distinction between signifier and signified) ...." (Luhmann 1997, p. 210). The receiver must not ascribe the possible signified strictly to the conveyor of the conveyance but he/she has to construct the signified himself/herself; the signified and hence the sign is constituted within the process of communication.

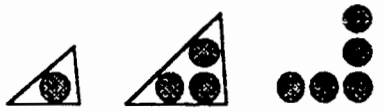
The possible detachment of the information belonging to the conveyance from the conveyor is the starting point of the autopoiesis of the communicative system. By this "mechanism" that describes the autopoietic functioning of the communicative system as an ongoing conveyance of signifiers which are simultaneously transformed into signs by the contrasting conveyance of other, new signifiers, general properties of the functioning of *mathematical communication* are explained, too. In a first approximation, the epistemological triangle can be seen as analogue to the semiotic triangle (according to de Saussure); in addition, the epistemological triangle contains very specific features with regard to the particularities of mathematical communication.

4. Open and Superimposed Discourses in Mathematics Teaching – Analysis of Exemplary Teaching Episodes

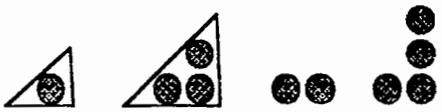


In the following, interactive patterns in two different teaching episodes are analysed in the course of constructing and justifying new mathematical knowledge. In the first episode students work within a learning environment about figurative numbers, where *geometric* reference contexts are offered for the interpretation of mathematical signs. The second episode is part of a teaching unit about special number squares, where the new mathematical signs have to be interpreted with the help of *structured arithmetical* reference contexts.

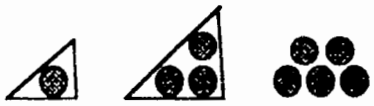
4.1 What is the "Correct" Representation of the Third Triangular Number?



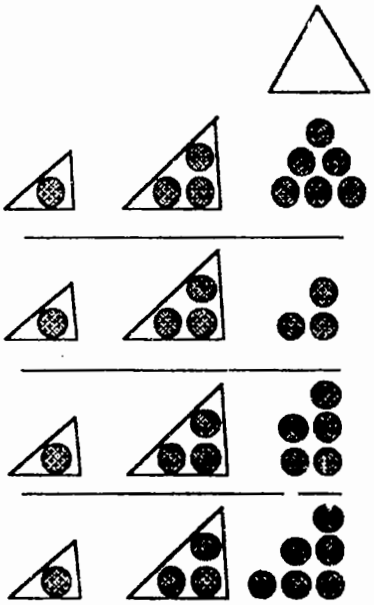
The content of the observed lesson in a 4th grade can be summarised in the following way. The teacher has placed a pattern of magnetic chips (little disks with one red and one blue side) on the black board. This pattern obviously should show the first two triangular numbers. The children are asked to construct the next pattern in this sequence. They offer different interesting proposals. The teacher guides the interactive construction process, and she asks for a justification of the last pattern she had accepted.



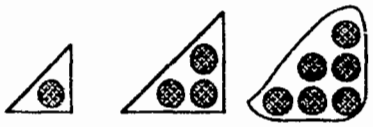
4.1.1 The Children's Proposals for Continuing the Pattern



The teacher places two patterns on the blackboard. How to continue? She emphasises that special numbers are involved having to do with the chips. Dennis continues the pattern in the following way. His proposal can be seen indeed as a possible correct continuation, in which the hook is extended by placing down left and right above one chip each time. The teacher comments this proposal: "Is this already correct? ... One could have the impression, but it is not yet quite right"(5). She refers to the shape and draws rectangular triangles



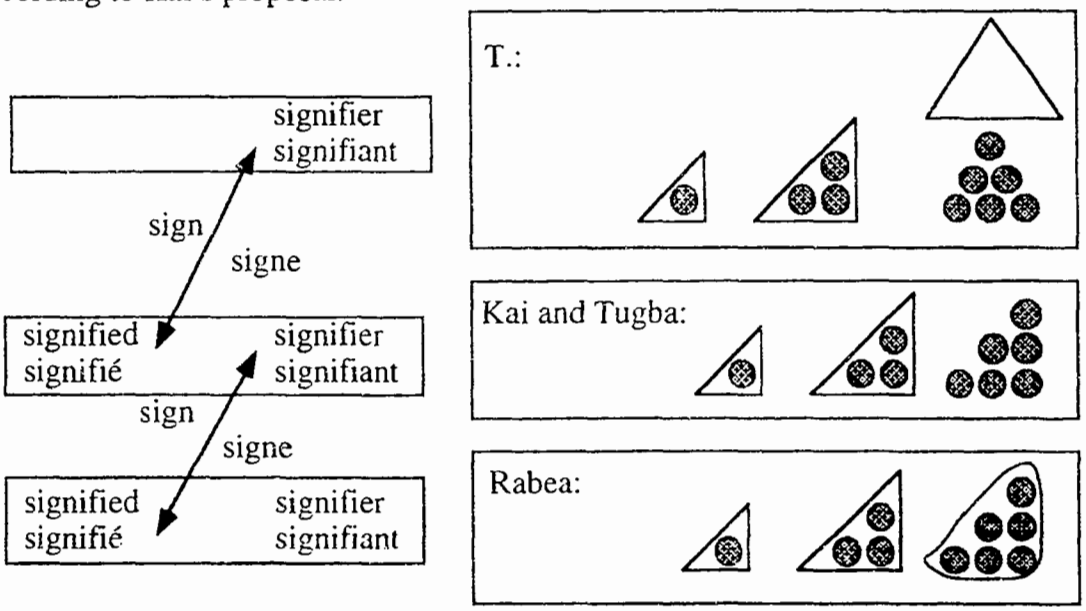
around the two first patterns. Then the teacher points to Dennis' pattern and she says that one could not draw such an triangle around it: "This could not yet be made here."(7). With her finger she goes around his pattern and in this way she outlines the shape of a hook or an angle. The teacher seems to have in mind that only one chip is still missing at the correct place and she tries to focus the children's attention to this fact. By asking the question: "Who could place this now, or use something else?" (7), the teacher expects that the one missing chip will be inserted now. But Lisa answers by making a completely different proposal and constructs the following pattern. She seems to take the initial patterns as one single figure and looks for a possible continuation. Her proposal is a plausible continuation in which to each part of the complete initial figure each time one chip is added, once in the horizontal line, and once in the vertical line. The teacher refuses Lisa's proposal by referring to the shape of the triangles. She points to the base line and to the inclined line of the triangle. Kai takes away all new chips from the blackboard and starts to place his configuration. With the help of his classmates he inserts the last missing chip. He has produced an isosceles triangle, as the teacher then accentuates: "Well, first I have to look here. We have had such a form there but now we have seemingly this [*she draws an isosceles triangle above the constructed configuration*]" (14). The teacher poses the question whether this is the same (16); in this way she refutes Kai's proposal. Kai takes his chips off from the blackboard. Once again the teacher tries to focus his attention to the drawn shape of the two first patterns and she says that the new figure should look the same as the two already existing figures, only with more chips (18). First Kai places exactly the same pattern as the second one. Then he adds two chips in the following way. The teacher confirms: "Ooh, he is very close!" (22). Also Kai's classmates make supporting comments that only one chip is still missing. But Kai is not able to finish the proposal. Tugba places the missing chip on the left side in the base row.



4.1.2 An Empirical Justification for the Correctness of the Third Pattern

Let us look more closely at the following short interaction phase wherein the justification of the correctness for the third pattern is negotiated.

24 T ... Who could now explain why this is correct now? That is correct, you must know. Rabea.



25 R Because it is again the same pattern.

26 L Mhm. Could you come and draw the pattern around it? *[Tugba goes to her place and Rabea comes to the blackboard]* … Draw first the pattern! Go once around it! *[Rabea draws with chalk a triangle around the third configuration]* Aha.

In principle, this justification consists of one statement: "Because it is again the same pattern.", which then is illustrated by Rabea as the "same pattern". How could this short statement gain the status of a justification? This justification function is only possible on the basis of the earlier interaction process. We have seen that the continuations of the teacher's two initial patterns as proposed by the students could have been possible and reasonable. But the teacher refused them one after the other and at the same time she explicated the conditions of "similarity" in the patterns. The children's proposed continuations are excluded until in the end the teacher's intended unique, correct third pattern is produced.

With the scheme of the communicative analysis the final interactive justification with Kai and Tugba can be described in the following manner. The teacher emphasises the rectangular property of the figures and as a contrast she draws the isosceles triangle according to Kai's proposal.

Kai changes his signifier, and after Tugba has completed the pattern, the teacher accepts this continuation of the series of patterns. By drawing the triangular shape of the pattern Rabea makes the "similarity" between the different shapes more explicit and in this way the "conformity" of the patterns becomes the justifying argument and this is legitimised and agreed upon interactively.

The functioning of the autopoiesis of the communication system requires that a given

signifier is not directly linked with the signified intended by the conveyor of the message. This openness is essential for the communicative process. During the analysed episode one can observe that the teacher's denials of the children's proposed signifiers aim at identifying a definite relation between the given signifier (the two first triangular patterns) and a fixed signified (the rectangular shaped pattern). The elaboration of this definite third pattern takes place by a kind of negative delimitation in the course of this interaction.

This mathematical interaction is dominated by the idea that there exists one single correct third pattern, and this idea is made explicit step by step. The teacher stresses this point at different occasions: "Is this already correct? ... One could have the impression, but it is not yet quite right"(5); "... mh, this is not yet quite correct." (10); "... he is very close!" (22); "... why this is correct now? That is correct, you must know." (24).

The communication analysis shows that the interaction is used to point out the teacher's a priori correct relation between the presented signifier (the two patterns) and the appropriate fixed signified (the shape of a rectangular triangle). To give an acceptable justification in this situation means to identify the correct relation between signifier and signified. The basis is the dogma that in mathematics there always exists one single correct relation between signifiers and signifieds. From an epistemological point of view, the new sign "third pattern" is interpreted with regard to a reference context of fixed rectangular shapes for triangles – all other possible shapes are excluded. News signs / symbols and corresponding elements in the reference context are strictly fixed with one another; the signs become names for observed empirical objects (in this case for chip configurations).

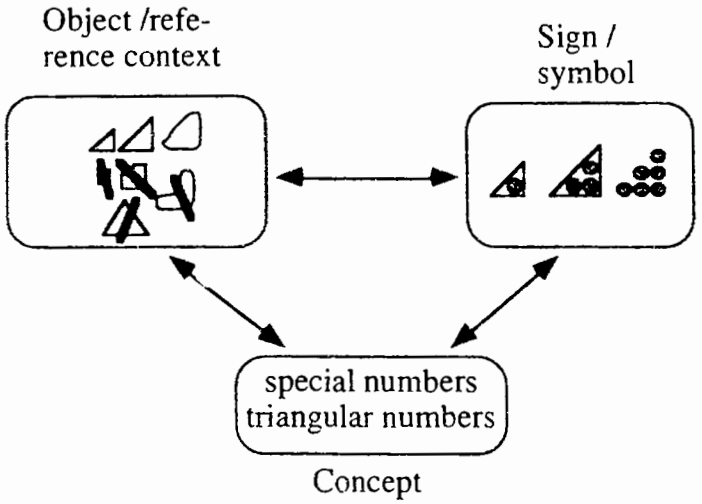


Fig. 3: The epistemological triangle

The justification of the correctness for the third pattern can be characterised in this way: The proposed patterns are compared with one invisible fixed pattern and differences or similarities are remarked until the new pattern is in agreement with the teacher's intended pattern. The last pattern is an admissible one, but it is accentuated in a special social manner as the only correct pattern. No specific reasons are provided for the choice of this pattern; the sole basis is the teacher's authority.

4.2 How is it Possible to Recover a Lost Number in the Number Square?

During this lesson in a mixed class of grade 3 and 4 the children had to work on the following problem: How could one recover a lost number in a certain number square,

in such a way that this number reproduces the former arithmetical structure? (cf. Fig. 4).The special number squares as used in this class can be constructed in the following way: First one adds some given numbers in the border row and border column of a table (cf. Fig. 5). The squares thus created have the following property: You can choose (circle) in a (3 · 3) number square three numbers arbitrarily such that in every row and in every column there is one and only one circled number. The sum of three numbers chosen is always constant – independent of its choice (cf. Fig. 6). Such squares are called "crossing out number squares", because when circling a certain number in the square, all

Fig. 5

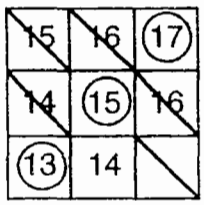

Fig. 6

other numbers in the same row and in the same column have to be crossed out. The children called such a square »magical square« and the constant sum the »magical number«. In this episode, the children reproduced the lost number with three different strategies.

4.2.1 First Strategy: Using Structures in the Arithmetical Pattern

By using the arithmetical pattern of the given numbers in the square, Kevin argues that 15 is the missing number: "... because here is the fifteen, sixteen, seventeen [*points at the first row of the magical square*]. There is the fif-, fourteen, fifteen, sixteen [*points at the second row of the magical square*]. And here is the thirteen, fourteen [*points at the two numbers in the third row of the magical square*]. And then comes there the fifteen [*points at the empty field in the third row*]" (12). Kevin completes his argument by refering to the arithmetical regularities in the columns, too.

4.2.2 Second Strategy: Reconstructing the Missing Number with Numbers in the Border Lines

Some students reconstruct possible numbers in the border column and border row from which the magical square could have been built up. They start with the additive decomposition of 15 = 10 + 5 (cf. Fig. 7) and they calculate further numbers in the border row (cf. Fig. 8) and finally in the border column (cf. Fig. 9). On this basis the children determine 15 as the missing number; this is justified by checking all calculations.

Fig. 9

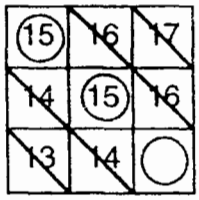
4.2.3 Third Strategy: Reconstructing the Missing Number by Using the Magical Number

Already earlier in the course of this lesson Kim has sketched her idea. Later she explains her plan in detail. First she calculates the magical number 45 by adding the numbers 13, 15 and 17 in the diagonal. With this proposal she expresses that one can determine the magical number in an incomplete magical square. Then her argumentation starts.

147 K And then one could already make it this way. One circles the fifteen [*points at 15 in the first row*] and this fifteen [*points at 15 in the second row*] and adds it up. And then one still calculates, how much there must be up to forty-five.

The signifier "One circles the fifteen and this fifteen and adds it up." denotes the intention to apply the known procedure for calculating the magical number to two numbers in the diagonal. The second signifier "And then one still calculates, how much there must be up to forty-five." could be understood in this way: One has to calculate how much is left from the sum of 15 + 15 up to 45 (one has to calculate the difference); seemingly, this number has to be placed into the empty field.

At this moment, several classmates object that nothing could be really calculated here. "Well, that really leads nowhere ... Where you would like calculate up to? ... Exactly. After all, you do not at all know which number is the result here!" (152, 153).



Kim formulates further explanations.

161 K First one calculates, one first calculates these numbers, that I have, which are there, what is their result. And then ..., and then one calculates ...

165 K These three, oh, yes, this, this and then afterwards one calculates fifteen [*circles 15 in the second row*], one takes this way. Cross out that, and that. And cross out that and that [*crosses the other numbers in the same column and the same row*]. Then one also takes the fifteen [*circles 15 in the first row*]. Crosses out then the seventeen and the thirteen [*crosses out the still uncrossed numbers in the same column and the same row*]. And then one circles this here, this here [*circles the empty field*]. And then one has to calculate, fifteen and fifteen this makes thirty, how much is left up to forty-five.

The signifier "And then one circles this here, this here." indicates the application of the crossing algorithm for calculating the magical number to a missing third number – to the empty field. On the one hand, the second signifier "...one has to calculate, fifteen and fifteen this makes thirty, how much is left up to forty-five." intends the calculation of the magical number from three circled positions: 15 and 15 makes 30. But with the third circled position one cannot calculate in the known standard way. On the other

hand, one should now calculate in a "reversal manner" with the empty field: Here one has to place the number that represents the difference between thirty and forty-five (the magical number). Later, the addition task is written as a complementary task "15 + 15 + __ = 45". This task displays the form of an addition task with three terms, but in an unusual way. It reflects a generalised structure allowing to express the calculation with a partially unknown number. In this way, new mathematical signs or symbols are created. By applying the calculation scheme for the magical number to the empty field and by writing the complementary task with an unknown term, new mathematical signs are expressed and are represented as abstract icons.

13 + 15 + 17 = 45

15 + 15 + __ = 45

Fig. 10

The epistemological analysis verifies that Kim constructs genuine new knowledge when including the empty field into the mathematical operation to determine the magical number. She argues that one cannot calculate with concrete numbers only, but the algorithm for the magical number can be extended also to arbitrary fields – with or without numbers. The new mathematical knowledge constructed in Kim's argumentation can be described with the help of the epistemological triangle. The new relation (resp. "unknown number" or "variable") is symbolised in two ways; once as a "circled number" and then as a missing term in the addition task. In this domain of representation and of mathematical operation we can observe how Kim works with the "unknown number" in a specific situated manner. Kim places the unknown number into a new mathematical relation with other numbers and in this way she constructs new knowledge; the new mathematical object is created as a relation in the extended and generalised operational structure of the number square.

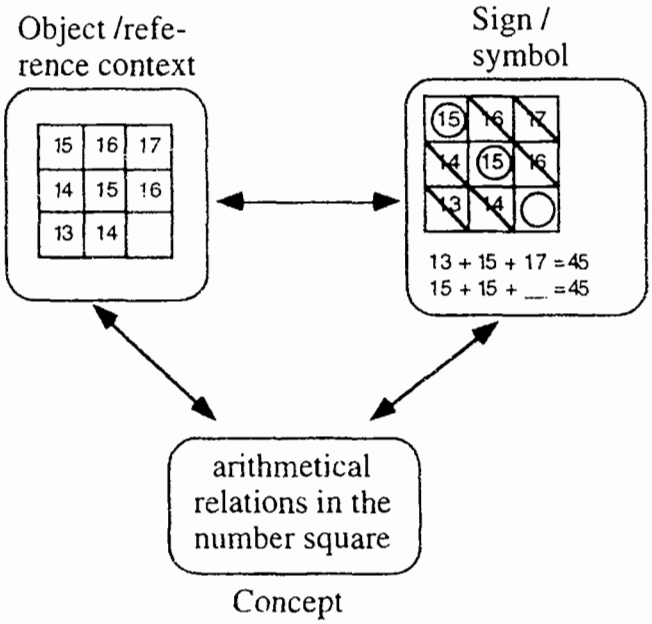


Fig. 11: The epistemological triangle

4.2.4 Eva Repeats the Strategy Using the Magical Number

During the discussion of Kim's strategy, the teacher encourages other children to explain how this "trick" works. Eva argues in the following way.

193 E Well. Ohm, one has to take three numbers out of the magical square. Add them up. But not the empty field,

there is not much to calculate, all right?

196 E Yes. And then you get the magical number. Then one must, ohm, that, ohm take again three numbers, but now also the empty field must be therein. And then you have to … from this number, you get then … from these two, one has still to go to forty-five.

With the first signifier, Eva intends the calculation of the magical number taking three concrete arbitrary numbers from the square. She adds: "But not the empty field, there is not much to calculate, all right?". One cannot and should not use this field for the calculation of the magical number.

The second signifier indicates that the scheme of the algorithm for the magical number shall be transferred to three other numbers: "… take again three numbers, but now also the empty field must be therein." Here, the empty field is identified in a way with a number; Eva characterises a mathematical unknown in a situation specific manner. When transferring the algorithm the following calculation cannot be done in the usual direct manner, because the third term is missing; consequently Eva modifies the calculation procedure: "And then …from these two, one has still to go to forty-five".

In her description, Eva makes the distinction between the *impossibility* to calculate a sum by using the empty field as one of the three terms and the *possibility* to operate with the empty field (as a kind of pre-variable) in the same way as with a known concrete number, provided that the result of the operation is already known. Her argument expresses a fundamental epistemological dialectic between old and new mathematical knowledge. In the frame of understanding subtraction as »taking away« – an example for old knowledge – the task "5 – 7" cannot be calculated; later, with a relational understanding of the number concept – an example for new knowledge – the same task can be calculated by developing and using the new concept of "negative numbers".

5. Interrelations between the Epistemological and Communicative Dimension of Mathematical Signs

Mathematical interactions are social systems, being at the same time characterised by very specific intentions. On the one hand they are *educational* or *instructional* communications, on the other hand *mathematical knowledge* is in some special way the object of these communication processes.

• Interactions between teacher and students are pedagogically intended social communications with the aim to mediate knowledge. This implies a superposition in the autopoietic development of the social communication with an "additional sense", which is the result of the teacher's intention linked with his *teaching* and *instruction*. This intention dominates the educational communication for all participants (teacher and students). When trying to realise their instructional intentions teachers often unconsciously make the assumption that the separation between the social and the psychic system could be bridged directly and the meaning conveyed in the communicative process could be transported instantly and unchanged into the student's consciousness (as it is

tried with the well known interactive funnel patterns; cf. i. e. Bauersfeld 1978; Krummheuer & Voigt 1991, p. 18; Wood 1994, pp. 153ff.; 1998).

• Mathematical communication copes with mathematical knowledge; this implies for the (external) observer (the researcher) to analyse the knowledge which is generated in the course of communication interactively from an epistemological perspective. The analysis of the specific status of school mathematics and its interactively constituted meaning shows that it can be interpreted as a "symbolically generalised communication medium" (Luhmann 1997, p. 316ff.); in analogy to "scientific truth" (Baraldi, Corsi & Esposito 1997, p. 190) one can speak here of "school mathematical correctness".

In the course of the first episode on "triangular numbers", one can observe a kind of "compensating communicative strategy". During the interactive process of constructing new knowledge up to the short phase of the accepted justification, the teacher assists, comments and refutes the children's proposals. She uses a number of similar key words: "... trying to place the next ..." (1); "Is this already correct? ... One could have the impression, but it is not yet quite right" (5); "...this is not yet the right." (10); "Is this the same?" (16); "Ooh, he is very close!" (22); "... Who could now explain why this is correct now? That is correct, you must know." (24). With these descriptions, the teacher indicates that she starts from a very definite idea about the third pattern. In the course of the episode, the students are led to find out what, according to the teacher's opinion, is the only correct pattern. After having given their own, correct proposals for continuing the pattern, now the students do no longer interpret the conveyed signifiers with reference to other *mathematical* signifiers for constructing in this way new epistemological mathematical relations, but they start to seek for the intended signified belonging to the teacher's signifier for attaining in this way the correct solution.

This episode shows in an exemplary manner that the necessary condition for starting the autopoietic behaviour of the *mathematical* communication is "destroyed". First of all, the receiver of the conveyance (a student) can ascribe the given conveyance only to the conveyor (the teacher or another student). The possibility to detach the information of the conveyance that the conveyor "attached" to his conveyance implies the possibility of the autopoiesis of the social system. The students are more and more urged to deduce directly from the teacher's signifiers the intended signified. Such a type of communication takes place with the tacit assumption that mathematical conveyances (the signifiers; or the mathematical signs) possess *unequivocal* information (definite referential signifieds), which can be derived in a communication *about* the conveyances. In this way, the referential links of the signifiers are shifted. The new signifiers no longer refer to mathematical referential contexts immediately but they refer to the interpretation that is postulated by the teacher in the existing reference context. The conveyances become the new, proper object of communication. The signifiers are no longer conveyed in communication for relating them to other *mathematical* signifiers or *mathematical* signs mediated in interaction and thus constituting an interpretation.

During the second episode, the communication has a different character. The attempts to reconstruct the missing number are not dominated by explicit aims of the teacher. Different proposed strategies are allowed: Kevin uses the number pattern of the given number square; then several children reconstruct the missing number by reproducing possible numbers in the border row and border column. Subsequently, Kim presents her ideas to calculate the missing number with the help of the magical number; moreover, three children explain this strategy with their own descriptions. The teacher does not confront these proposals with her own fixed ideas about the correct solution; she moderates and supports the children's construction of new knowledge that develops in the course of interaction. Instead of pushing ahead her own ideas, the teacher places the students' solution strategies into the foreground of the communication process, and this makes possible to maintain a "true" mathematical discourse in this classroom.

The autopoiesis of the communication system is possible only if the signifiers are not connected with the intention of the conveyor strictly but always have to be interpreted in the course of communication in a new manner. For a given signifier there is no definite, fixed signified in communication, and therefore there is no unique universal sign, but different interactively evolving interpretations. Accordingly, a successful authentic mathematical interaction requires that a communicated (new) mathematical sign is not fixed a priori by a given referential object, but the participants have to develop their own different and multiple readings of the communicated sign. Such multiple, evolving interpretations of mathematical signs are possible only if these signs are not explained by linking them with concrete properties of pre given empirical objects but if the referents of mathematical signs are seen as relational structures.

An open referential interpretation of communicated signifiers or of mathematical signs is indispensable for the progression of a *mathematical* communication process. A successful mathematical discourse requires not to fix the mathematical signs definitely and once for all, but to respect a rather open relation between mathematical signs and referential contexts the learner permanently has to establish in new ways in interaction. The realization of an open interpretation of mathematical signs strongly depends on the acceptance of mathematical objects as »symbolic relational structures« in interaction. When mathematical knowledge is reduced to its formal terminology and its logical consistency with reference to fixed referents then the mathematical discourse is in danger to turn into a communication about the definte "correct" interpretation of mathematical signs what in the end is decided by the teacher's authority.

The successful functioning of authentic mathematical interaction requires "open" mathematical objects. A central implication is that every theoretical analysis of possible reasons for the success or the failure of everyday mathematical interaction has to take into account the very specific epistemological nature of mathematical knowledge as "symbolised relations" and it has to reconstruct the social epistemology of mathematics in interaction, i.e. the characteristic forms and situated descriptions for this knowledge. The particularity of the mathematical in classroom interaction – and also in any

reconstructing analysis of such interaction – is basically established by the symbolic, relational character of mathematical concepts; these concepts represent open interrelations between formal sign systems and situated referential structures that have to be negotiated in mathematical interaction.

Consequently, the manner of interpreting mathematical knowledge influences the mathematical communication process essentially: Strictly fixed readings of mathematical signs may cause a paralysis of mathematical communication and they also may lead to a transformed, a ritualised communication. Open readings of mathematical signs with regard to multi relational, structural reference contexts are preconditions for any authentic mathematical interaction. The development of a successful mathematical communication requires to take into account the epistemological particularities of mathematical knowledge and at the same time the specificity of instructional interactions between teacher and students. Direct, intentional teaching and interactive construction of new mathematical knowledge often constitute a fundamental dilemma that cannot be dissolved easily in mathematical discourse.

Constructing a calculator-aware number curriculum: the challenges of systematic design and systemic reform

Kenneth Ruthven, University of Cambridge School of Education

Abstract: *In England, the idea of developing a 'calculator-aware' number curriculum for the primary school has been pursued over a lengthy period. Initial explorations within a government-supported curriculum development project proved a significant influence on the design of a national curriculum for mathematics. Hence, the English experience provides an unusual case in which the attempt to frame and implement a calculator-aware number curriculum has moved beyond localised innovation to an attempt at national institutionalisation.*

This paper will examine this experience, and some important emergent issues of wide interest. First, it will outline the approach of the pioneering Calculator-Aware Number (CAN) project, and its influence on the design of the national curriculum for mathematics. Second, it will investigate the continuing experience of CAN schools after the end of the project, coinciding with the introduction of the national curriculum. Third, it will examine the progress of the cohort of pupils who entered these schools at the start of this period. Fourth, it will relate pupils' mathematical strategies to aspects of the curriculum framework. Finally, it will suggest some lessons to be learned from this experience.

The development of calculator use in English primary education

The Calculator Aware Number project

The Calculator-Aware Number (CAN) project (Shuard et al., 1991) was a component of the Primary Initiatives in Mathematics Education (PrIME) programme, sponsored by the government curriculum agency. Before recruiting schools and teachers, the project team formulated a set of basic working principles:

- classroom activities would be practical and investigational, emphasising language and ranging across the whole curriculum;
- exploring and investigating 'how numbers work' would be encouraged;
- children would always have a calculator available; the choice as to whether to use it would be the child's not the teacher's;
- the importance of mental calculation would be emphasised; children would be encouraged to share their methods with others;
- traditional pencil-and-paper methods of column addition, subtraction, multiplication and division would not be taught; children would use a calculator for those calculations which they could not do mentally.

Between 1986 and 1989, the project team worked collaboratively with several clusters of primary schools and teachers. The tangible outcomes of the project were these curriculum principles, illustrated through a range of classroom activities and accounts, rather than a structured curriculum plan. This reflected the pedagogical approach adopted by the project teachers:

The teachers began to develop an exploratory and investigative style of

working, which allowed the children freedom to take responsibility for their own learning. Topics for exploration took the place of practice exercises as the prevailing classroom activities. Because the number sections of the mathematics schemes used in the schools had been discarded, the teachers were able to move towards a different style of working. No longer did they have to 'cover' set topics in a set order. They began to notice that children's mathematics learning did not seem to progress in the ordered linear way in which it was traditionally structured. Individual children seemed to be putting together the network of mathematical concepts in their own individual ways (Shuard et al., 1991, 44).

The project team reported favourable findings from a participating local authority in which the mathematical achievements of first cohort of project pupils were compared with those of peers in other schools (Shuard et al., 1991). The following year, the second cohort was involved in a similar comparison. The comparison was still favourable, but less strongly so (Foxman, 1996).

Framing the National Curriculum

When the decision was made to introduce a national curriculum, it was not surprising that the CAN project and its personnel should influence the proposals of the working group charged with devising the programme of study in mathematics:

> The universal availability of electronic calculators is changing our views about the kinds of facility in computation which are needed of pupils ... Along with the ability to use and interpret the results obtained from calculators there is general agreement that a greater facility in mental arithmetic should be encouraged (National Curriculum Mathematics Working Group, 1997: 8).

The rejoinder of the then minister of education was that:

> it must be important that pupils themselves understand and are proficient in the various mathematical operations that can now be done electronically (Department of Education and Science, 1988: 100).

Later, he asked still more more pointedly:

> Is it justifiable to exclude the pencil and paper methods for long division and long multiplication from the attainment targets for mathematics, as the mathematics working group have recommended? (National Curriculum Council, 1988: 92).

The final programme of study achieved a superficial resolution of this conflict through the deliberate ambiguity of its references to 'non-calculator' methods of computation, with a more explicit account of the approach favoured by the working group confined to the accompanying pedagogical guidance which suggested that:

> For most practical purposes, pupils will use mental methods or a calculator to tackle problems involving calculations. Thus the heavy emphasis placed on teaching standard written methods for calculations in the past needs to be re-examined. Mental methods have assumed a greater importance through the introduction of calculators, and the use of mental methods as a first resort in tackling calculations should be encouraged. Work should be based in a firm understanding of number operations, applied to problems in a variety of

contexts, and encourage pupils to select from different methods with confidence depending on the nature of the problem and the suitability of the method. (National Curriculum Council, 1989, E6).

Discussing the new national curriculum, the CAN project team wrote:

> The CAN project has been very fortunate that National Curriculum mathematics is much in line with the thinking the project has developed. Teachers who work in the project have welcomed the emphasis in the National Curriculum on a broad curriculum in mathematics, on using and applying mathematics, on the encouragement for children to use their own methods of calculation, and on the possibility of using calculators for much of the work. Teachers in project schools have commented on a number of occasions that they need to make many fewer changes to their curriculum than other teachers (Shuard et al., 1991, 71).

Calculators in the National Curriculum

The programme of study was designed within a levelled framework intended to prescribe progression within teaching programmes and to describe the resulting development of pupil capabilities. The expectation was that pupils in the lower primary (infant) phase (known as Key Stage 1) would cover the material of levels 1 to 3, and that by the end of that phase (at age 7), the great majority would be assessed as attaining a level between 1 and 3, with the average pupil at level 2. Similarly, during the upper primary (junior) phase (known as Key Stage 2), it was anticipated that, by the close of the phase (at age 11), the great majority of pupils would achieve a level between 3 and 5, with the typical pupil at level 4, having covered the programme of study to level 5; with level 6 'intended for only the most able children performing significantly above the normal range' (School Curriculum and Assessment Authority, 1995).

Table 1 abstracts, from the mathematics programme of study, those references to calculators relevant to the primary school (excluding levels 1 and 6 which make no references of this type). This is certainly a curriculum which acknowledges the calculator; but is it a calculator-aware curriculum? References to 'using a calculator' start warily. At levels 2 and 3, this is to be for checking or 'where necessary'. Half of the examples concern money calculations. At levels 4 and 5, cautiously affirmative references to 'using a calculator where necessary', working 'with the aid of a calculator' and 'check[ing] using a calculator' are easily outnumbered by prohibitive references to working 'without a calculator' or 'using non-calculator methods'. A product of the fudged compromise over the relative emphasis to be given to mental and written, standard and nonstandard methods, this negative phraseology comes over as subversive of calculator use.

While there is an emphasis on interpreting results 'on a calculator' and 'reading calculator displays', there is only one reference to the need to 'translate the problem...in order to use a calculator'. However, there is one important innovation, in the form of 'trial and improvement' as a solution strategy. Clearly dependent on calculator availability, although avoiding reference to it, this is the sole recognition of the possibility of distinctive calculator methods.

Table 1: Calculator references in National Curriculum mathematics programme of study (1989 & 1991)

Level	Programme of Study	Example
2	Describe current work, record findings and check results.	Devise stories for adding and subtracting numbers up to 10 and check with calculator or apparatus. [1989]
3	Solving problems involving multiplication or division of whole numbers or money, using a calculator where necessary.	Find the cost of four calculators at £2.45 each. [1989, 1991]
	Using decimal notation in recording money.	Know that three £1 coins plus six 1p coins is written as £3.06, and that 3.6 on a calculator means £3.60 in the context of money. [1989, 1991]
	Appreciating the meaning of negative whole numbers in familiar contexts.	Understand a negative output on a calculator. [1989, 1991]
4	Adding and subtracting two 3-digit numbers, without a calculator.	Work out without a calculator how much longer 834 mm is than 688 mm. [1989]
	Multiplying and dividing 2-digit numbers by a single-digit number, without a calculator.	
	Solving addition and subtraction problems using numbers with no more than two decimal places, and multiplication and division problems starting with whole numbers.	Work out how many chocolate bars can be bought for £5 if each costs 19p, and how much change there will be. [1989, 1991 without the aid of a calculator]
		Find out how many 47-seater coaches will be needed for a school trip for a party of 352. [1991 with the aid of a calculator, interpreting the display]
	Reading calculator displays to the nearest whole number and knowing how to interpret results which have rounding errors.	Interpret $7 \div 3 \times 3 = 6.9999999$ if it occurs on a calculator. [1989]
	Recording findings and presenting them in oral, written or visual form.	Translate the problem of finding the number of 28p packets of crisps that can be bought for £5 into $500 \div 28 =$ in order to use a calculator; record the result as 17.857142 and thus decide that the result is 17. [1991]
5	Understanding and using non-calculator methods by which a 3-digit number is multiplied/divided by a 2-digit number	Use any pencil-and-paper method to find the number of coaches needed to take 165 Year 7 pupils on an outing if each coach has 42 seats
	Calculating fractions and % of quantities using a calculator where necessary.	Calculate 15% of 320; $^3/_5$ of 170 m; 37% of £234; $^1/_{10}$ of 2 m. [1989]
	Using 'trial and improvement' methods and refining.	Estimate the square root of 10 and refine to 3 decimal places. [1991]
	Approximating, using significant figures or decimal places.	Read a calculator display, approximating to 3 significant figures. [1989]
	Make and test simple statements.	Explore the results of multiplying together the house numbers of adjacent houses, make a statement about the results, and check using a calculator. [1989]

Calculators and national testing

As the first pupils completed each Key Stage, a national programme of assessment was introduced, incorporating external testing. Again, at first sight, the place of calculators is acknowledged. To take the example of the 1995 Key Stage 2 mathematics tests, the opening instructions explain the use of icons to indicate where the use of a calculator is stipulated or prohibited, and state that its use is permitted on items without an icon. Of the 40 items across the two test papers, 14 prohibit use of a calculator. A number of these items took the form of missing digit problems presented in the vertical format of standard written methods, rather than in a more methodically neutral, horizontal format. Such presentational features, combined with concern about the acceptability of nonstandard approaches when meeting requirements that pupils should show their working, led many teachers to conclude that the testing process entailed a preference towards standard written methods. Use of a calculator is stipulated on only one item within the two test papers. Only one further item might be regarded as calculator affirmative both uses the machine as its setting, and permits its use.

Beyond the optimistic speculation, then, and beneath the veneer of calculator recognition, both national curriculum and national testing emerge as more 'calculator-beware' in spirit than 'calculator-aware'.

Impact of the reforms on professional practice

The official evaluation of the implementation of the new curriculum found that teachers made little reference to the non-statutory guidance, and were already confident of their teaching of number (Brown et al., 1993). Combine these factors with the tone of the curriculum document and national testing, and it is not startling to find school inspections reporting a largely unchanged pattern of professional practice:

> In all the schools visited the teachers placed a strong emphasis on the written practice of the basic operations of addition, subtraction, multiplication and division. This dominated the work in half the schools ... For many schools there was an imbalance between the written practice of basic number skills and mental, oral and practical work involving number...The skills of using a calculator were neglected in a high percentage of the schools; in only a tenth of the lessons seen were calculators used ... Only in the most successful schools was a policy of calculator use thought out in relation to the acquisition of mental and 'pencil-and-paper' skills (Office for Standards in Education, 1993: 9-11).

However, let us now turn to examine a group of schools which had been involved in the CAN project.

The evolution and long-term impact of CAN in project schools

As the CAN project drew to a close in the summer of 1989, the National Curriculum came into force. A Cambridge research study examined the mathematical experience of a cohort of pupils who entered reception class during the 1989/90 school year, progressing to the final year of primary education in

1995/96. Data was gathered in six neighbouring primary schools, all covering the full primary phase. Three of these schools participated in the CAN project between 1986 and 1989, and in the much smaller-scale continuation project to 1992.

The influence of national reforms

The accounts of teachers in the post-project schools indicate how their practice was influenced by the national reforms. The general tenor was of seeking to retain valued principles and activities from CAN; to establish the legitimacy of these principles and activities within the new order; and to tighten aspects of their implementation.

> It's made very little difference in the way I taught maths personally. Very little. The other thing it had done in this school - it would have happened without the National Curriculum anyway - it refocused people's ideas on the structure that was needed right through the year groups. [Richard]

> I don't think the delivery has done anything except become a little cleaner. It's forced me to sharpen up my act. I think if we want to hold on to this we've got to really be able to...justify it. We've got to show that it can be done in this way...It's not that we're being subversive. It's there in the National Curriculum. It's that it's not terribly common what we do. I feel we have to justify it. [Stephanie]

The substantive influence of these external pressures had been threefold. First, some of the expansiveness of investigative work had gone, with a stronger tendency to structure and foreclose an activity than in the past.

> I think what's altered is that pre National Curriculum I would have had a much broader, less clear picture of what I wanted to get out of a session, and therefore I would have been more open to other things that came up, and would have been able to pick up on those other things and delve a bit deeper with the children. I think what its forced me to do is to keep on a much narrower pathway. [Stephanie]

> I would probably [have done] more longer investigations. Now, I do a lot more shorter activities, to get the coverage in a year. [Tracy]

Second, although calculators continued to be readily available in the classroom, there were occasions when their use was challenged or proscribed.

> There might be some negative reference: 'How are you going to do that, to use the calculator?'... So there might be some kind of sideways swipe at it. [Stephanie]

> The policy is that they are there all the time, but [sometimes we say] 'Actually for this activity I don't want you to use a calculator'. [Tracy]

Third, standard written methods of recording and calculating were now taught. At Key Stage 1, teachers felt obliged to introduce pupils to vertical methods of recording, and to 'sums' presented in this way.

> [Tests] brought back more formal work. Having been through the first maths test - it was formal sums set out, which the children were not used to seeing. That's when we decided that we were going to have to introduce formal sums set out ready for them. They'd set them out any way they wanted. [Rachel]

> The first [tests] affected [the Key Stage 1 teachers]. After being used to CAN and recording in their own way, after the first [tests] they were suddenly putting everything in columns. Worried children wouldn't understand. [Tracy]

At Key Stage 2, standard written methods were more prominent, although the expectations of secondary schools were often cited as the direct reason for this.

> Conceptually they had a pretty good insight of number, but on paper, when they were presented with any kind of traditional sum on paper, which they would be at the high school, the children were worried and the parents were worried. We just felt we had to teach it them. [Richard]

> [Emphasis on pupils' own strategies] has caused some difficulty on transfer. If they don't use a traditional method, it is considered that they can't do it. So even if it is not their preferred option, they have been taught a traditional method so they know how to use it, for that reason. [Stephanie]

Awareness of tensions within the CAN model

Teachers had developed a more subtle view of the complexities of supporting pupils' development of methods of calculation. They were conscious of having to manage an important tension between personal insight and authenticity on the one hand, and accuracy and efficiency on the other.

> We've built on what the children have actually used... try out the different methods and encourage them to find the one they feel most happy with...There is one child I did change ... because he was not accurate, and he was slow. His methods were so long-winded ... It is important that children do have quick accurate methods. One of the things which is really important is ... that the children have conceptual awareness of what's happening with the numbers. If they know that then they are secure. But some of the children are going through the motions with methods they don't understand. [Richard]

> We put [pupils' strategies] very high up [but] the older a child is the more likely I am to say 'That's fine but it takes twice as long as this one'...There is kind of a seductiveness in working investigatively...and they forget that there can be a directness that is important as well. [Stephanie]

Another issue which emerged from teachers' accounts related to the systematisation of CAN within schools. Salient themes here were of the uncertainty and effort arising from the abandonment of a conventional mathematics scheme, with limited alternative means of support.

> I came to this school having a fairly sketchy knowledge of CAN, having seen it in operation, but having a sketchy knowledge about how to proceed, and finding no resources. The resources there were were photocopiable resources and packs. There would be one copy so you had to have copies made. It was incredibly hard work preparing lessons each day. [Richard]

> We more or less abandoned schemes and went in at the deep end with CAN. Two members of staff in particular were heavily involved with it and went to meetings and then fed back to staff. But, as I remember, you were left floating about a bit and not knowing what was right or what was wrong to do. I remember thinking if I just give them investigations and problems and help

them to solve them, that's how I'll survive this. You felt as thought there was nothing to support you...When you have a scheme, you don't use it rigidly, but you know it is there as a support for you if you need it...The two who went to the meetings seemed to be more capable at it. You needed to go to the meetings. They got the ideas from the meetings. We just got the 'trickle down'. [Tricia]

In these circumstances, it was difficult to plan for continuity and progression in children's learning, both from lesson to lesson and from year to year.

In CAN it was difficult to know how to progress. After an exciting lesson you thought 'Where do I go now? Where do I take them next?' You'd be rooting around for ideas. [Tricia]

There was no structure through the school...I noticed in my first year that teachers were photocopying an investigation for Year 3 children and the same one was being used for Year 6 children, and nobody knowing what the children had covered at all. [Richard]

One important effect of the national curriculum and assessment reforms had been to press schools to develop a more systematic approach to number, building on the national frameworks. Indeed, this was an important strand of the 'focusing' and 'sharpening up' attributed to the reforms in the opening quotations of the previous subsection.

The long-term influence of CAN on pupil attitude and attainment

The Cambridge study compared the progress of pupils in the post-project schools with that of their peers in the non-project schools (Ruthven, Rousham & Chaplin, 1997). National assessment levels awarded at the end of Key Stage 1 (aged 7) and of Key Stage 2 (aged 11) were analysed, to determine whether the odds of high or low attainment in mathematics differed between schools, after taking account of the general scholastic attainment of pupils.

At Key Stage 1, the odds of high mathematics attainment (level 3) were found to be significantly greater in the post-project schools, as were the odds of low mathematics attainment (level 1), with no individual school in either group diverging from this pattern. In the post-project schools, then, pupils were more likely to be found at either extreme of the attainment distribution. Comments from the teachers of the CAN cohort suggest that a plausible explanation is that the emphasis on investigative and problem-solving tasks within CAN produced a greater differentiation of experience between pupils, creating higher expectations of, and greater challenges for, successful pupils, but providing less systematic structure and support for the learning of pupils who were making poor progress.

One of the things that keeps me working in this way is that low ability children don't get so complexed about it...I think the weak ones do benefit from a lot of talk and being involved in things. They are not excluded because they didn't manage to get quite as much done. And for the high flyers, I think it is a brilliant way of working because they can go as far as they want; there is no ceiling on them. They can take off and go a long way with things and the talk is good for them at that end. [Stella]

> You always thought 'Do children really understand - particularly the less able children? Do they really understand what it is they are doing? I think it showed up with more able children, if they got an answer which was clearly wrong, they knew it was wrong. But that estimating thing was not there with less able. You'd have outrageous answers and they wouldn't have a clue it was not right...I didn't ensure that, like I do now, that children could add up quickly, mentally in their head...Looking back I think I should have done that. That would have helped the less able with their estimating...Some children struggled, but the children who had a gift for maths did very well. If they had a good understanding of the structure of numbers and estimating skills, then they went quite far. [Tricia]

However, this differential pattern did not persist through to the Key Stage 2 results, where no significant group differences were found between non-project and post-project schools, although in one non-project school the odds of low mathematics attainment (level 2 or 3) were significantly greater.

Pupils were also tested on a range of concepts related to place-value, using five blocks of items involving larger whole numbers and numbers with decimal parts. Relative to overall mathematical attainment (as assessed by national test levels), patterns of achievement on these blocks of items did not produce any significant effects interpretable as differences between the groups of schools.

Pupils also completed an attitude questionnaire. No significant differences between schools were found on the constructs *Enjoyment of number work*, *Reluctance to use a calculator* and *Calculator use as a support for number learning*. However, on the construct *Preference for mental over machine calculation*, there was a discernible, but non-significant, trend for pupils in the post-project schools to be more positive. And on the construct *Mental calculation as a support for number learning*, pupils in the post-project schools were significantly more positive.

A further study strengthened these findings (Ruthven, 1998). It examined the strategies used by a structured subsample of pupils -excluding those at the extremes of attainment- in tackling a set of number problems. Whereas 38% of pupils from post-project schools tackled all problems mentally, without any use of written or calculator computation, and only 24% had recourse to these supports on more than one occasion, the corresponding proportions for non-project schools were 19% and 52% respectively. Pupils from post-project schools were not only more prone to calculate mentally, but also more liable to adopt relatively powerful and efficient strategies for doing so.

These outcomes seem to reflect contrasting numeracy cultures in the two groups of schools. In the post-project schools, pupils had been encouraged to develop and refine informal methods of mental calculation from an early age; they had been explicitly taught mental methods based on 'smashing up' or 'breaking down' numbers; and they had been expected to behave responsibly in regulating their use of calculators to complement these mental methods. In the non-project schools, daily experience of 'quickfire calculation' had offered pupils a model of mental calculation as something to be done quickly or abandoned; explicit teaching of calculation had emphasised approved written methods; and pupils had little experience of regulating their own use of calculators.

Pupils' computational strategies and the curriculum framework

We now return to consider the programme of study which guided the primary schooling of these pupils, in the light of further evidence from the Cambridge study. At level 4, pupils are expected to be able to 'Find out how many 47-seater coaches will be needed for a school trip for a party of 352', 'with the aid of a calculator, interpreting the display'; and at level 5, to 'Use any pencil-and-paper method to find the number of coaches needed to take 165 Year 7 pupils on an outing if each coach has 42 seats'.

In the Cambridge study, then, pupils in the structured subsample were presented with a version of the 'coach problem': *313 people are going on a coach trip. Each coach can carry up to 42 passengers. How many coaches will be needed? How many spare places will be left on the coaches?* (Ruthven & Chaplin, 1997) Pupils had been told that they could work out the problem however they liked: using their head, pen and paper, or calculator, or a mixture of these. Drawn from across the six schools, their attainment distribution corresponded very closely to that which would have been found in a similarly truncated national sample.

Direct strategies for the coach problem

The first strategic idea used by most pupils was some form of direct division. Some attempted to use a non-calculator method of computation (typically a standard written method). None was able to accomplish the computation successfully. Around a third proposed, nonetheless, an incorrect solution; around a third switched to use a calculator to carry out the division; and around a third abandoned the problem, or changed approach.

Many pupils appeared surprised by the result of the calculator division.

Karen keys [313][÷][42][=]7.452380952
Karen: Whoopsee!
Interviewer: What have you got?
Karen: I've got loads of numbers.
Interviewer: Are they any good to you?
Karen: No
Interviewer: Why?
Karen: I don't know
Interviewer: Can you understand what they say?
Karen shakes her head
Interviewer: Okay.
[pause]
Rekeys [313][÷][42][=]7.452380952
[pause]
Keys [42][÷][313][=]0.134185303

Karen's initial interpretation of the string of digits on the calculator display was that she has miskeyed; and when rekeying produced the same result, she then supposed that she must have reversed numbers within the calculation. Behind such responses lay an expectation -or perhaps an aspiration- that the result of a division should be a whole number. Certainly, the 'commonsense' of this problem points in this direction, as in Tom's initial reaction: 'You can't split a coach up'. But other

factors are also in play. For these pupils, from their experience of mental and written calculation, division was a process yielding whole numbers as quotient and remainder. By contrast, the calculator provides a (not necessarily whole) ratio. The results of the two processes are the same only for 'exact' division. Karen did not recognise the string of digits as incorporating a decimal resulting from a division. Yet -on the evidence of testing a few weeks earlier- she was capable of working successfully with the one- and two-digit decimals specified by the curriculum.

Although Damon did recognise the result as that of a division, his response illustrates a common difficulty: that of confusing decimal part with remainder.

Damon keys [313][÷][42][=]7.452380952
Interviewer: What have you got? Any good?
Damon: About seven coaches.
Interviewer: About seven coaches.
[pause]
Damon: I think it's four.
Interviewer: Four.
Damon: Yeah.
Interviewer: Spare places?
Damon: Yeah.
Interviewer: How did you work that bit out?
Damon: Because it's seven point four.

None of the pupils attempting this calculator division proceeded successfully to interpret the calculated result as implying 8 coaches. Around a quarter carried forward an estimate of 7 into a further strategy.

Vera shows how the calculator itself could be deployed to make sense of the result.

Vera keys [313][÷][42][=]7.452380952
Interviewer: What does it say?
Vera: I don't know
Interviewer: Okay, so that's not helpful. What else could you do?
[pause]
Keys [313][÷][14][=]22.35714285
Interviewer: Oh there's another one.
[pause]
Interviewer: What do you think you could do?
Keys [42][÷][10][=]4.2
Vera: Four point two.
[pause]
Interviewer: Any ideas?
Keys [42][x][7][=]294
Interviewer: Why did you try that?
Vera: I don't know really

Vera gave little away, and any interpretation of her intermediate moves must be speculative. One conjecture is that they enabled Vera to build a bridge between incongruous digits and familiar decimals. The division of 313 by another number resembling 42 confirmed the 'appropriateness' of the original result. By then dividing 42 by 10, Vera produced a simple decimal, completing the process of

anchoring the unexpected result in a familiar category, and supporting the idea of carrying forward 7 to the next move. In this interpretation, then, these moves become transitional ones of sense-making.

Kylie, too, carried forward 7, to the written multiplication 7 x 42 = 294, followed by the written subtraction, 313 - 294 = 19, in effect translating the ratio result of the calculator division into quotient and remainder form, although she then fell for the tempting interpretation that this implied 7 coaches and 19 spare places.

These episodes highlight the special character of calculator division and the demands that it makes on pupils' mathematical understanding. Carrying out this apparently simple computation proved to be anything but the mindless, automatic process that using a calculator is commonly reputed to be.

Indirect strategies for the coach problem

Less direct strategies were also used to tackle the problem. Two pupils adopted forms of trial and improvement as their opening strategy, using a calculator to carry out the trial computations. Both solved the problem successfully in this way.

Joanne employed trial multiplication.

Joanne keys [42][x][12][=]504
Interviewer: Why did you do that?
Joanne: Forty two times any number, but it was a bit too high.
Keys [42][x][10][=]420
Joanne: Forty two times ten, that's too high so..
Keys [42][x][8][=]336
[pause]
Joanne: They'd need eight coaches, and they'd have..
[pause]
Joanne: Twenty three places left over.

Note Joanne's use of the calculator to multiply 42 by 10. Using the machine to carry out computations in a predictably routinised way, Joanne freed her attention to monitor her strategy and interpret results. She was very capable of doing such a calculation mentally; a few minutes earlier she had successfully multiplied 24 by 10 in her head, answering within one second.

Around 30% of pupils employed some form of repeated addition as their opening strategy, and a further 16% took up this type of strategy at a later stage. Around a quarter of such attempts used the calculator for computation. Liam's experience was typical.

Liam: So you need to add up how many forty twos go into. I'll do that. I'm sure you could do it a quicker way but, well.
Keys [42][+] [42][+] [42][+] [42][+] [42][+] [42][+] monitoring intermediate totals
Keys [252][+]
Liam: Oh no!
Interviewer: Where have you got to? What's happened?
Liam: Hmmm. Don't know.

The calculator leaves no trace of intermediate results, making any extended calculation incorporating a parallel mental computation extremely vulnerable to

failure through miskeying or losing track of where the calculation has reached. All calculator attempts of this type broke down in this way. Pupils who tried to compute mentally without recording had similar difficulties.

Reviewing the curriculum framework

These pupil responses to the coach problem can be related to characteristics of the National Curriculum under which their primary schooling had been conducted; notably, to features of the progression implied within the levelled framework.

First, pupils such as Karen and Damon had difficulties in making sense of the result of the calculator division. Interpretation of division calculations certainly features explicitly in the curriculum framework in the form of 'understanding remainders in the context of calculation and knowing whether to round up or down' at level 3; and 'reading calculator displays to the nearest whole number' at level 4. For this problem, however, pupils needed not so much to read the display to the nearest whole number, but to recognise it as a number lying between 7 and 8. Equally, they needed not so much to understand remainders, but to distinguish them from decimal parts. This highlights the importance of seeing curricular objectives as embedded in a wider conceptual system.

Decimals appear in the curriculum framework for the first time at level 3: explicitly in 'using decimal notation in recording money', and (hence) implicitly in 'solving problems involving multiplication or division of whole numbers or money, using a calculator where necessary'; then at level 4 in the form of 'using, with understanding, decimal notation to two decimal places in the context of measurement' exemplified as 'read scales marked in hundredths and numbered in tenths (1.89m)', and 'solving addition and subtraction problems using numbers with no more than two decimal places'. Gaining familiarity with these monetary and measurement contexts and the corresponding calculation schemes is undoubtedly important, but too literal a treatment risks encouraging a view of the decimal point as a 'separator' within a system of super- and sub-ordinate units such as pounds-and-pence or metres-and-centimetres. Not until level 6, is there explicit reference to underlying relationships between division, fractions and decimals in the form of 'understanding and using equivalent fractions and equivalent ratios and relating these to decimals'.

A similar issue arises in relation to checking. Repeating the original computation, as illustrated by Karen, appeared to be the major strategy employed by pupils to check their calculations and solutions. There was no evidence, in particular, of pupils mentally calculating an approximate value for 313÷42, either as a rough check on a non-calculator or calculator division, or as the basis of some further strategy. The pedagogical guidance certainly emphasises this issue.

> Whether using mental, pencil and paper or calculator methods, pupils must be able to estimate, approximate, interpret answers and check for reasonableness. The development of these skills is crucial to pupils becoming effective and confident in performing calculations, and should match the development of methods and techniques for calculating. (National Curriculum Council, 1989).

However, closer analysis suggests that the curriculum framework does not actually make provision for suitable methods of checking. The type of approximate mental

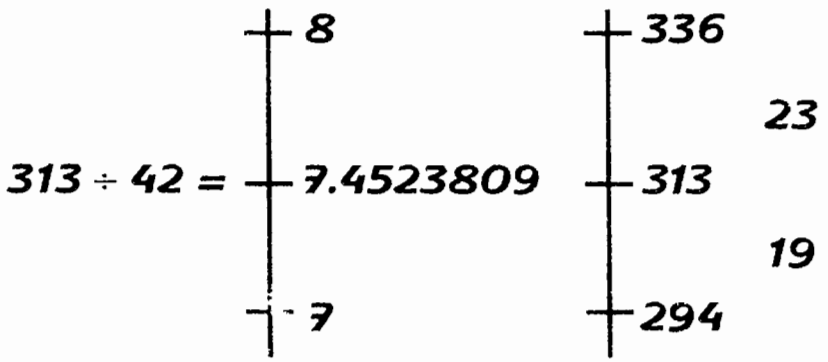
calculation appropriate for estimating the result of this level 4 calculator division or level 5 written division does not feature until level 6, in the form of 'using estimation and approximation to check that answers to multiplication and division problems involving whole numbers are of the right order', exemplified by 'Estimate that 278 ÷ 39 is about 7'. And no explicit reference is made within the framework to the more viable alternative of checking the solution through working back to the original data.

A third issue is the assumption that such checks should be mental; related to the wider assertion -prominent within the pedagogical guidance- that pupils should be encouraged to view mental methods as a first resort. Clearly, developing pupils' expertise in mental calculation is an important curricular goal, not least because components of this expertise underpin estimation through approximate calculation as well as written methods of calculation. But an overgeneralised insistence on prioritising mental calculation can impede pupils' thinking and inhibit their learning of other aspects of mathematics. We have already seen how, while focusing on a higher level solution strategy, Joanne employed a calculator to execute a computation which, under other circumstances, she had shown herself perfectly capable of carrying out mentally. Equally, the reluctance of some pupils to make use of a calculator to implement a direct division led them to adopt alternative strategies based on addition, which they felt better able to compute mentally, but which often proved unreliable.

Again, the programme of study largely ignores such issues. In particular, there is no explicit reference to the importance of developing effective use of the calculator constant. This reflects a more general lack of vision. With the exception of trial-and-improvement, there is no recognition of the possibility of distinctive calculator methods to parallel those of written computation.

Here, Kylie's approach points the way to a distinctive calculator-based method of 'quotient and remainder' division. Figure 1 shows a systematic version, capable of incorporating a range of checks. The scheme incorporates two parallel number lines, spatially encoding the relationships between different elements of the record. Might such a calculator method serve to cap the calculator-aware number curriculum, drawing together and integrating important strands, in much the same way as the proponents of the written long division method see it as capping the traditional number curriculum?

Lessons of the English experience



There are two important lessons to be learned from the English experience. The first is that the design of a calculator-aware number curriculum calls for more thoroughgoing analysis -both of content and progression- than it has received to date. This emerges both from the accounts of the teachers involved in CAN, and from the analysis of pupils' performance in terms of the National Curriculum framework. This is an important issue which deserves attention from researchers: they should aim to develop and evaluate both a systematic design for a calculator-aware curriculum and an appropriate pedagogy of calculator use (Ruthven, forthcoming).

The second lesson is that, however well designed such a curriculum, its successful implementation is likely to depend on it being treated as part of a coherent and committed process of school development -and ultimately of systemic reform- rather than as the isolated responsibility of individual teachers. This can be seen both in the problems of coordination which emerged within the CAN schools, and in the limited impact of the National Curriculum reforms on the teaching of number across the system. These organisational issues are often neglected by mathematics educators, but they emerge as critical to the successful institutionalisation of change.

One and a half of these lessons have now been learned in England. A National Numeracy Project has piloted and refined a more systematic programme for the primary number curriculum; and its implementation has been treated as an aspect of school improvement, calling for sustained commitment and support from school managers, as well as the involvement and professional development of all teachers. This will form the basis of a forthcoming national programme (Department for Education and Employment, 1998).

And the missing half? The new programme of study will be systematic, but far from calculator-aware. In the moral panic over standards of numeracy in English primary schools, the calculator has been cast as scapegoat, despite evidence that it was little used; and that, where it was used, this was not to the detriment of pupils' achievement (School Curriculum and Assessment Authority, 1997a; 1997b). The political compromise that has emerged confines use of calculators to the last two years of primary education, treated as a relatively isolated element of the number curriculum, concerned with teaching children 'when it is, and is not, appropriate to use a calculator' and 'the technical skills needed to use it constructively and efficiently' (Department for Education and Employment, 1998: 53).

Figure 1:Calculator-based method for 'quotient and remainder' division

PLENARY PANEL

Theme:
Doing Research in Mathematics Education in Time of Paradigm Wars

Coordinator:	Anna Sfard
Panelists:	Ellice Forman Stephen Lerman Pearla Nesher

Plenary panel:
Doing research in mathematics education in time of paradigm wars

Coordinator: Anna Sfard, The University of Haifa, Israel

Panelists: Pearla Nesher, The University of Haifa, Israel
Stephen Lerman, South Bank University, London, UK
Ellice Forman, University of Pittsburgh, USA

1. Panel overview

These days we are witnessing an unprecedented proliferation of research frameworks in human studies at large, and in the field of mathematics education in particular. Along with the wide range of traditional cognitive approaches and their updated current versions, there is a steadily intensifying socio-cultural trend including a whole spectrum of research frameworks, from situated cognition through distributed cognition to a number of schools that include the term 'discourse' in their name. This unusual situation provides researchers with many exciting possibilities, but at the same time creates communication problems and leads to partitioning of the community into a growing number of 'camps', only too likely to argue against each other (see, e.g. Anderson et al., 1996; Greeno, 1997). The aim of the panel is to raise and discuss some questions about research, which in these circumstances must urgently be answered. This will be done by considering a research proposal of a Ph.D. candidate who wants to devote her dissertation to mapping student's difficulties with negative numbers. The panel members will act as a Ph.D. committee, which has to decide whether to accept the proposal. Each of the panelists will review and evaluate the proposal from the vantage point of a certain well-defined research framework: Pearla Nesher will take a *cognitive approach*, with its roots in Piagetian theory, Steve Lerman will speak from a strong *sociological/postmodern position*, and Ellice Forman will try to present a more moderate vision by taking a *developmental social constructivist* stance. Discussion will then be opened to the audience who, by the end of the session, will be required to decide whether the proposal should be accepted, substantially modified, or simply rejected.

2. Research proposal by Ph.D. candidate Angelica L. Pabst: Investigating and informing middle school students' conceptions of the negative numbers

1. The theme of the study and its rationale. Negative number is one of the most fundamental, and at the same time most problematic mathematical concepts taught today in our middle schools. Its central role in modern mathematics can hardly be overestimated. The appearance of negative numbers in Medieval Indian mathematics and then through Arab texts in Renaissance Europe (see e.g. Boyer, 1985; Kline, 1980) was as a groundbreaking event, which led to important developments in algebra and beyond. One can hardly envision the impressive mathematical advances of the last three centuries without it. Neither can one imagine an educated citizen of the third millenium society who is not familiar with the notion.

In spite of the retroactive obviousness of their usefulness and indispensability, the negative numbers had a difficult and prolonged birth. The doubts and mistrust with which Renaissance mathematicians greeted this important notion had been obstructing their progress for centuries. Today these difficulties should be of special interest for the mathematics education researcher. The historical phenomena may be indicative of an inherent difficulty of the concept – a difficulty that is only too likely to hinder its learning in our schools today. There is much evidence that, indeed, the idea of negative number is a major challenge to many learners. To illustrate the nature of the most common difficulties, let me use the personal testimony of the French writer Stendhal who, after stating his inability to cope with the concept on his own, issues the following complaint about his teachers: "Imagine how I felt when I realized that no one could explain to me why minus times minus yields plus!" (Stendhal, quoted in Hefendehl- Hebeker, 1991). That Stendhal's case is not exceptional is evidenced, among others, by a number of studies (see e.g. Hart, 1981).

In spite of the importance of the concept, the issue of its difficulty and, more generally, the question of how it is being acquired by the learner has not been given the due attention by the mathematics education community. When surveying the work done during the last few decades one cannot help being surprised by the striking difference between the abundance of studies devoted to basic arithmetic and algebraic concepts, to the concept of function and to rational numbers on the one hand, and the scarcity of research on negative numbers, on the other hand. Thus, considering the fact that our knowledge and understanding of the topic are still fragmentary, there a study such as the one to be presented in this proposal seems to be urgently needed.

*2. **The purpose of the study.*** The study has a double goal. First, it aims at enhancing our knowledge of the processes underlying the acquisition of the concept of negative number and our understanding of the difficulties which obstruct this process. Second, it is expected to lead to operative implications about the ways in which teaching and learning of the subject may be improved.

With respect to the first, more theoretical, goal, the intention is to get to know types of misconceptions about negative numbers and kinds of repetitive procedural errors that commonly appear in the middle school population. The study will suggest a categorization of students` mistakes and will attempt an explanation of their deeper cognitive roots.

The second goal is to formulate and to test some operative didactic ideas based on the findings on students' misconceptions and procedural errors. In the most extreme case, if the results of our investigations show a definite prevalence of faulty conceptions and procedural difficulties in the middle school population, we may conclude that the children of this age are not yet developmentally ready for this intricate topic. In this case, we shall recommend delaying it to later grades. With the intention to improve the learning of the subject we will then develop a new teaching unit on negative numbers aimed at students of the proposed age.

*3. **Theoretical framework.*** Thanks to a few generations of cognitive psychologists, but mainly to Piaget, the human mind is no longer conceptualized as a mere reservoir of accidental concepts, facts, and procedures but rather as a well organized structure, composed of ever growing mental schemata. Thus, once a person learns a mathematical concept, this concept becomes a part of a web-like cognitive system that connects it to other mathematical and non-mathematical notions. This is what keeps this new concept conveniently in the student's long term memory, and this is what makes it meaningful in his or her eyes. Cognitive schemata, and thus individual understanding of concepts, may change from person to person, and in any given person all these cognitive entities may vary considerably over time; nevertheless, at any given moment any given notion is conceived by a person in a specific, rather well defined way. It is this private conception which is responsible for the way its owner acts whenever application of the given notion becomes appropriate. Thus, the researcher or teacher endowed with the knowledge of a learner's understanding of negative number has a reliable basis for predicting this student's behavior in situations involving negative numbers.

Within this theoretical framework, learning is defined as an ongoing process of construction and modification of mental schemata. It is the basic tenet of this theory that rather than being a passive recipient of knowledge, the student is the builder of his or her own cognitive structures. Sometimes, the individual constructions resulting from school learning are incorrect and must therefore be termed *misconceptions*

Misconceptions are faulty understandings resulting from inadequate cognitive schemata. These inadequacies may be an outcome of an inappropriate former learning that failed to prepare the necessary foundations. They may also stem from the lack of developmental readiness on the part of the learner. For example, there is little doubt that such an advanced and overly abstract mathematical idea as negative number requires fully fledged formal thinking, whereas there is no guarantee that the target population of twelve and thirteen year olds has, indeed, the required cognitive maturity.

According to another basic assumption of this study, an appropriate instructional strategy may greatly reduce the occurrence of misconceptions and procedural difficulties related to such concepts as negative number. Documentation of common mistakes and underlying cognitive schemata may be expected to help in finding an appropriate teaching approach. It is also believed that computers, with their power of turning abstract mathematical ideas into perceptually accessible objects, are a highly desirable ingredient of the learning environment. Finally, it is assumed that team learning should be promoted as an instructional approach, which greatly increase the chances for effective learning and diminishes the danger of misconceptions.

4. Design and method of the study. The study will be performed in two steps. First, an investigation of students' conceptions of negative numbers will be conducted among seventh and eighth graders in a number of middle school classes. At the second stage, the implications of this investigation will be translated into a teaching unit on negative numbers. The unit will subsequently be experimentally taught in one or two classrooms.

Part 1: Study of students' conceptions of the negative number. The population in this part of the study will be 12 to 14 year old middle school students, all of whom have learned the concept of negative numbers according to the obligatory curriculum and in the ways implied by the regular curriculum. This means that their first formal encounter with the subject was at the beginning of the seventh grade, just before an introduction to algebra, and that ever since they are supposed to use the concept of negative number and to be able to perform computations involving these numbers. The study will include at least 300 students of varying age and ability.

Within this population a comprehensive survey will be conducted with the help of a specially designed questionnaire. The written responses will be followed by in-depths interviews with a representative sample of the respondents. The questionnaire will be built according to a prognosis on possible learning difficulties and resulting misconceptions designed on the basis of historical investigations, subject matter analysis, and findings of the few former studies reported in the literature. A few examples of questions to be included in such questionnaire are shown in the box below (cf. Hart, 1981).

QUESTION 1: Calculate:

-8+4= 2+(-2)= -6-(-8)= -5+(-6)= (-3)•2= 5•(-7)= (-11) •(-3)=

QUESTION 2: Order the following numbers in a line, according to their magnitude (from small to large): 45.3, -11, 0.2, -1/2, -18.1, 18, 3, 2, -2, -3

QUESTION 3: For each of the following calculations, write a word problem which would lead to this calculation:

a 13+(-3)

b 18.5 – (-5)

c. (-6) •12

d. (-5) •(-4) (-5) •(-4)

Data analysis will be carried out in a number of steps. First, students' written responses will be scrutinized for errors and inaccuracies, which will subsequently be systematized and divided into categories. With the help of the in-depth interviews we will then try to formulate some conjectures as to the nature of the cognitive schemata underlying different types of students' mistakes.

Part 2: Curriculum development and formative evaluation. The curriculum development part of the study will begin with an examination of the existing textbooks with an intention to identify those aspects of the current teaching methods that may be held responsible for the students' misconceptions and common computational errors found in the first part of the study. On the basis of our findings we will then propose an alternative approach, in which a special care will be taken of the problematic aspect of the traditional instruction. Eventually, we will produce new technology intensive teaching materials, aimed at students learning in pairs in a computer laboratory. While developing the teaching unit, we will try to remain within the boundaries of the obligatory curriculum. The proposed teaching sequence will subsequently be run experimentally in two or three classes. To assess the effectiveness of the method, the students will undergo a series of interviews and will eventually be administered the same questionnaire which had been used in the survey part of the study.

5. ***The importance of the study.*** We believe that the proposed study has the potential to make significant contribution both to educational theory and teaching practice. Its theoretical importance expresses itself in the way the powerful conception of cognitive schema is applied to the investigation of the learning of a particular topic. This investigation promises to bring new knowledge on the hitherto unstudied subject and, at the same time, to put to the test the theory of cognitive schemata itself. The practical importance of the study is in the explanatory and predictive power of the theoretical model that will be built, and in the improvements of teaching it is expected to bring.

3. Reviews of the proposal

Review 1
by Pearla Nesher, The University of Haifa, Israel

In the review that follows I would like to draw a distinction among the *historical*, *cognitive* (psychological), and *didactical* paradigms for research, each of them mentioned in Ms. Pabst's proposal. Each one of the above paradigms formulates differently the research questions and employs different methodologies. Each one of them is a legitimate research framework, but they should not be confused since this can lead to confounded results.

I see serious problems with the Ph.D. proposal. I could not find the research question. Among the five sections of the proposal I miss even the title of a section named "the research question". There is a section "Themes and rationale". There are sections dealing with the "Purpose of the study", "Theoretical framework"; "Design and method" and the "Importance of the study". But nowhere do I find a clear research question based on the theoretical framework, from which methodology and design are derived. It could be framed within the section of "purpose". Unfortunately I missed it even there.

Since I should be constructive with my review I will try to help the candidate in this most difficult part of planning Ph. D. research: formulating and selecting a research question. If I read carefully the content of the various chapters of the proposal we have here more than one possible proposal.

First, there is an introduction where students' difficulties in learning negative numbers are related to the historical perspective, that is to the question how negative numbers have evolved through ages. The second deals with the cognitive aspects of the issue and connects cognitive theories (in particular about cognitive schemata) to students' misconceptions. The third is of a completely different nature. It deals with pedagogy. Though Ms. Pabst speaks about "translation", there is no direct (and maybe even non-direct) translation from answering a cognitive theoretical question and writing a learning unit. Preparing a learning unit calls for much more than cognitive theoretical implications. It calls for other theories about classroom interactions, the role of the teacher, etc. Understanding the underlying cognitive schema is just a part of the story.

Each of the above three main parts (or perspectives) calls for a completely different methodology The historical approach will require making comparisons and finding parallels between certain difficulties occurring now in learning negative numbers and

their historical evolution. Actually, the relation between the historical dilemmas and present learning difficulties is a very interesting question. We should note that in dealing with practical instances of debt, temperature, etc. one can operate merely with natural numbers (or positive integers), avoiding negative numbers. When one speaks about a debt of $100, he speaks in terms of positive numbers: "a debt of $100" and not "a debt of -$100". One speaks about "5 degrees below zero", and not "–5 below zero", which is redundant. It is only when we move to a uniform scale of money at the bank or temperature that we need the zero point of departure and the negative numbers.

Those who point to the usefulness of negative numbers in the context of the simplistic everyday applications, as it is done usually in schools to justify their introduction, do not tell the whole story. The real historical reasons for the introduction of negative numbers as objects in mathematics were different. These numbers were recognized as proper numbers only when they became legitimate members of the number system within an algebraic framework. The algebraic notions of groups as mathematical objects helped to define rigorously the operations with negative numbers. The everyday applications could not serve this purpose. Whether all this is related to the difficulties encountered by students of middle school is an interesting question. In order to answer it, one has to delve into historical research, asking about stages in the evolution of negative numbers into the mathematical structure and investigating the reasons for their gradual acceptance by the mathematical community. Following that, the researcher might ask whether his findings bring any support to what can be found in the textbooks used today to teach negative numbers. However, none of these were mentioned in the proposal. The nomenclature is also changing along the proposal: "students' difficulties" become "misconceptions" in the second part, even though the notion of misconceptions is taken from a completely different paradigm, one that belongs to a psychological perspective rather than historical.

The second part of the proposal suggests a cognitive perspective. According to my reading of the candidate's proposal, the purpose of the study is "... *understanding difficulties which obstruct the process of acquisition of the concept of negative numbers* (I omit purposely the didactic goal). Since I am supporting the cognitivist approach, I will invest most of my comments here.

As Ms. Pabst already pointed out, the cognitivist research that started with Piaget has demonstrated the fruitfulness of this paradigm. Indeed, during the last three decades it spurred much insightful studies on learning of mathematics. Findings about early counting, addition and subtraction at the primary level, multiplication, estimation, algebra concepts, etc. have changed completely our notions about the process of learning. The constructivist approach dominating now in many schools have emerged

as a pedagogical outcome of the findings of the research from the cognitivist point of view, although not by a direct translation.

Ms. Pabst is right to point out that cognitive research on negative numbers is scarce. However, what is suggested by the candidate, cannot qualify as a typical cognitive study.

First, there is some confusion about the notion of schema. Referring to this notion is important. Lets remember Rumelhart's very useful formulation: "*..schemata truly are the building blocks of cognition*" (Rumelhart, 1980). The emphasis in the candidate's proposal, however, is on a schema as an individual understanding. This is a partial and narrow interpretation of Piaget's and others notion of schema. Piaget himself wrote that:

> *A schema of an action consists in those aspects which are repeatable, transposable or generelisable, i.e. the structure of the form in distinction to the object which represent its variable content.* " (Piaget, 1950).

Fischbein (1997) in his last year worked on the notion of schema He writes:

> *The term schema covers a large variety of psychological phenomena and for that reason it is difficult to express its meaning in commonly accepted definition.*

According to him:

> *Schemata play in the adaptive process of human beings, a role which is similar to that of instincts at lower level .Schemata which develop after the child is born may also be based on some innate structures. They also are complex programs for interpreting information and adequate reactivity ..they develop with age by maturation and exercise.*

True, every aspect of development leaves much room for individual differences. Not every child starts to walk or speak at the same time. Every individual behaves according to his available schemata at any given time. Yet, there is also a general notion of schema typical of mature (or expert, if you wish) mental structures that enables the shared cognition of human beings. The notion of schema includes the tension between the individual development and the shared cognition. Schema is very important in the process of assimilation and accommodation (which are the mechanism of development). These are schemata, rather than isolated pieces of events, which are taking part in that process.

I do not want to continue this already too long list of characteristics of the notion of schema, or speak of its categorization either according to Piaget (into Presentative, Procedural and Operative), or according to Fischbein (into Specific and Structural). I would like to see how all this is connected to the issue of mathematical learning, in general, and to the learning of negative numbers, in particular.

First, the question is what constitutes the presentative, procedural and operative schemata for the domain of negative numbers. Unfortunately, whilst there are abundance of studies describing procedural errors students tend to commit while working with negative numbers, and equally many studies describing linguistic difficulty connected to the pejorative connotations of the word "negative", I cannot recall, in the field of mathematical education or psychology, a study of negative numbers that rely on schemata and structures. This is surprising because, as mentioned before, the essence of mathematical operations with negative numbers was born within the structure of a group.

Past research shows that examining procedural and algorithmic errors proved to be very illuminating only when done from the "schematic" point of view. All the difficulties in learning decimal numbers could be explained via the existence of the whole number schema and the fraction schema that could not be structurally integrated into the decimal schema. A program like "Buggy", that detailed all possible errors existing in students' performance, cannot help us. It is the presentative and procedural schemata the student already constructed, and the ones that he did not yet construct that can help us understand his behavior and predict his future cognitive growth.

While proposing to employ the cognitive notion of schema Ms. Pabst should be more specific and say explicitly what *kinds* of schemata related to negative numbers she is going to deal with. It is our understanding of the particular schemata underlying the notion of negative numbers that will allow us to understand better what is going on in the process of developing and building up these schemata.

Here are the possible research questions she could focus on in her research.

a) Where in the hierarchy of schemata of the number system can one expect to build up a schema for negative numbers? What are the necessary sub-ordinate schemata? How is the newly built schema different from previous number system schemata (already constructed by the student)?

b) Where can we expect the learner of negative numbers to be misguided by his old numeric schemata? Does the hypothetical schema model suggested in (a) enable the interpretation of observed behaviors, erroneous as well as correct ones?

Such questions are derived from the theoretical review Ms. Pabst has written. Note, that I do not include direct implications for pedagogy among the above research questions. Possible implications could be mentioned at the end of the dissertation, but should better be left for a separate research. The proposal intends to enrich our knowledge about schemata underlying negative numbers. Better understanding, which will be attained in this way, is important for teachers. Yet, none of the methods used in this research are directly transferable to schools. The empirical part of the study will include individual open-ended interviews with students, the aim of which is to reveal various aspects of the negative number schemata and their sub-ordinate schemata, as they occur within individuals at a certain level. These interviews are not units of learning, despite the fact that students might learn a lot from them.

I come now to the third point in the proposal, the pedagogical one. I think it would be too hasty to conclude on the basis of one cognitive study about the proper ways to teach the subject matter. First, before running with the results to the classroom, I would expect to see more studies replicating or elaborating on the finding of the first study. I would like to remind us how many studies were performed on elementary addition and subtraction word problems, before 'combine', 'change' and 'compare' could be introduced to the classroom teachers.

I also want to mention, in brief, that the methodology of research which aims at the question what works at school is completely different from the methods one employs when trying to understand a cognitive schema. Research that aims at testing a teaching approach must include many classes rather than a single group and one teacher; it must involve a long term teaching, because we cannot expect the student to construct a schema in just two or three weeks; and, of course, it must include a comparison to other approaches. If we do not do it in the proper way, we end up with systems of beliefs rather than with scientifically sound findings.

To sum up, the issue of learning negative numbers is important. Yet, the proposal, as it is, includes too many questions and I cannot support it. I suggest that Ms. Pabst defines better the paradigm within which she would like to investigate the learning of negative numbers.

Review 2
by Stephen Lerman, Centre for Mathematics Education, South Bank University, London, UK.

The candidate has chosen a most important topic for her study. There are certainly a great many confusions and difficulties around the teaching and learning of negative numbers. However, I fear that the candidate will not resolve any of these problems if she pursues the perspective outlined in the proposal. I will indicate some concerns and then I will make some suggestions below for what I consider a more appropriate study.

Understanding. First, it is high time we abandoned words and phrases such as 'understanding', 'misconceptions', and 'acquisition of concepts' in mathematics education. They are useless from a teacher's and a researcher's point of view, since they are in essence totally unobservable, and are effectively tools of regulation, since we take it upon ourselves to be the only ones qualified to identify when understanding has taken place. They are predicated upon a notion of the gaining of knowledge as an individual cognitive process. 'Real understanding', with the associated ideas of its non-occurrence, is interpreted as the construction of context-free mental schemata. These schemata, when properly formed, ought to be available for operationalisation and application whenever the 'situation', which is interpreted unambiguously, requires it. We tend to be very isolationist in mathematics education research, relying on psychology as an explanatory domain long after socio-linguistics and cultural studies, to name just two domains, have altered all other fields of social and intellectual inquiry.

A far more useful notion than 'understanding' is that of the forming of identity in the mathematics classroom (Lave, 1996; Winbourne and Watson, 1998). To know something is to use that something in an appropriate way, at appropriate times, these being judged by those who are already initiated. Identity is constituted in discursive practices, which carry what constitutes knowledge in that practice. That approach directs us to study what it is to become a person who functions knowingly in particular social, historical and cultural situations, and how one will be apprenticed into that practice (following Bernstein's (1996) use of the term apprentice, rather than Lave's (1988), although there are similarities between them). One will need to focus on conscious desires and goals but identity will also be conceptualised through the unconscious (Evans & Tsatsaroni, 1993; Pimm, 1994). One needs to be acutely aware of the regulative practices of initiation and to view the task of teaching mathematics as initiation into a hierarchical knowledge structure, with boundaries between school mathematics and everyday knowledge which must be recognised if

they are to be traversed in any way.

In relation to the classroom, and to school mathematics in particular, the research focus must be on: the regulating structures of society and the classroom through the pedagogic mode; the changing identities, goals and needs of the pupils; and the modification and adaptation of their language and behaviour, and the development of meanings, towards those of the teacher. There is a danger in using 'behaviour' as contrasted against 'cognition', since these are usually presented as bipolar alternatives, the former being 'bad' and the latter 'good' in popular discourse of course. What I am referring to here is neither, it is rather a social epistemology, which is materialist whilst not merely behaviourist. Knowledge is what the various social formations in which we live deem to be knowledgeable ways of being, with the multiplicity and fragmentation of identity that this implies.

It will be clear that I am proposing a deconstruction of 'individual' in the often used duality of social/individual but I want also to deconstruct the notion of 'social'. Any situation, including particular activities in the mathematics classroom, is experienced differently by the pupils, and the teacher as a matter of fact, according to their positioning in overlapping social and cultural histories, such as gender, ethnicity, class.

Mathematical meanings. The proposed study falls into following the nineteenth century reductionist theory of ontogeny replicating phylogeny, suggesting the need to find, through historical studies, the obstacles to the development of the currently accepted concept of negative numbers. as these are "only too likely to hinder its learning in our schools today". Such an approach has been a self-fulfilling prophecy in mathematics education in recent decades. We teach to a curriculum constructed around proposed epistemological obstacles, thus ensuring that they will become learning obstacles. I would suggest that we must see mathematical concepts as cultural tools, through which thinking in society is transformed, for all time. The number line, infinitely extensible in both directions, has transformed the discourse of number, but whilst its emergence in history is important, there is no reason to assume that pupils must proceed through the same steps to construct the number line. Today, we can recognise the integers as forming a group under addition, and that can offer us ways of teaching negative numbers, even to young children (Lerman, 1996), by fore-grounding sign-sign connections.

Models of negative numbers and their operations are just that: bank debt or credit, sub-zero temperatures or whatever, are not the 'meaning' of negative numbers. All such metaphors bring with them inevitable limitations (Lins, 1994). That is not to deny the role of models in mathematics, nor their usefulness in teaching, but to question the ubiquity of such approaches which only contribute to what the candidate calls misconceptions. It makes the mistake of confusing metaphor, the link into other systems of meaning, with metonym, where meanings are internal to the system. I was asked, some years ago, by a group of primary teachers on an inservice course, to

explain why $(-1)\times(-1) = +1$. They expected an explanation based on such metaphors. My reply was "What else could it be?"

Readiness. I am convinced that ages and stages, or its consequent notion of readiness, is not a useful way to think about children's development. Indeed the notion of 'development' retains the modernist themes of universality and naturalness and obscures the ideological intent. Notions of normality, which enable teachers to speak of a particular child being ready, pathologises other children as not ready and therefore somehow deficient. The alternative I am proposing, namely a focus on the ways that children form their identities in the practices of school mathematics, admits to the regulating function of teaching. At the same time the teacher and researcher are forced to acknowledge the multiple practices in which each child is already situated, and enable them to bring those identities, gendered, ethnic, class-based etc., into the learning situation (Ellsworth, 1989). The notion of the zone of proximal development, seen as a product of the moment, of the teacher, the pupils, the texts and all the other available resources (Meira & Lerman, forthcoming), is the focus I would recommend for thinking about the problem of when to teach anything. Thus, in the paper I mentioned earlier (Lerman, 1996) the need for negative numbers arose in a problem on which I was working with a group of 9/10 year olds, adding two numbers to make a third, and in that context it presented no difficulties for them.

The study. I would suggest that you abandon the programme of pre-test, investigating existing texts, designing new ones, and testing their efficacy. In its place, you and your teacher(s), should immerse yourselves in the body of literature to which I have referred above, in order to theorise the notion of pupils becoming mathematical actors, in the specific context of negative numbers. You should then design activities, both with and without technological tools, which elicit the need for negative numbers in the solution of those problems. As with all tools, the various forms of IT have specific features that structure and transform the world for the student. I am sure the number line extended infinitely in both directions from zero is analogous. You should pay attention to the role of metaphor and its limitations, enabling a shift of signification towards sign-sign foregrounding (Vile & Lerman, 1996), or metonymic links, in the tasks you devise. You should then undertake ethnographic studies of the students' discussions, actions, reactions to questions, and their other productions, as well as those of the teacher(s) and yourself. You should design tasks that require writing, both to elicit descriptions of meanings and to encourage the development of those meanings. The aim of the study would be to investigate the internalisation of the cultural tools that mediate the appropriate actions of operations with the integers.

Following this programme, you should have something to say about this important problem, through a focus on the ways that pupils' ideas and actions become orientated to working with negative numbers, by the teacher, other students, the tasks and the texts.

3. Reviews of the proposal (cont.)

Review 3
by Ellice Forman, Department of Psychology in Education, University of Pittsburgh, Pittsburgh, USA

Teaching and learning about negative numbers is clearly an important and under-investigated topic. Unfortunately, Ms. Pabst has not explicitly chosen a consistent theoretical approach to this topic. In her review, Pearla finds at least three paradigms in the proposal (historical, psychological, pedagogical) and each requires a different methodology. Using three different paradigms in a study can also create purely theoretical problems. Each paradigm may depend upon different (and perhaps contradictory) assumptions about learning (such as an active versus a passive learner). For example, it seems that Ms. Pabst assumes an active learner when she refers to the psychological paradigm but implies a passive learner when she discusses instruction.

Both Pearla and Steve propose different theoretical frameworks, each of which are internally consistent, instead of the inconsistent paradigm of the original proposal. It seems to me that another way to think about paradigms is to consider the two broad theoretical frameworks currently in use in mathematics education. These frameworks have been called a variety of names (e.g., cognitive science vs. situated cognition; radical constructivism vs. social constructivism; acquisition metaphor vs. participation metaphor; cognitive vs. situated social practice) and their strengths and weaknesses are currently being debated in the education literature (Ernest, 1996; Greeno et al., 1998; Sfard, 1998). In the interests of consistency, I suggest that Ms. Pabst consider selecting one of the above frameworks to guide her research study.

Supporters of either framework are unlikely to admit that their theory is incapable of addressing important practical questions in mathematics education. To the contrary, adherents of both positions claim to provide the most comprehensive and useful set of concepts needed to address any meaningful basic or applied question. Each perspective, however, begins its analysis with a set of assumptions and concepts that take us only so far. For example, Greeno and his colleagues note that the cognitive science approach begins with the analysis of individual cognition and gradually works outward to incorporate individuals learning in social contexts whereas situated cognition begins with complex activity settings and works inward to individuals. Yet, it is unlikely that either one position will be able to realize its ambition to be everything for everyone (Sfard, 1998). In education, we can't afford to be doctrinaire in our research or practices. Nevertheless, eclecticism can be confusing. One way out of this relativist dilemma is to let our practical concerns guide our theoretical choices. I suggest that Ms. Pabst clarify the practical aims of her research and then select one of the two theoretical frameworks that is most likely to help her attain her goals.

The first choice: A study of the acquisition of negative numbers. As Pearla has argued in her review, a cognitive approach would be the best way to investigate the acquisition of negative numbers by middle school students. The term, acquisition, as a synonym for learning, implies that the individual student is expected to gain some mental entity (concepts, representations, schemas, rules, etc.) as a result of prior knowledge and particular experiences (Sfard, 1998). Moreover, as Pearla has noted, schemes do not exist in isolation but in hierarchies or complex structures. These mental entities, in Steve's view, are "context-free", in the sense that they would be available for use in situations other than those in which they were first encountered (i.e., transfer of knowledge from one context to another would be possible, at least in principle). The unit of analysis for this type of investigation would be the individual learner who is presumed to change (at least mentally) as a result of experiences with material and symbolic objects. The nature of this change can be quantitative (e.g., enriched domain-specific knowledge) or qualitative (e.g., stage-like transformations of schemes as in Piagetian theory).

If Ms. Pabst's goals are to expand our notions about the nature of students' knowledge base in the area of negative numbers, then she should go with the cognitive science position. From this perspective, she would be able to focus on the contents and organization of an individual's mental structures. Although this position is closest to the one in her original proposal, I want her to rid herself of this deficit model of students' understanding that is inherent in constructs such as misconceptions and developmental readiness. We have characterized students' thinking for too long in terms of what it lacks (as a result of no instruction or poor instruction). The notion of "misconception", for example, is theoretically misguided, from a cognitive developmental point of view. As Siegler (1976) has shown us in his investigations of children's scientific concepts, many mature conceptions, such as torque, arise when children are able to revise and integrate their previous notions of distance and weight in increasingly sophisticated ways. That is, children initially predict that a balance beam will tip in the direction of the greater amount of weight (and ignore the relative distances of the weights from the fulcrum). Older children take distance as well as weight into account but in an unsystematic fashion. Adolescents and adults use a mathematical formula to compute the relative contributions of both weight and distance. Thus, development does not involve the replacement of misconceptions with correct conceptions but, instead, involves the improved ability to encode or understand more relevant features and to quantify the relationships between those features. A similar issue may occur in the domain of negative numbers.

The second choice: A study of situated social practice in a mathematics classroom. I agree with Steve that if one is primarily interested in understanding the complex social, institutional, personal, and discursive dynamics of the classroom, then one should abandon notions of learning as acquisition of decontextualized mental schema. This Platonic view of mathematics learning is inconsistent with a focus on situated

social practice. If one were primarily interested in understanding how mathematics is practiced by mathematicians and by students of mathematics, then one needs to change one's views of both mathematics and learning. In this alternative approach, mathematics is defined by what mathematicians do—communicate with other members of the professional community, explicate their arguments through the use of cultural tools (graphs, symbols and operators), make conjectures, pose puzzles, etc. (Rotman, 1993). Likewise, learning mathematics should resemble, to some extent, an apprenticeship in thinking, speaking, and acting mathematically (Lampert, 1990; Rogoff, 1990).

Returning to Ms. Pabst's research proposal, if she is truly interested in understanding teaching and learning activities in a classroom community, then she would need to reconceptualize her study from a situated social practice perspective. Like Steve, I feel that Vygotsky's writings about the zone of proximal development would help her articulate a dynamic perspective to understanding teaching and learning. Vygotsky argued that we must study not just the fruits of intellectual development but the process by which the fruits are created (1978). Thus, he proposed the integration of teaching and learning in his famous concept of the zone of proximal development—the difference between assisted and unassisted performance on a task. The notion of developmental readiness has no real validity from this perspective. As Bruner noted, "we begin with the hypothesis that any subject can be taught effectively in some intellectually honest form to any child at any stage of development" (1960, p. 33).

The unit of analysis for this investigation would have to be larger than the individual—it could be a dyad, small group, classroom, etc. This is because learning is no longer viewed as an individual accomplishment or possession. In contrast, indices of learning would involve analyses of group participation patterns. Also, the design of the study should include evidence of change over time: the genetic analysis that is a key component of a Vygotskian approach. For example, changes over time in teachers' and students' involvement in posing problems, arguing solution strategies, orchestrating discussions, integrating alternative explanations, and inscribing justifications would indicate how expertise was socially created in this community. In addition to examining expertise as an emergent phenomenon, this study could focus on affective issues. How do students' and teachers' motives for participating in mathematical activities change over time? Who is seen as resistant to learning about negative numbers? Who is viewed as eager to master the cultural tools necessary for effectively communicating about negative numbers? How are those notions of resistance or eagerness to learn socially constructed?

Summary. Ms. Pabst's topic of interest allows one to conduct at least two quite different types of studies, employing two distinctly different theoretical frameworks. The choice of one approach over the other should be done for pragmatic reasons. Once a choice is made, however, it is essential that the concepts employed and the methods used to investigate those concepts be convincing and coherent (Sfard, 1998).

ONE THEORETICAL PERSPECTIVE IN UNDERGRADUATE MATHEMATICS EDUCATION RESEARCH

Broni Czarnocha, Hostos Community College
Ed Dubinsky, Georgia State University
Vrunda Prabhu, William Woods University,
Draga Vidakovic, Georgia State University

This presentation is based on three principles. First, research in undergraduate mathematics education (RUME) should be closely connected with, if not embedded in, and at least potentially applicable to, curriculum development and teaching practice. Second, a theoretical perspective involving one or more theories of learning, should play a major role in any research project; this role should be explicit and chosen at the beginning of the research so as to provide direction for the investigation and analysis of results. Finally, empirical data is also important and the best research synthesizes theoretical analysis, pedagogical applications, and the gathering and analysis of data.

We begin, in Section 1, with a discussion of how we go about conducting research that is both theoretical and empirical and relates to teaching practice. In Section 2 we give a very brief discussion (with references to more extensive descriptions) of APOS Theory which is the main theoretical perspective used in the program. This is followed in Section 3 by examples in which our approach is used --- both by its developers and others and for both postsecondary mathematics for which it was designed and for K-12 levels from which it came. In Section 4 we describe the pedagogical component of some projects that use our approach. Next, in Section 5 we describe our methods of analyzing and gathering data with some
indications (together with references) of the results. Finally, in Section 6, we consider approaches that are alternatives to our use of APOS Theory.

1 An approach to research and curriculum development in undergraduate mathematics education

As Alan Schoenfeld argues (Schoenfeld, 1998), models and theories should support prediction, have explanatory power, and be applicable to broad ranges of phenomena. To this we have added (Dubinsky & McDonald, 1999) that a theory should help organize one's thinking about complex, interrelated phenomena, serve as a tool for analyzing data, and provide a language for communication of ideas about learning that go beyond superficial descriptions.

We have tried to develop APOS Theory so as to meet these criteria and combine with teaching practice and empirical data to form a paradigm consisting in a repeated traversal of a circle of the following activities: theoretical analysis, empirical data, and design and implement instruction.

In this paradigm, investigation of a particular topic begins with a theoretical analysis based on APOS Theory, the researchers' own knowledge of the mathematics involved, and any informal observations of students, for example, in teaching the material in a traditional way. The purpose of this analysis is to propose, in a preliminary and tentative manner, what we call a *genetic decomposition* of the concept in question. That amounts to suggesting specific mental constructions which a student can make in order to learn the concept. The next step is to design and implement instruction aimed at getting students to make the proposed mental constructions. As the students are experiencing this instruction, data is collected in several different ways, using both quantitative and qualitative methods of gathering information.

The final step in the traversal is to coordinate the empirical data obtained with the theoretical analysis. This means, on one hand, that the theoretical analysis suggests questions to ask of the data: to wit, does it appear that the proposed mental constructions were made by students? Focusing the analysis of data in this way can help the researcher deal with a huge amount of information meaningfully, but far from exhaustively. Indeed we have very often used the same data more than once in studies differentiated by the questions to which a theoretical analysis points us. On the other hand, it sometimes occurs that the mental constructions students appear to be making are different from what has been proposed. One possible response to this is to reconsider one or more aspects of the particular theoretical analysis of the concepts in question. Another response which we have been forced to make, albeit rarely, is to reconsider the theory itself and make appropriate revisions.

It is important to note that it is here that APOS theory exhibits yet another important feature. There is contained within its use the potential for completely rejecting it, which would happen if it had to be revised too often in order to fit with the data.

To summarize, the theoretical analysis drives the instruction which creates the data. The theoretical analysis directs the analysis of data and is simultaneously subject to revision as a result of this data analysis. This circle of activity is then repeated with the (possibly new) theoretical analysis. It is repeated as often as appears necessary to understand the epistemology of the particular topic.

If things work properly, then learning should improve in a natural way as a result of instruction that relates to how the students can learn the concept or concepts. For a more detailed discussion of this approach, see Asiala et al. (1996).

2 APOS Theory

In this section we will sketch the general theory in its present stage of development and describe the nature of mental constructions that the theory proposes along with some examples.

The original source of APOS theory was Piaget's epistemology of mathematics learned from infancy through adolescence (see, for example, Beth & Piaget, (1966)) and an attempt to apply his mechanism of reflective abstraction to learning post secondary mathematics. For more details on the relation between Piaget's ideas and APOS Theory, see Dubinsky (1991). The fact that the development of a theory for advanced mathematical thinking is based on a theory for thinking about elementary mathematics raises the question of the applicability of APOS theory to elementary concepts. We will return to this question in Section 3.

APOS theory begins with a statement of what it means to learn and know something in mathematics.

> An individual's mathematical knowledge is her or his tendency to respond to mathematical problem situations by reflecting on them in a social context and constructing or reconstructing mathematical actions, processes and objects and organizing these in schemas to use in dealing with the situations

There are, in this statement, references to a number of aspects of learning and knowing. For one thing, the statement acknowledges that what a person knows and is capable of doing is not necessarily available to her or him at a given moment and in a given situation. All of us who have taught (or studied) are familiar with the phenomenon of a student missing a question completely on an exam and then really knowing the answer right after, without looking it up. A related phenomenon is to be unable to deal with a mathematical situation but, after the slightest suggestion from a colleague or teacher, it all comes running back to your
consciousness. Thus, in the problem of knowing, there are two issues: learning a concept and accessing it when needed.

Reflection is an important part of both learning and knowing. Mathematics in particular is full of techniques and algorithms to use in dealing with situations. Many people can learn these quite well and use them to do things in mathematics. But understanding mathematics goes beyond the ability to perform calculations, no
matter how sophisticated. It is necessary to be aware of how these procedures go, to get a feel for the result without actually performing all the calculations, to be able to work with variations of a single algorithm and to understand relationships among algorithms.

It is a controversial point, but this theory takes the position that reflection is best performed in a social context. There is evidence in the literature (see Vidakovic (1993), for example) of the value to students of social interaction and there is also the cultural fact that almost all research mathematicians feel very strongly the need for interactions with colleagues before, during, and after creative work in mathematics.

APOS theory asserts that "possessing" knowledge consists in a tendency to make mental constructions that are used in dealing with a problem situation. Often the construction amounts to reconstructing (or remembering) something previously built so as to repeat a previous method. But progress in the development of
mathematical knowledge comes from making a reconstruction in a situation similar to, but different in important ways from, a problem previously dealt with. Then the reconstruction is not exactly the same as what existed previously, and may in fact contain one or more advances to a more sophisticated level. This whole notion is
related to the well known Piagetian dichotomy of assimilation and accommodation (Piaget, (1972)).

Finally, the question arises of what is constructed, or what is the nature of the constructions and the ways in which they are made? It is when we talk about this that our theoretical perspective, which may appear applicable to any subject whatsoever, becomes specific to mathematics. We will deal with this question in the next paragraph.

2.1 Mental constructions for learning mathematics

Understanding a mathematical concept begins with manipulating previously constructed mental or physical objects to form actions; actions are then interiorized to form processes which are then encapsulated to form objects. Objects can be de-encapsulated back to the processes from which they were formed. Finally, processes and objects can be organized in schemas.

Actually, there is a potentially misleading aspect of this description in that there may be two much of a suggestion of a linear progression from action through process to object and, ultimately, schema. In fact, although something like a procession can be discerned, it often appears more like a dialectic in which not only is there a partial development at one level, passage to the next level, returning to the previous and going back forth, but also the development of each level influences both developments at higher and lower levels.

In describing briefly the main mental constructions, we will use the example of cosets of a subgroup, Lagrange's Theorem and quotient groups of a

group and carry this example through the remainder of the paper to illustrate other points.

Action. A transformation is considered to be an action when it is a reaction to stimuli which the subject perceives as external. This means that the individual requires complete and understandable instructions giving precise details on steps to take in connection with the concept.

One example of an action conception comes from the notion of a (left or right) coset of a group in abstract algebra. Consider, for example, the modular group $[Z_{20}, +_{20}]$ --- that is, the integers $\{0,1,2,\ldots,19\}$ with the operation of addition mod 20 --- and the subgroup $H = \{0,4,8,12,16\}$ of multiples of 4. It is not very difficult for students to work with a coset such as $2+H = \{2,6,10,14,18\}$ because it is formed either by a listing of the elements according to some rule ("begin with 2 and add 4") or an explicit condition such as, "the remainder on division by 4 is 2". This is an action conception. Something more is required to work with cosets in a group such as S_n, the group of all permutations on n objects where simple formulas are not available. Even in the more elementary situation of Z_n, students will have difficulty in reasoning about cosets (such as counting them, comparing them, etc.)

According to APOS theory, all of these difficulties are related to students' inability to interiorize these actions to processes, or encapsulate the processes to objects.

Although an action conception is very limited, it is an important part of the beginning of understanding a concept. Therefore, instruction should begin with activities designed to help students construct actions.

Process. When an individual reflects on an action scheme and interiorizes it then the action can become perceived as a part of the individual who can establish control over it.

For cosets, a process understanding consists of thinking about the formation of a set by operating a fixed element with every element in the subgroup. It is not necessary to perform the operations, but only to think about them being performed.

Object. When an individual reflects on operations applied to a particular process, becomes aware of the process as a totality, realizes that transformations
(whether they be actions or processes) can act on it, and is able to actually construct such transformations, then he or she is thinking of this process as an object.

In the course of performing an action or process on an object, it is often necessary to de-encapsulate the object back to the process from which it came in order to use its properties in manipulating it.

In the case of cosets, given an element x and a subgroup H of a group G, if an individual thinks generally of the (left) coset of x modulo H as a process of operating with x on each element of H, then this process can be encapsulated to an object xH. Actions on cosets of H, such as equipping the set of cosets with a binary operation (quotient group), or counting their number, comparing their cardinality, and checking their intersections (Lagrange's Theorem) can make sense to the individual. Thinking about the problem of investigating such properties involves the interpretation of cosets as objects whereas the actual finding out requires that these objects be de-encapsulated in the individual's mind so as to make use

of the properties of the processes from which these objects came (certain kinds of set formation in this case.)

In general, encapsulating processes to become objects is considered to be extremely difficult (Sfard, (1991)) and not very many pedagogical strategies have been effective in helping students do this in situations such as functions or cosets. A part of the reason is that there is very little in our experience that corresponds to performing actions on what are interpreted as processes

Schema. Once constructed, objects and processes can be interconnected in various ways. for example, two or more processes may be coordinated by linking them through composition or in other ways; processes and objects are related by virtue of the fact that the former acts on the latter. A collection of actions, processes, and objects can be organized in a structured manner to form a schema which may also include previously constructed schemas. The structure of a schema has coherence in the sense that an individual understands, implicitly or explicitly, which phenomena the schema can be used to deal with.

Schemas themselves can be treated as objects and included in the organization of "higher level" schemas.

For example, sets can be formed as objects and linked with binary operations are linked to form pairs which may or may not satisfy certain properties All of this can be organized to construct the schema for coset. Groups and rings and other such mathematical objects might be organized in a schema called algebraic structures

The idea of schema is very important for our story in that it is one of the few cases in which difficulties in analyzing data have led to significant revision of the theory. In research studies connected with the chain rule (Clark et al, 1997), using properties of the derivative to draw the graph of a function (Baker et al, in preparation) and understanding sequences of numbers (Mathews et al, in review), researchers found the mechanisms of actions, objects and processes inadequate. Moreover, the idea of schema had only a superficial description as given in Dubinsky (1991) where the development of a schema is not explained. The notion of the *triad* developed by Garcia & Piaget (1983) could be seen to be very closely related to that of schema and it turned out that it could be used to provide better explanations of what a schema is and how it is constructed.

In the triad notion an individual's understanding of a concept develops through three stages: the *intra* stage in which there is a focus on single objects (which might be encapsulated processes or thematized schemas); the *inter* stage in which there is a construction and understanding of transformations between these objects (such as the relations of Skemp (1976) or interiorized actions); and finally *trans* in which there develops a coherence among the transformations in that the individual understands and is ready for, explicitly or implicitly, an organized system of transformations including both those which have been experienced and those that are only potential. It is this coherence that gives substance to our notion of schema and connects the various actions, processes, objects and other schemas.

Thus, for example, in the concept of the chain rule, and individual might begin at the intra level by being able to take the derivative of individual expressions obtained by replacing the variable in a given expression with another expression. Then at the inter level there are certain "rules" such as the "power rule" or the "inside-outside" rule; finally at the trans level, all of these individual rules are encompassed by a single operation of taking the derivative of the composition of two functions. The result is a schema in which the individual understands that if a function can be written as a composition of functions whose derivatives are known, then the derivative of the original function can be obtained.

In this way, APOS Theory connects with the Triad Theory through the notions of coherence and schema, to form a more powerful mechanism for studying learning advanced mathematical concepts.

The Triad Theory is not the only case in which APOS Theory relates to other theories of learning found in the research literature. Other examples include the operational/structural characterization of Sfard (Sfard, 1991) which is very similar to our process/object analysis, the concept image/concept definition dichotomy of Tall and Vinner (Tall and Vinner, 1981), The procept notion of Gray & Tall (1991, 1994), and the didactical engineering of the French school (see, for example, Farfan (1997) and references therein.) In some cases such as the use of the Triad to develop the schema concept discussed above and the work of Arnon, to be discussed below, in combining APOS Theory with Nesher's Theory of Knowledge and Exemplification Components a synthesis of two different but related theories leads to advances in our understanding of the learning process and improvements in our students' learning.

3 Examples of research projects using APOS Theory

There are three categories of examples of research projects using APOS Theory that we wish to consider: studies of advanced mathematical concepts by those who are engaged in developing the theory; studies of advanced mathematical concepts by those other than the developers; and studies of elementary mathematical concepts that use APOS Theory.

3.1 Developers of APOS

After a period of several years in which the approach described here was used by only a few people who were the original developers, an organization, called a Research in Undergraduate Mathematics Education (RUMEC) was formed for the purpose of bringing together experienced and novice researchers to work in teams to conduct specific research studies. This group, which consists of 30-35 members, decided to focus on the development and use of APOS Theory and engaged in a large number of projects, following the paradigm described in

Section 1, most of which have already resulted in published research reports and applications to teaching practice.

Completed and ongoing RUMEC studies include investigations of understanding the behavior of functions, infinity, existential and universal quantification, permutations, symmetries and cooperative learning. Studies of calculus are about the chain rule, slope, limits, graphical understanding of the derivative, using the derivative to draw graphs, intuitive conceptions of the definite integral, sequences and series. There is a long-range study of the effect on student learning and involvement with mathematics of pedagogy based on our paradigm in comparison with pedagogy in traditional courses. In statistics, studies have considered means, medians and the central limit theorem. In abstract algebra there are studies of binary operations, groups, subgroups, cosets, normality and quotient groups. There is a study of the attitudes towards abstract algebra in particular and mathematical abstraction in general as a result of pedagogy based on our paradigm, again in comparison with pedagogy in traditional courses.

Details of these studies and the specific results are summarized in Clark et al (In preparation). The results presented in this paper represent a vast amount of information, both quantitative and qualitative in nature, about learning the topics. It is possible to draw some general conclusions for which justification can be found in the references. First of all, it seems that APOS Theory (including the more sophisticated version of schema) and the genetic decompositions it provides are effective as tools for analyzing and describing what might be the mental processes involved in learning a wide variety of topics. Second, in a fairly weak, but not totally meaningless, sense it can be argued that the theory is predictive in that one can postulate that if students make the mental constructions in a genetic decomposition that an APOS-theoretical analysis of a concept provides, then they are likely to learn the concept. Third, the comparisons, taken as a whole, seem to point to the effectiveness of pedagogy based on APOS Theory in comparison with traditional pedagogy. There is a large number of comparisons in which the former leads to substantially better learning (both in the sense of statistical significance and in the sense of differences that are so large that statistics are unnecessary). There are even more cases of differences that are small, often not statistically significant, but all in the same direction, favoring APOS-based pedagogy over traditional. There are almost no examples in which students taking courses with traditional pedagogy appear to learn better than the students in the APOS-based courses. Finally, in addition to these results in terms of learning, APOS students end up with better attitudes about mathematics and abstraction, they are more likely to take more math courses after, for example, calculus, and they are not adversely affected in their other university courses by what appears to be more time spent outside of class on working on APOS-based courses.

One of the major RUMEC studies was in abstract algebra and concerned the concepts of cosests, Lagrange's theorem and quotient groups. The design of this study very closely followed the paradigm and is taking place in several phases. The first phase considered a group of high school teachers taking a professional development course in abstract algebra that made use of an early version of what would become our pedagogical approach (the ACE Teaching cycle, which is described below in Section 4.) The result was a preliminary genetic decomposition describing mental constructions that might help someone understand cosets and quotients. The second made use of this decomposition, designed a course following very closely the ACE cycle (it was necessary to produce a textbook), and then designed a number of instruments to try to find out about what the students had constructed and what they had learned. The results of this study can be found in Clark et al (In preparation). Finally, a follow-up study is in progress to see if the (very encouraging) results could be obtained by teachers other than those who had developed the course.

3.2 Users of APOS

Use of APOS Theory has not been restricted to those who have been involved in its development. For example, Carlson (1998) has used it to help categorize students' understanding of the concept function; in their doctoral theses, Tostado (1995) and Carmona (1996) applied APOS Theory to analyze student responses to a questionnaire and transcripts of interviews about thei. understanding of the idea of a tangent to a curve and its relationship to the derivative of a function; Wahlberg (Submitted) used the theory to analyze both interview transcripts and writing assignments in an experimental approach to helping students in a calculus course understand the limit concept; Zazkis & Gunn (1997) worked out action-process-object developments of pre-service elementary school teachers' understanding of sets, elements, cardinality, subset and the empty set.

In all of these (and other) studies, the theory invariably proved to be a useful tool for explaining the development of understanding and the difficulties students had with mathematical concepts at the post-secondary level. In some cases, APOS Theory also served a predictive and applications role in that it pointed to pedagogy that could help students learn better and when such pedagogy was developed and employed, the results were very encouraging.

3.3 Elementary mathematical concepts

It is both interesting and satisfying that a theory based on an epistemology of elementary mathematical concepts (that of Piaget) but developed explicitly in relation to advanced concepts, turns out to also be useful in studies of elementary concepts. The circle is completed.

For example, an interesting approach of I. Arnon is to combine APOS Theory with one or another theory developed in the elementary context, such as Perla Nesher's Theory of Knowledge and Exemplification Components, to obtain a powerful tool for studying children's construction of their conceptions of fractions. Using a synthesis of these theories, Arnon is able to establish a stage in the development of concrete actions into abstract objects: children use mathematical language to describe imaginary concrete activity. The results of pedagogy based on these ideas compare favorably with that of other approaches. Her results are reported in several papers, for example Arnon (1998).

Another example is the work of Zazkis who, in collaboration with Gunn, Khoury and Campbell, used APOS Theory in studying pre-service teachers' understanding of several elementary concepts: the positional number system using bases other than 10 and focusing on numbers between 0 and 1 (Zazkis and Khoury (1994); sets, elements, subsets, cardinality and the empty set (Zazkis & Gunn (1997); and divisibility (Zazkis & Campbell (1996).)

Finally, in a study in progress A. Brown and G. Tolias are using APOS Theory to explain difficulties students are having with the idea of factoring a positive integer into primes and representing this with a "factor tree".

These investigations indicate that APOS Theory has grown both beyond the community in which it was born and raised and beyond the content area for which it was intended.

4 Teaching practice

A second component of our framework is the design and implementation of instruction. What sort of pedagogical approach can be used in our paradigm to support the theoretical analysis, that is, to induce students to make the mental constructions proposed by the theory and to help them move from these constructions to understanding and knowledge of mathematics per se? Our response to these questions has been to design a pedagogical approach called the *ACE Teaching Cycle*. It is a methodology that makes use of cooperative learning and students writing computer programs. In this design, the course is broken up into sections, each of which runs for one week. During the week, the class meets on some days in the computer lab and on other days in a regular classroom in which there are no computers. Homework is completed outside of class. We have the students working in cooperative groups in all of these activities.

Following is a description of the three components of this structure with some indications of the pedagogical goals of each component and examples for the topic of coset.

Activities:

The course meets in a computer lab where students work in teams on computer tasks designed to foster the specific mental constructions proposed in the genetic decompositions of the course topics. The lab assignments are generally too long to finish during the scheduled lab and students are expected to come to the lab when it is open or work on their personal computers, or use other labs to complete the assignment.

In the abstract algebra course there were a large number of computer activities through which students could construct, on the computer, many of the basic processes and objects of elementary group theory such as: examples of binary operations, examples of groups; tests for closure, associativity, existence of an identity and inverses, and commutativity.

After some work with such constructs, the students were given a rather difficult task. They were asked to write a computer program that would accept a set and a binary operation that formed a group and return a new binary operation that could accept any of the four combinations of inputs that were either elements of the set, or subsets. This binary operation would then determine what the inputs were and, as they dictated, return the product (in the group) of the two elements, a left coset, a right coset or the set of all products of elements of the two sets.

This is an extremely difficult task for the students, but the program they must write is actually very simple. As a result, all of their struggles to get this program working correctly lead them to confront important mathematical issues and construct deep meanings for concepts related to cosets. Here is a program that solves this problem.

```
PR := func(G,o);
                return =func(x,y);
                      if x in G and y in G
                    then return x .o y;
                  elseif x in G and y subset G
                    then return { x .o b : b in y};
                  elseif x subset G and y in G
                    then return { a .o y : a in x};
                  elseif x subset G and y subset G
                    then return { a .o b : a in x, b in y};
                  end;
            end;
      end;

oo := PR(S5, comp);
GH := {{g .oo h : h in H } : g in G };
K .oo L;
```

In the last three lines, the program defines the new operation, computes the set of all cosets of the group G by the subgroup H and computes the coset product of the two cosets K and L.

Class:

The course meets in a classroom where students again work in teams to perform paper and pencil tasks based on the computer activities in the lab. The instructor leads inter-group discussions designed to give students an opportunity to reflect on the calculations they have been working on and further construct their own meaning for their mathematical

experiences. On occasion, the instructor will provide definitions, explanations and overviews to tie together what the students have been thinking about.

In the case of cosets, constructing the lines of the program that form left and right cosets leads, according to APOS Theory to students constructing in their minds a process conception of cosets. Returning the two cosets as the result of the operation fosters development of an object conception. Finally, writing code to form the product of all pair of elements from two cosets relates to de-encapsulating these objects back to the processes from which they came. There are also many other examples of constructions in this short program that relate to process and object conceptions of other mathematical entities such as group as object and binary operation as both process and object.

After writing and working with the above program **PR** students can find it meaningful when they are asked in class to talk in their groups about the possibility of the intersection of two cosets, the number of elements in a coset, and set of all elements that are in at least one coset. Each of these questions has a complete answer for which the formal proof is rather easy for students who have constructed meanings for all these ideas. It is not difficult for the instructor to lead a discussion that brings out, not only the facts, but reasonable proofs of what amount to the steps in a proof of Lagrange's theorem. Furthermore, the computer experiences lead many students to think about cosets as objects and the result of PR as a binary operation on them. In class, they are asked to consider if the group axioms are satisfied and the notions of normality and quotient groups emerge.

Exercises:

Relatively traditional exercises are assigned for students to work on in teams. These are expected to be completed outside of class and lab and they represent homework that is in addition to the lab assignments. The purpose of the exercises is for students to reinforce the ideas they have constructed, to use the mathematics they have learned and, on occasion, to begin thinking about situations that will be studied later.

In the above-mentioned papers by the RUMEC teams, the results are based on pedagogy that uses the ACE Teaching Cycle. In other studies (some of which we have mentioned here), other pedagogies supporting this theoretical perspective have been used by a variety of authors.

5 Gathering and analyzing data

Gathering and analyzing data in our approach is a complex matter. This is for several reasons. One reason is that as we indicated in Section 1, our analysis of data is both driven by and drives our theoretical analyses and possibly even the development of the theory itself. Another is that we do not feel that a choice between gathering quantitative or qualitative data is appropriate. In our view, the best research will combine the two forms of information. This introduces complexity both in the interaction of two different types of results and the special needs of qualitative research which can be less straightforward than quantitative investigations.

We have already discussed the interaction between data and theory in Section 1. Regarding the qualitative/quantitative approaches, we don't just use

both, but try to develop a synthesis of the two. For example, one can administer a written instrument to a large number of subjects. We do this at times and analyze the results statistically. But we also use such data in the following way. Often it is possible to partition a large number of subjects into a relatively small number of categories by putting together people in a category whose responses on the written instrument are similar. Then we can apply the more time-consuming and laborious
qualitative methods, such as in-depth interviews, to one or two representatives in each category. Our assumption is that the interview transcripts we obtain in this manner both tell us a great deal about the student being interviewed and are also, to a greater or lesser degree, representative of all of the students in the same group.

Another purpose of combining the two kinds of data is triangulation. An in-depth interview can bring out a perhaps unexpected phenomena that needs to be explained. One can use written instruments to prepare for an explanation for example by considering questions such as: With how many subjects does this phenomena occur? What are its variations? What relationships does it have to other features of the subjects? Triangulation is of course, of critical importance in qualitative research. In addition to using combinations of different forms of data, we also take advantage of the fact that research in this approach is generally conducted by a team. This allows us to have different people on the team interpret qualitative data independently. Some of our best insights have been obtained from discussions designed to resolve the inevitable differences in interpretations. Triangulation consist in that when several researchers can agree on an interpretation, its validity and reliability is enhanced.

Again returning to Section 1, we recall that our data, both quantitative and qualitative tries to answer two kinds of questions: Have the students made the mental representations that the instruction was designed to foster? and To what extent do the students appear to understand the mathematics? Of course, the critical issue for our approach is whether there seems to be a causal relation from the former to the latter. Without giving details, to complete our discussion of the example of cosets, Lagrange's Theorem and quotient groups, we can report that a very high percentage of the students who experienced the pedagogy described here appeared to construct strong conceptions of cosets as processes and objects. As a result, they performed very well on examinations, for example, most could prove
Lagrange's Theorem, and indicated in interviews a good understanding of it and related notions. The results for quotient groups were not so strong, but this is an extremely difficult topic at the undergraduate level and what we saw in our data was much better than one gets from traditional courses in abstract algebra. The interested reader can pursue these questions by looking at the large amounts of

information about all of the RUMEC studies that appears in Clark et al (In preparation).

6 Alternative approaches

We have taken the position in this paper that good research in undergraduate mathematics education *must* be based on one or another kind of theoretical perspective. There is value in making assertions of universality in full awareness of the existence of counter-examples. This is the situation here. We believe our assertion is true almost all the time and that is important. We also believe that there are, and should be, a small number of counterexamples and they are important as well. Between the two extremes of *always* using a theory and use one or not as seems most reasonable, we believe there is a middle ground. We suggest that a research program should always expect to use a theory and one should proceed without one only if there is compelling reason to do so. Moreover, one should be quite concerned if the latter occurs very frequently.

Here is one example of research conducted by a RUMEC team that did not involve a theory. In the work reported in Dubinsky & Yiparaki (in review), we were interested in understanding student difficulties in interpreting mathematical statements involving two quantifications, one existential and one universal. Such statements are at once among the most difficult for students to grasp and absolutely essential to understand modern mathematics. Our basic premise was that people are successful in interpreting such statements when the context has to do with phenomena, not from the world of mathematics, but from the world(s) that most people in our society can think about. We thought that if we could understand how people did this, we could use that knowledge to get them to apply the same thinking to mathematical statements. This was a purely exploratory study and there did not seem to be much sense to involving theoretical considerations, at least at first.

All of this worked and we feel that we learned a great deal from the study without using any theoretical analyses. What we learned, incidentally, was that in fact, people *do not* tend to understand statements about the standard world if they include two quantifiers Moreover, when they do, this understanding does not appear to transfer very well to mathematical contexts.

7 Conclusions

We do not have any definitive conclusions to which the considerations of this paper force us, or should force the reader. We do feel that we have made a strong case supporting a critical role, in research in mathematics education, for theoretical perspectives in general and APOS Theory in particular. Regarding the latter, we can say that its use seems to be increasing internationally. Indeed, there are at least 40-50 researchers throughout the world who are engaged in active research projects that make explicit use of APOS Theory. It is hard to say how

this compares with other theoretical perspectives. We can say, however, that we are obtaining results that may have some importance both for a basic understanding of learning advanced mathematical concepts, and for developing a basis for pedagogical reform that has the potential for making significant improvements in student learning. For this reason, we feel that APOS Theory and its applications deserve a place of some importance in the mathematics education enterprise.

Finally, we want to say that if the reader is at all convinced of the last point, or even curious about it, then he or she might be pleased to know that, in addition to the topics mentioned here, it seems that our approach can be applied to all topics in mathematics at the undergraduate level and at least some topics at the K-12 level. We have only scratched the surface and there is much to be done and plenty of room for more people to come in and see if this kind of approach makes sense to them and if the work might be something they would like to do.

Reflections on APOS theory in Elementary and Advanced Mathematical Thinking

David Tall

Mathematics Education Research Centre
University of Warwick, UK
e-mail: David.Tall@warwick.ac.uk

What are the processes by which we construct mathematical concepts? What is the nature of the cognitive entities constructed in this process? Based on the theories of cognitive construction developed by Piaget for younger children, Dubinsky proposed ***APOS*** *theory to describe how* ***actions*** *become interiorized into* ***processes*** *and then encapsulated as mental* ***objects****, which take their place in more sophisticated cognitive* ***schemas****. He thus takes a method of construction hypothesised in (elementary) school mathematics and extends it to (advanced) college/university mathematics. In this paper I respond to Dubinsky's theory by noting the need for cognitive action to produce cognitive structure, yet questioning the primacy of action before object throughout the whole of mathematics. Biological underpinnings reveal cognitive structures for object recognition and analysis. I use this to suggest that APOS theory has already shown its strength in designing undergraduate mathematical curricula but question its universal applicability, in particular in geometry, and, more interestingly, in the formal construction of knowledge from definitions to deductions in advanced mathematical thinking.*

Introduction

The purpose of this paper is to respond to the research forum presentation of Ed Dubinsky (Czarnocha et al, 1999) on APOS theory as "one theoretical perspective in mathematics education research". It is clearly more than this, offering a major contribution to mathematics education at the undergraduate level. Indeed, in the Calculus Reform in the United States in the late 80s, it formed the basis of the *only* curriculum project that had a coherent cognitive perspective.

My response will analyse APOS theory within wider realms of mathematical learning and thinking, in particular a comparison of its roles in various contexts in elementary mathematical thinking (EMT) and its extension to advanced mathematical thinking (AMT). (These acronyms were introduced by Gontran Ervynck who was responsible for the formation of the AMT Working Group at the Psychology of Mathematics Education Conference in 1985.) AMT referred initially to "mathematics learning and teaching at 16+" including the activities of mathematicians in research. The work of Dubinsky and his colleagues has focused on undergraduate mathematics (RUME), in particularly in developing suitable working practices (eg co-operative learning) and learning sequences (genetic decompositions) in a wide range of specific mathematical areas, including discrete mathematics, logic, calculus, linear algebra, group theory. In this paper I shall concentrate on the role of APOS theory.

The biological foundation of action-process-object-schema

I wish to begin by showing that the broad brush-strokes of APOS theory seem to have a deep underlying biological structure. Figure 1 shows a simplified model of three stages of brain development as a result of successive stimuli (which could be perceptual or reflective). Stage represents an external stimulus to neuronal group 1, which is sufficiently strong to fire neuronal group 2 but not group 3. The firing causes the link between 1 and 2 to become more sensitive for a period of hours or days (so that we are more likely to recall recent events). If the connection is reactivated, it becomes more easily fired until it reaches as stage where any excitation of 1 also fires 2. This *long-term potentiation* of the neuronal connections builds new structures. The combined strength of 1 and 2 may now cause group 3 to be excited, and so on. In this way an external stimulus can cause a firing between two states perceived initially as separate, then joined together, then part of more complex neuronal groupings that can fire in more complex situations. The broad action-process-object-schema therefore has a natural biological underpinning.

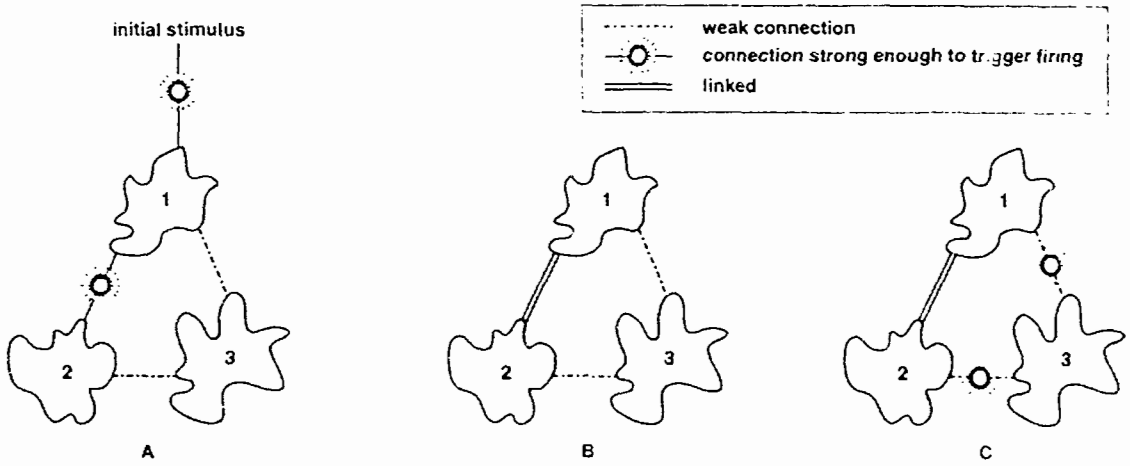

Figure 1: building memories in the brain by long-term potentiation (Carter, 1999, p. 160)

However, suppose that the first stimulus is a perception of an *object*. Then the same sequence of diagrams could represent a growing relationship with the properties of that object and the building of a more complex system of properties and connections. Both of these theories occur within the description of APOS in Czarnocha et al, (1999). There is a sub-sequence beginning with actions and moving to objects, and a further sub-sequence beginning with objects and moving to a broader schema.

The primacy of actions and objects

APOS theory begins with actions and moves through processes to encapsulated objects. These are then integrated into schemas—consisting of actions, processes and objects—which can themselves be encapsulated as objects. This suggests a primacy of action over object. At a fundamental level it absolutely clear that cognitive actions are required to construct cognitive objects. This I refer to as an application of "strong

APOS", in which the actions and processes are *any* cognitive actions or processes (conscious or unconscious), not just (conscious) mathematical ones.

However, even with this strong interpretation of the theory, the primacy of actions needs to be questioned. Dubinsky and his co-workers have made an impressive effort to formulate everything in action-process-object language. However, the urge to place this sequence to the fore leads to a description that, to me, soon becomes over-prescriptive.

The part of development that uses the triad theory of Piaget and Garcia (1983) moving from object to schema describes the initial object as "an encapsulated process" or a "thematized object" to maintain the primacy of the APOS sequence. The first stage of the triad, denoted *intra*, is simply described as "focus on a single object", followed by *inter* (study of transformations between objects) and *trans* (schema development connecting actions, processes and objects). Such a description (based on the language of action, process and object) seems to be at pains to avoid other more widely used terms such as "inter" including the study of *properties* of objects, or "intra" being concerned with *relationships* between them. The term "transformation" is one that I sometimes find impenetrable. Sometimes it has a mathematical meaning, but at others it seems obscure. In comparing the size of one object with another, is there a transformation of objects in some sense, or does the child just declare one is bigger because it pokes out beyond another?

APOS theory even formulates the notion of "permanent object" as arising through "encapsulating the process of performing transformations in space which do not destroy the physical object" (Dubinsky *et al.*, 1988, p.45). Thus the permanent mental object in the mind is created by a physical or perceptual action on an external object, to maintain the primacy of process over object.

Looking closer at the structure of the brain suggests a distinctly different scenario. The research of Hubel & Wiesel (1959) revealed single neurons in a cat's brains that respond to orientation of an edge. Similar experiments with other animals revealed the same phenomenon. In the brain of Homo sapiens, in addition to a specific area of the cortex that builds a point by point copy of the visual field, other brain modules specialize in a variety of analytic activities, including the perception of edges, orientation, movement, colour, binocular vision, and so on. Homo sapiens and many other creatures therefore have complex systems for the visual perception and analysis of *objects*. One may attempt to state that such objects only arise as the result of cognitive actions, and this use of *strong* APOS cannot be denied at a theoretical level. However, the practicalities of consciousness tell a different story. When an individual is looking at an object, the *conscious* experience is that of the object being seen, not of the multi-faceted unconscious processes by which the internal brain processes information.

Furthermore the brain has a highly subtle collection of modules to detect object properties. Recent research has shown that animals and very small babies have primitive brain modules that distinguish between one object, two objects, and perhaps more. This distinction occurs in babies at a far earlier age than Piaget's theories predict. (See "Piaget's errors, p.44 *et seq.* in Dehaene, 1997).

The primitive brain also operates in other ways that impinge on high mathematical and philosophical constructions. Lakoff & Johnson (1999, p.16) hypothesize that the primitive "embodied mind" plays a role in *all* our thought, including what may be perceived as logical deduction when brain modules sense such things as "inside inside" is "inside" (ibid, p.32). This occurs not through logical deduction but because the brain modules just observe that "it is". Furthermore, intuitive deduction occurs using "embodied arguments" such as the use of "prototypical" exemplars rather than strict quantification (ibid. chapter 7). The objects of the world and the embodied structures in the brain have a full role to play in learning and thought.

The previous discussion, whilst failing to deny the primacy of *cognitive* action to construct *cognitive* concept, indicates that the brain observes objects, and what seem to be primitive mathematical and logical concepts in ready-made brain modules. This seriously questions a rigid Action-Process-Object-Schema strategy in every curriculum. Even the APOS curriculum has sub-sequences building on objects.

APOS Theory in Elementary Mathematical Thinking

To see the relevance of APOS in mathematics, I begin with its source in EMT. Here Piaget spoke of three modes of abstraction: *empirical abstraction* from objects of the environment, *pseudo-empirical abstraction* from actions on objects in the environment and then *reflective abstraction* from mental objects.

Geometry includes many acts of empirical abstraction focusing on objects, beginning with an intra stage coming to terms with the nature of objects themselves. I contend therefore that geometry starts as an *object-based theory*. This is not to say that there are no processes—of course there are (drawing, measuring, constructing etc). However the focus of these processes is to gain knowledge about the objects themselves.

Concepts in geometry occur with many parallel activities involving physical interaction with the real world, but also, in a very real sense, they depend on the growing sophistication of language. Rosch's theory of prototypes (Rosch et al, 1976) shows that children first recognize "basic categories" such as 'dog', or 'car', only later moving to super-ordinate or sub-ordinate categories, such as 'poodle-dog-animal' or 'Ford-car-transport'. Such basic categories have properties that relate naturally to immediate perception. A basic category can be represented by a prototypical mental image; it is the highest level at which category members have similarly perceived overall shapes and the highest level at which a person uses similar motor actions for interaction with the members. The focus on a category of basic *objects* occurs naturally through a coherent combination of perceptions. I would contend here that it is the *object* that is the focus of attention, with the actions being the agents of that perception. It is only later, in a Van Hiele type growth (using a dialectic back and forth rather than a strict sequence of stages) that language used for description enables the conscious mind to build platonic objects such as lines with "no width" and "infinite extensibility".

On the other hand, the growth of knowledge in arithmetic and algebra begins with *pseudo-empirical* abstraction and hence more closely follows an APOS sequence. In counting, there is the action of repeating the number words and beginning to accompany

this by pointing at objects in turn. Later various learning sequences set up neuronal connections in the brain, routinizing the procedure, seeing it as a process when it is realised that different orders of counting the same set give the same number, and then "encapsulating" the process into the concept of number. In fact the encapsulation follows a sequence of counting "one, two three, four", then silently counting all but the last number, then saying just the last number without counting at all. Number names and number symbols play an essential role in this development.

I was utterly flabbergasted to see that *nowhere* in Czarnocha et al, (1999) is there a single mention of the word *symbol.* Symbols are at the heart of cognitive development of arithmetic (and later in algebra). They can be spoken, heard, written, read, used in action games and songs. They are the stuff that children work with. Indeed, those who focus more on the objects being counted than on the symbols for the counting prove to have much greater difficulties in later development (Pitta & Gray, 1997).

To develop a more elaborated theory to describe these phenomena, Gray & Tall (1994) formulated the notion of procept as follows:

> An *elementary procept* is the amalgam of three components: a process which produces a mathematical object, and a symbol which is used to represent either process or object.
>
> A *procept* consists of a collection of elementary procepts which have the same object.

The procept notion has strong links with APOS theory, but there are significant differences. We have always insisted on focusing on the cognitive structure itself and do not imply that the mathematical process involved must first be given and "encapsulated" before any understanding of the concept can be derived. For instance, in introducing the notion of solving a (first-order) differential equation, I have designed software to show a small line whose gradient is defined by the equation, encouraging the learner to stick the pieces end to end to construct a visual solution through sensori-motor activity. This builds an embodied notion of the existence of a unique solution through every point, with difficulties only occurring at singularities where the differential equation does not give the value of the gradient. It provides a skeletal cognitive schema for the solution process before it need be filled out with the specific methods of constructing solutions through numeric and symbolic processes. It uses the available power of the brain to construct the whole theory at a schema level rather than follow through a rigid sequence of strictly mathematical action-process-object.

Figure 2 shows a succession of uses of processes and concepts in symbolic mathematics (Tall, 1998). Arithmetic has computational processes, algebra has potential evaluation processes but manipulable concepts, the dynamic limit concept at the beginning of calculus involves potentially infinite computational processes that lead to the mental imagination of "arbitrarily small", "arbitrarily close" and "arbitrarily large" quantities. It is no wonder that so many students cling to the comfort of rote-learned finite rules of the calculus.

In Advanced Mathematical Thinking, students meet an entirely new construction: the axiomatic object in which the *properties* (expressed as axioms) are the starting point and the *concepts* must be constructed by logical deduction. Although (strict) APOS again can

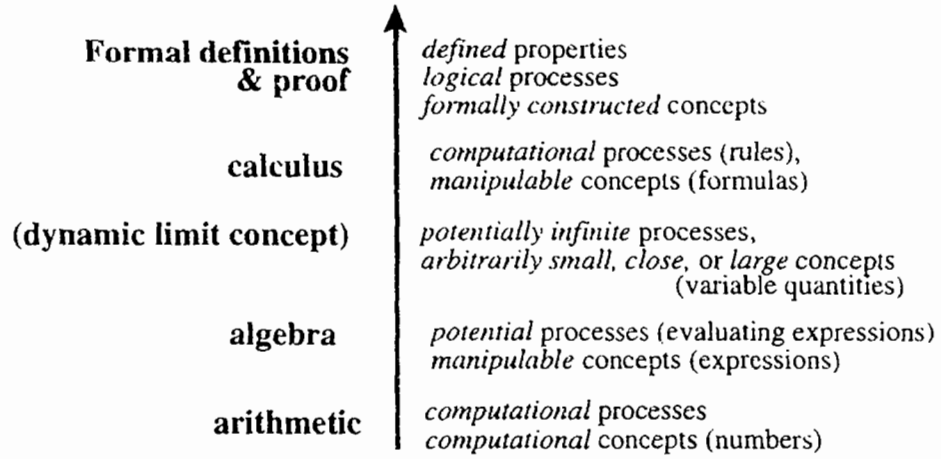

Figure 2: Development of process/concept in symbolic mathematics (Tall, 1998)

describe the learning processes (as it always will), there is a far more serious area of study in the relationship between embodied knowledge and formal deduction (Alcock and Simpson, 1999). Procepts are only of value here in certain aspects (for instance, in the element of a transformation group can be both process and an object), but the notion of group is not as it does not have a symbol dually representing process and concept. Is this a failure of the notion of procept compared with the broader application of APOS theory? Superficially, of course. However, the very fact that there is a serious cognitive reconstruction using symbols in formal mathematics in an entirely different way from the procepts of elementary mathematics suggests a chasm that many students have difficulty in crossing.

Dubinsky and his colleagues have a *brilliant* way of looking at the group axioms: formulate it as a function which outputs whether a set and its operation is a group or not. This to me is a fantastic solution (both in terms of computers and cognition). However, I still have serious concerns about the cognitive constructions made in such a sequence.

Different styles of Advanced Mathematical Thinking

One of my favourite quotations, which I have used often before, is the following:

> It is impossible to study the works of the great mathematicians, or even those of the lesser, without noticing and distinguishing two opposite tendencies, or rather two entirely different kinds of minds. The one sort are above all preoccupied with logic; to read their works, one is tempted to believe they have advanced only step by step, after the manner of a Vauban who pushes on his trenches against the place besieged, leaving nothing to chance. The other sort are guided by intuition and at the first stroke make quick but sometimes precarious conquests, like bold cavalrymen of the advanced guard. (Poincaré, 1913, p. 210)

The approach to the development of APOS is closer to Vauban than the bold cavalryman. As implemented it often begins with symbolic procedures or programming activities with visual activities coming later, if at all. Such a curriculum clearly can be of great value but I cannot help sensing we need to develop bold cavalrymen with insight, even if it is flawed for these leaps can be the stuff of future solid conquest.

There is such a difference between analysts who fear the fallibility of pictures and geometers or topologists that live by them. But this does not mean that either style is necessarily always superior:

> In the fall of 1982, Riyadh, Saudi Arabia ... we all mounted to the roof ... to sit at ease in the starlight. Atiyah and MacLane fell into a discussion, as suited the occasion, about how mathematical research is done. For MacLane it meant getting and understanding the needed definitions, working with them to see what could be calculated and what might be true, to finally come up with new "structure" theorems. For Atiyah, it meant thinking hard about a somewhat vague and uncertain situation, trying to guess what might be found out, and only then finally reaching definitions and the definitive theorems and proofs. This story indicates the ways of doing mathematics can vary sharply, as in this case between the fields of algebra and geometry, while at the end there was full agreement on the final goal: theorems with proofs. Thus differently oriented mathematicians have sharply different ways of thought, but also common standards as to the result. (Maclane, 1994, p. 190–191.)

Even though different approaches to research both end up with formal proof, the mathematical insights gained are very different. In a time of fast technological development, it is clear that we need our cavalrymen to make precarious advances as well as those who carefully operate safely step-by-step.

Pinto and Tall (1999) reveal a wide spectrum of thinking processes in undergraduate mathematics students including some who build meaning for definitions from their own experiences and others who take the definitions given by others and build meaning mainly by deducing theorems. The latter students seem more amenable to an action-based APOS course than the former, who build on a whole range of embodied cognitive constructs. Whilst cognitive actions are always necessary to construct cognitive concepts, is it providing a service to necessary diversity in human thought by restricting the learning sequence to one format of building mathematical actions, mathematical processes and mathematical objects?

Summary

Strict APOS can be used to formulate the idea that cognitive concepts must be preceded by cognitive operations. In this sense APOS theory is a "ToE" (Theory Of Everything). However, given that the learner has a wide range of embodied constructs in need of reflection and reconstruction, I contend that the accent on sequences solely built on action-process-object-schema distorts the wider enterprise. Figure 3 shows my own vision of the development of major themes in mathematics. APOS theory has many applications in the elementary mathematics of arithmetic, algebra, and calculus, but is of less relevance in the study of space and shape. In RUME the evidence shows its power in designing certain types of highly successful curricula. However, it is not the whole world. The varieties of thinking in professional mathematicians need an expression beyond that of the measured action-process-object-schema development. For instance, in my own approach to calculus, I begin not with the new process of programming functions in a computer language, but with the embodied visuo-spatial notion of "local straightness" which is then explored in parallel with the symbolic operations of differentiation. I welcome APOS as a major contribution to the understanding of mathematical cognition, but as a valued tool, not a global template.

TEACHING AND LEARNING LINEAR ALGEBRA WITH CABRI

Anna Sierpinska, Jana Trgalová, Joel Hillel, Concordia University, Montréal, Canada

Tommy Dreyfus, Center for Technological Education, Holon, Israel

Abstract: *The paper gives an account of a research program concerned with the study of computer environments in the teaching and learning of linear algebra. In an attempt to help students overcome the so called 'obstacle of formalism', we designed an entry to linear algebra based on a geometric model of the two-dimensional vector space within the dynamic Cabri-geometry II environment. We present (i) the theoretical framework of the research whose main ideas are the necessity of the use of 'multiple representations' in the learning of mathematics and the notion of quasi-fundamental situation, (ii) the methodology which is close to didactic engineering, and (iii) the design and its evaluation in terms of an analysis of discrepancies between the objects constructed by the students and the intended ones.*

1. Introduction

Our research program inscribes itself within the large domain of mathematics education which is concerned with the *design and study of the computer environments for human learning* ('environnements informatiques de l'apprentissage humain', Balacheff, 1998), whose main questions regarding mathematics learning are:

- How are the computer representations of mathematical objects related to the meanings of these mathematical objects in the mathematical theory?
- What should be the conceptual furnishings of the student's mind in order for him or her to interpret these representations not in phenomenological terms of what is happening at the interface between the user and the computer program but in terms of mathematical theory?
- Can the computer learning environment be designed so as to promote the development in the student, of such conceptual, rather than phenomenological, interpretations?

There is already an awareness in the mathematical community of the general 'disparity between mathematical conceptual structures and their software manifestations' (Burton & Jaworski, 1995, p. 8) and this phenomenon has been thematized in the concept of 'computational transposition' (Balacheff, 1993, p. 147). According to Balacheff (1998), the study of the transformations of meaning and of the epistemological status of objects in the computational environments should become an important field of research in mathematics education.

At the source of our research there lies the practical didactic problem of overcoming, in students of linear algebra, the quite widespread 'obstacle of formalism' (Dorier, Robert, Robinet & Rogalski, 1997). We have considered this obstacle as responsible for, among others, the notorious confusion of linear transformations with their matrix representations and lack of awareness of the

relativity of the matrix representations with respect to a basis (Hillel & Sierpinska, 1994). In order to overcome the obstacle of formalism, our idea was to design an entry into the topic of linear transformations using a definition of this concept condition, without, however, using only the discourse of the axiomatic theory in which vectors and linear transformations are nothing more than variables (e.g. 'let $\{v_1, v_2\}$ be a basis of a two-dimensional vector space'; 'let T be a linear transformation on V', etc.). We needed an informal way of speaking about vectors without immediately speaking about their coordinates.

The Cabri-geometry II environment appeared to provide us with some means to reach this goal: We have created a geometric model of the two-dimensional vector space where vectors are positions of points with respect to a fixed point called the origin and where to describe the position of a point one needs only two independent oriented directions and units in each direction. The arbitrary element of the vector space was represented, in Cabri, by an arrow - the Cabri 'vector' - whose tail was attached to a fixed point O and whose head could be dragged freely on the screen. Linear transformations were introduced as transformations preserving vector addition and scalar multiplication. Transformations in general were given, in Cabri, by representations of dependencies between two vectors: One 'free' vector would be put on the Cabri screen, labeled v, its image under a transformation would be constructed, labeled T(v), and all traces of the construction would be hidden. The construction would be recorded in Cabri as a macro and given a name. It would be possible to obtain images of vectors under the transformation by using this name. If a transformation was given this way, the only way to know whether the dependence between v and T(v) is linear was by checking the conditions of the definition.

Thus the Cabri environment appeared to make it possible for the students to achieve a more direct contact with the objects of the abstract theory without too quickly replacing these objects by computational procedures.

From the point of view of the idea of the relativity of the matrix representation of a linear transformation with respect to a basis, a very useful feature of Cabri is the possibility of creating systems of axes on an arbitrarily chosen pair of non-collinear vectors ('New Axes'). Moreover, the dynamic features (the dragging mode) of Cabri and the possibility of obtaining simultaneous geometric and arithmetic representations of vectors and linear transformations, supported our theoretical perspective on the role of multiple representations in grasping abstract mathematical objects.

An experimentation, with several groups of students, of a series of activities based on the above ideas, has shown, however, that our expectations are not easily realized. This problematized our approach and our use of the Cabri technology for the teaching of linear algebra. Since then our research efforts have been directed towards explaining the sources of the perceived discrepancies between our expectations and students' reactions to the designed activities.

2. Epistemological position

The theoretical framework underlying our research program is constructed on a set of *epistemological assumptions* (rather than psychological ones). A detailed presentation of this framework can be found in Sierpinska, Dreyfus and Hillel (1999).

Our main assumption is that there is no direct access to objects of scientific knowledge; scientific knowledge, by definition, is semiotically mediated. The development of scientific knowledge was triggered by the need to compare, order, and predict the behavior of objects whose identity, magnitude, appearance in time, etc. could not be evaluated with the use of the senses alone. Direct observation had to be replaced by the construction of technical instruments, and of systems of representation, notation and computation, as well as of theories containing means of the validation of inferences made on this basis. In the absence of direct access to an object, one of the main questions is: how can we tell whether two given representations are, in fact, representations of the same object? Each representation captures certain aspects of an object and ignores other aspects, and, therefore, the answer to this question is not obvious (for a thorough presentation and justification of this epistemological position, see Duval, 1998).

Much of the scientific effort is invested in the development and study of instruments and systems of representations. This is especially (but not solely) the case of mathematics. The objects of mathematics being theoretical objects, the question of their identity is a particularly delicate one.

We take mathematical objects to be the invariants in the reference of several semiotic representations (Duval, ibid.). In other words, we do not take them to be the contents of mental representations in the psychological subject, nor do we consider them as mind independent entities. One consequence of this epistemological position is the necessity of the existence of several representations of an object of knowledge. If there was only one, there would be no reason to distinguish between the object and its representation. A learner of mathematics can grasp an object of this knowledge only through working with several representations of this object, processing them and converting from one to another.

Some caveats are in order with respect to the above presentation of our theoretical perspective. We assume an independent existence of mathematical objects (independent of individuals' minds and social conventions), but we do not award mathematical objects any kind of absolute character. What is the object and what is its representation may well depend upon the context of the mathematical situation at hand. For example, in Analysis, an equation like $y=2x+3$ is usually the object and a straight line drawn in a system of coordinates is its geometric representation; but in Geometry the line will be regarded as the object and an equation like $y=2x+3$ as one of its possible representations relative to one of the many possible systems of coordinates. What accounts for the 'objectivity' of

mathematical concepts is their theoretical and systemic character (cf. Steinbring, 1998). The existence of mathematical objects is of a logical, not psychological or sociological order.

But, in taking this epistemological position, we are not denying that the processes of construction of mathematical knowledge do indeed have a psychological and social character. We are only saying that what we shall call 'knowledge' will be the *products* of these processes in the form of systems of signs and that we are interested in studying the internal logical coherence of these systems, their field of reference (i.e. the objects of the signs), and their relations and relevance with respect to other sign systems. As mathematics educators looking at groups of undergraduate students learning linear algebra under the guidance of a teacher, we study what is being said and written and drawn on paper or on a computer screen, in the aim of creating theoretical models of the sign systems used by the groups. Our analysis and evaluation of this model is done not in terms of the cognitive characteristics of individual students and the teacher as psychological subjects, nor of the nature of the social interactions in the group, but in terms of the mathematical and logical relations between the knowledge produced by the group and the 'intended knowledge' assumed by the didacticians who planned the teaching/learning activities. This is not to say that the impact of didactic phenomena such as 'contract didactique' or 'effet Topaze' (Brousseau, 1986a) on the knowledge produced by a group of students and a teacher is not taken into account. It is, but we require that this impact be described in terms of a mathematical model of the difference between the intended objects and concepts and the actually constructed objects and concepts.

3. Quasi-fundamental situations

The methodology of our research is close to (but not identical with) *didactic engineering* (Artigue, 1990; Artigue and Perrin-Glorian, 1991) in that (a) both the *a priori* decisions and the analysis following a realization of the design are founded on epistemological, cognitive, and pedagogical considerations, and (b) its methods of validation are internal, based on an interaction between the *a priori* and the *a posteriori* analysis, and not external, based on a comparison between experimental and control groups.

Didactic engineering methodology has been originally based on Brousseau's theory of didactic situations (Brousseau, 1997; Perrin-Glorian, 1994). Our design deviates from the classical applications, usually structured along the situations of action, formulation and validation. In Brousseau's theory, one of the basic distinctions is between didactic and a-didactic situations, and it is assumed that, for some important elements of mathematical knowledge, it is possible to construct a-didactic situations in which this target mathematical knowledge will emerge as an optimal solution to a problem for the students ('*fundamental situations*').

Considering that the specific character of linear algebra concepts (generalizing, unifying existing theory rather than tools for solving specific problems, see Dorier, 1995) does not allow for the construction of a-didactic, 'fundamental situations' in this sense, and acknowledging the importance of the 'didactic contract', we propose a somewhat different categorization.

We consider only didactic situations and we divide them into 'social' and 'cognitive' ones. 'Social didactic situations' are those based on a social contract; 'cognitive' ones are those based on a cognitive contract. In a social contract, the object of the negotiations between the students and the teacher are the social and institutional rules governing the process of following and passing a course within the given institution. The students' most frequent questions are concerned with the presentation of their solutions, e.g. 'Do we have to write the solution with these curly brackets, or is it enough to write x equals something?', or 'Do we have to justify our answer or is it OK if we just write the numbers?'. If a teacher 'teaches to the test', the contract is of this 'social' nature. In a cognitive contract, the object of the negotiations between the students and the teacher are the interpretations of the representations used in the communication of knowledge and the nature of the studied [mathematical] objects.

We shall call a didactic situation a '*quasi-fundamental situation*' (QFS) with respect to a given mathematical object if it has a high potential to evolve into a 'cognitive didactic situation' in which the nature of this mathematical object will not fail to be discussed. This does not mean that it has to evolve into such a situation for all students and in all circumstances. We do not assume any kind of 'epistemological necessity' or determinism in the development of knowledge. We admit that much depends on the students' attitude towards learning mathematics, their previous mathematical experience, as well as on the teacher's perception of the meaning of the subject matter. (For the presentations and discussions of the concept of fundamental situation, see Brousseau, 1986b; Berthelot et Salin, 1995; Legrand, 1996; Sierpinska, to appear).

4. The evolution of the research program

Our research program has been evolving within the framework described above since 1996. It is also then that the idea of using the Cabri-geometry software arose. From the outset, our work concentrated on the development, within this environment, of (a) a coherent system of representations of objects such as two-dimensional vector space, linear transformation, eigenvector, and (b) a set of activities and problems for the students using this system of representations. A sequence of experimental sessions with students was designed aiming at testing whether, in this linear algebra enriched Cabri environment students develop a better grasp of the mentioned mathematical objects than is usually the case in ordinary lecture style, paper and pencil setting.

The first experimentation took place early in 1997: There were 7 highly controlled sessions with only a pair of students, both after a college level vectors and matrices course. The students were working together, partly with a teacher, partly without his intervention. A computer with the enriched Cabri environment was always there and the students could use it whenever they wanted. Most, but not all, activities were to be done using the computer. The students' interpretations of the Cabri representations and the activities and problems turned out to be rather far from those that we had intended and expected, yet logically quite justifiable. Our *a posteriori* analyses concentrated on modeling the mathematical objects that appeared to emerge in the interactions of the students with the learning environment, and justifying them on the basis of, mainly, the characteristics of the representations and the activities and problems proposed to the students. The results of these analyses can be found in Sierpinska et al. (1999).

A second experimentation (spring 1998) was then prepared, based on a revised version of the previous design. Only five sessions were designed, focusing on those concepts about which there was the most confusion in the first experimentation: vector, basis, linear transformation and especially the notion that the values of a linear transformation on a basis determine the transformation completely. Three pairs of students worked each with a different teacher. The experiment was still very tightly controlled: The students were not given any materials to study outside of the sessions, and all their conversations were recorded. The *a posteriori* analyses of this experimentation concentrated, as before, on understanding the mathematical objects that have emerged in the interactions within the environment, but not so much on ways to improve the design of the representations, activities and problems. It appeared to us that some unintended interpretations are inevitable, whether due to the specificities of the Cabri environment or to the axiomatic nature of the linear algebra concepts, or to other reasons. We started thinking that, instead of trying to avoid them, we might capitalize on the didactic situations that bring them to light, and create follow up activities that would allow the students to become aware of these interpretations, and see the possibility of alternative ones.

This led us to the notion of the 'quasi-fundamental situations' and the preparation of the third experimentation focused on the development of these for the notions of vector, linear transformation and eigenvector. These situations had to be tested in an ordinary course context, not an experimental context, because in the latter, the risk of the evolution of a 'social type of contract' is rather unlikely (the situation may not even be perceived by the participants as a didactic situation). We chose a course in linear algebra for students preparing for a master's degree in mathematics education. The course, taught by A. Sierpinska, was titled 'Linear Algebra with Cabri and Maple' and lasted 13 weeks, at the rate of one 2 hour meeting per week. It took place in the fall term of 1998. It was only partly controlled (materials to study between classes and assignments were given, but the students' activities between classes were not recorded nor monitored). In the class,

or rather computer lab, the students were given worksheets in which they had to write the results of their activities with Cabri and solutions to problems. These worksheets were collected each week. The students were also writing diaries. At the end of the course, the students wrote a test. Nine students started the course, seven completed it. Two students dropped out, feeling unable to cope with the material and the pace of the course.

All these students had taken undergraduate linear algebra courses prior to entering the master's program. The course was not planned as a re-take of an undergraduate course; rather the students were supposed to experience this course both as students and as potential teachers of linear algebra courses at the college level. The aim was to help them see the presumably known concepts from a different perspective and judge of the potential or pitfalls of this technological approach for the teaching of college students. The course started with the notions of vector, operations on vectors and linear transformations like the previous experiments but then continued with the arithmetization of these notions: coordinates, change of basis, matrix representations of linear transformations, 'eigentheory' and its applications to dynamical systems.

The analysis of the outcomes of this last experiment is ongoing at the time of writing this text. So far, the analysis has focused on the potential of some of the designed situations to evolve into quasi-fundamental situations.

5. Samples of results

The results of our research comprise

- descriptions and justification of the didactic situations as designed;
- description of the students' behavior during the experimentation of the designed didactic situations;
- models of the mathematical objects constructed by the students; their analysis in terms of their inner consistency and possible differences between them and the intended mathematical objects; and possible reasons why the students constructed these objects;
- evaluation of the potential of some of the designed didactic situations to evolve into quasi-fundamental didactic situations.

The results reflect the foci of our experiments: the *a priori* analysis of the linear algebra-extended Cabri environment in the first experiment; models of the objects constructed by the students in the second, and the identification and study of the candidates for quasi-fundamental situations relative to the basic objects of linear algebra in the third.

In the sequel we present some samples of such results of our research. We omit an example from the first experiment, whose thorough description can be found in Sierpinska et al. (1999).

5.1 The second experiment: models of mathematical objects created by the students

The results of our research in relation to the second experiment are a product of a confrontation of an analysis of the students' behavior with our theoretical assumptions and expected behavior. We give here a sample of these results, focused on the concept of linear combination of vectors.

5.1.1 Overview of the design with respect to the notions of vector and linear combination

These concepts were addressed in the first two sessions. In the first session, the students became acquainted with a representation of the two-dimensional vector space, constructed in the dynamic geometry environment Cabri-geometry II. Vectors were introduced as models of translations in geometry and of forces in physics, and were represented by an arrow produced by the Cabri command 'Vector'. A scalar k was represented in Cabri by a variable point attached to a number line; its coordinate on this number line was the value of the scalar k. The first activities were aimed at focusing the students' attention on two characteristic features of a vector: length and direction, and at introducing the notion of equality of vectors. Then the convention of representing all vectors by arrows starting from the same point called the 'origin' was introduced. The second part of the session was devoted to the operations of addition and scalar multiplication defined on vectors. The operations were introduced by defining new vectors produced by Cabri macros 'Vector addition' and 'Scalar multiplication' respectively, and the students were asked to explore the properties of these new vectors. They were expected to focus on those properties that appeared as invariants of the representation when the given vectors and scalars were dragged around the screen. The notions of zero vector and opposite vectors were introduced at this stage.

The second session was devoted to the notion of linear combination. The linear combination of two vectors v_1 and v_2 was introduced algebraically as a vector $w = k_1v_1+k_2v_2$, where k_1 and k_2 are scalars. The students were asked to translate this definition into a Cabri representation of a linear combination and construct w on the screen. For this purpose, two number lines with variable scalars k_1 and k_2 were created on the screen and two vectors v_1 and v_2 starting from the origin were given. The students were then asked to explore the properties of a linear combination and examine special cases when one of the scalars is set to zero and when both scalars are equal to 1. In the next activity, the students were asked to put any vector u on the screen and express it as a linear combination of the vectors v_1 and v_2. This could be done by adjusting the scalars k_1 and k_2 so that the vectors u and $k_1v_1+k_2v_2$ overlapped. This activity aimed at creating an intuition that any vector in a two-dimensional vector space can be decomposed into a linear combination of two given non-collinear vectors. In the next activity, the students were composing and decomposing vectors on the Cabri screen as well as on paper. At the end of the

session, the students were asked to determine which vectors in the plane can be obtained as linear combinations of (a) one vector and (b) two non-collinear vectors and which vectors cannot be obtained. This question aimed at an intuition of the notion of basis in two dimensions.

5.1.2 Description and analysis of students' behavior with respect to the notion of linear combination

The design described above was experimented with three pairs of students who had not taken any linear algebra course yet, but some of them, one pair in particular, had encountered vectors in physics classes.

As we said above, a linear combination of two vectors v_1 and v_2 was defined algebraically as a new vector w given by the formula $w = k_1v_1+k_2v_2$. The invariant of this representation was intended to be *the sum of scalar multiples of v_1 and v_2*. The students were asked to construct a representation on the computer screen of a linear combination of two given vectors v_1 and v_2 stemming from the same point, using two scalars already on the screen. Following the formula, the students constructed first the scalar multiples k_1v_1 and k_2v_2, and then added these two together to obtain the vector w. To explore the properties of w, they were invited to move the scalars along the number lines and observe what happens to w. To help them identify the invariants of this dynamic representation, they were asked to connect by segments the endpoint of w with the endpoints of k_1v_1 and k_2v_2 respectively, thus obtaining a parallelogram with w as a diagonal. The intended invariant of the dynamic representation on the screen was: Linear combination of v_1 and v_2 as *a diagonal of the parallelogram built on vectors k_1v_1 and k_2v_2*.

As intended, the students were focusing on the parallelogram and its diagonal, however they seemed first to be overlooking its sides. The object 'linear combination of v_1 and v_2' became for them the sum v_1+v_2 with a specific property: *The lengths of v_1 and v_2 were variable and adjustable by the scalars*. This was the difference between linear combination and vector addition, the latter being defined for *vectors with fixed lengths*. The object that for the students was referred to by the term 'linear combination of v_1 and v_2' was '*a set of all vectors v_1+v_2, with v_1 and v_2 having fixed direction, but variable length*'. Such an object could only exist in the dynamic environment; in the paper and pencil context it was identified with the vector addition. In the activities to be done on the computer, such as expressing a given vector as a linear combination of two given vectors, the students were successful and it was impossible for a teacher to notice that the concept being developed in the students was not exactly the intended one. It was only revealed when the students were asked to find scalars k_1 and k_2 such that the linear combination $k_1v_1+k_2v_2$ is a zero vector. The task was to be done away from the computer. It is clear that, within the students' understanding of linear combination as being the sum, the only possible answer, when v_1 and v_2 are non-collinear, is that both vectors are zero, and when v_1 and v_2 are collinear, they are opposite to each

other. These were exactly the students' responses. This concept became even more transparent in the activity of decomposing a given vector w into a linear combination of two given non collinear vectors u and v. The students were able to solve this problem on the computer: They first constructed the linear combination of the given vectors using the values of scalars that were already on the screen, and then adjusted the scalars so that the linear combination and the given vector w overlapped. When they were presented the same problem on paper, they claimed that it was impossible to solve it because w could not be expressed as u+v and they said they '*don't have a scalar*' to adjust the lengths of u and v so as to make w the diagonal of the parallelogram on u and v.

We now analyze in more detail the activities of composing and decomposing vectors into a linear combination of two given vectors. These activities were to be done both on paper and with the computer. The composition of two given vectors into a linear combination did not present any difficulty for our students: all necessary information (vectors and scalars) was explicitly given in both environments, and the students knew 'what to do' with the givens. The students needed only to draw scalar multiples of the given vectors, using the given scalars, and then draw the sum of those multiples. On the other hand, the decomposition of a vector into a linear combination of two given vectors v_1 and v_2 is, in general, mathematically more difficult. This task cannot be done without thinking about the linear combination as an object described by its definition (rather than thinking about it as a sequence of things to do). One needs to, in fact, create the parallelogram whose diagonal is the vector to be decomposed, and express the sides of the parallelogram in terms of the given vectors, i.e. find the corresponding scalars. However, when working on the decomposition with the computer, one can easily bypass this difficulty and solve the problem via composition, by first constructing a linear combination w with scalars that are on the screen, and then adjusting the scalars to make w overlap with the vector to be decomposed. This approach had even been encouraged by the teachers in order to avoid the technical problems related to the accurate geometric construction of the parallelogram with Cabri. For this reason, only the decomposition on paper, where there was no other way of solving the problem, presented real difficulties for the students and thus allowed to reveal the students' understanding of linear combination.

As the students were working on generating vectors from a set of given ones, they developed other objects that were for them referred to by the term linear combination. For example, when asked which vectors can be obtained from two non-collinear vectors by way of linear combinations, the students first drew two vectors v_1 and v_2 stemming from the same point, perpendicular to each other, one horizontal, the other vertical, and they started generating the new vectors as follows: The vector v_1 being given, one can obtain all vectors on the line through v_1 using scalar multiplication. One can obtain the line through v_2 in the same way. One can also obtain the vector v_1+v_2 and the whole line through this vector. By symmetry of the figure that the students were drawing simultaneously, one can obtain the

vector v_1-v_2 and the whole line through it. One can then obtain the vector $v_1+(v_1+v_2)$ and the whole line through this vector. After that, the students concluded that all directions can be obtained, a vector in a new direction being obtained as a sum of any two given or previously obtained vectors, and any other vector in this direction being obtained by scalar multiplication. This object developed by the students and standing, for them, for a linear combination can be expressed by the formula '*$k(mv_1 \pm nv_2)$, where m, n are integers and k is a real number (scalar)*'.In this formula, mv_1 and nv_2 represent the additions of m times the vector v_1 and n times the vector v_2 respectively, and only $k(mv_1 \pm nv_2)$ represents the multiplication of the sum by the scalar k.

5.1.3 Possible reasons for the discrepancies between the expected and observed behavior

Reasons related to the graphical representation of linear combination. The processing of the graphical representation of a linear combination w of two given vectors on the screen (by changing the values of the scalars) made the students focus on the parallelogram whose diagonal was w, and the diagonal was for them associated with vector addition. Moreover, the way of decomposing a given vector w into a linear combination of vectors v_1 and v_2 in Cabri by first constructing any linear combination and then adjusting the scalars in an appropriate way, seems to have conveyed the idea that scalar multiplication occurring in the definition of linear combination is just a tool to control the length of the component vectors v_1 and v_2 to obtain the desired diagonal (sum).

Reasons related to some students' background in physics. As mentioned, one pair of our students were already familiar with vectors and operations on vectors, in particular vector addition, which they encountered in their physics classes. Indeed, they were often referring to vectors, even in an abstract context, as representing forces (e.g., one of these students described the sum of two vectors as a vector having '*the same force with the same effect with these two vectors*'). In physics, vectors usually represent forces applied to objects. Typical problems involving forces concern combining forces acting on an object to find the resultant force (which is in fact vector addition), or the converse, decomposing a given force into forces acting in given directions (decomposing a given vector into a sum of vectors). The fact that the forces are multiples of a unit force remains implicit in the sense that the unit force is never drawn in the diagram representing a composition or a decomposition of forces. In other words, the notion of linear combination is never explicitly encountered in physics. This fact might have been at the origin of the students focusing on the vector sum exclusively.

Reasons related to the student's 'elastic' view of vectors. From the students' behavior when faced with various problems involving the operations on vectors, it seems that while, for them, vector addition produces a new vector (in a new direction between the two components), this is not the case for scalar multiplication,

which just makes a given vector longer or shorter (elastic view). Such a conception of scalar multiplication goes hand in hand with the concept of linear combination as '*a set of all vectors* v_1+v_2, *with* v_1 *and* v_2 *having fixed direction, but variable length*'. In addition, it allows to explain the emergence of the concept of linear combination as a vector given by '$k(mv_1 \pm nv_2)$': in fact, the students were first generating new directions using the operation of vector addition, and then were making the new vector longer or shorter by scalar multiplication, thus obtaining the whole line.

5.2 The third experiment: the search for quasi-fundamental situations

Several of our candidates for QFS were designed so as to fully take into account the indirect access to scientific knowledge. We give two examples: A situation based on a game of communication ('jeu de message') and a situation in which the students are asked to find some information about an object in two cases: (a) the information can be almost directly read off a graphical representation; (b) the information can only be derived using analytical means (a definition, an equation, etc.).

Example 1. *A game of communication*

One of this type of situations was aimed at bringing to the students' awareness the need for a reference system in communicating the position of a point in a plane. This situation was meant to address the students' interpretation of vector as 'an elastic arrow' with no definite length nor direction, which we observed in the first and second experiment.

The students worked in pairs. Each member of the pair had a circle cut out of paper with its center marked and (a) nothing else marked, (b) one other point marked, (c) two more points marked. One of the students had to put a point in the circle and communicate its position to the other student in writing, without using drawings. The other student had to follow the instructions to reproduce the position of the point in his or her circle. In case of ambiguity, he or she would ask the first student additional questions. They had then to compare their circles. The rationale behind this activity was the following: A coordinate system is necessary only when the position of an object cannot be given by ostension. This is why, historically, the first coordinate systems were constructed in the areas of cadastral surveys, navigation and astronomy (Boyer, 1994). This situation did, indeed, bring an awareness, in all the students in the class, of the need for a reference system. Pairs did, however, differ in the number of attempts needed to obtain an unambiguous message, and in the degree of mathematical sophistication of the reference system they came up with. An interesting observation is that students used polar coordinate systems rather than Cartesian ones.

Example 2: *From reading an information off the screen to calculating it*

The concept targeted by this situation was that of the coordinates of a vector in a basis. The students were asked to put, on the Cabri screen, two non-collinear

vectors v_1 and v_2 stemming from the origin, and draw NEW AXES on them. They were asked to construct the vectors $w_1 = .5\ v_1 + .3\ v_2$ and $w_2 = .8\ v_1 - 2.3\ v_2$ and put NEW AXES on these vectors, as well. Next, the students were asked to put any vector u from the origin on the screen and find its coordinates in both bases $\{v_1, v_2\}$ and $\{w_1, w_2\}$. This task did not require any use of algebra. The coordinates could be read directly off the screen with the Cabri command EQUATION and COORDINATES. It was not even necessary to use the notion of coordinates of a vector in a basis. The notion of coordinates of a point in a system of axes was sufficient: In the latter the notion of linear combination is not necessary; the notion of unit of length is implicit and the coordinates are found by dropping parallels (and not by linear decomposition). However, an awareness of the process of dropping parallels is needed because the systems of axes created by the students were not orthonormal and were not in a horizontal/vertical position.

The next question required a very different approach: the students were asked to find the coordinates, in the basis $\{w_1, w_2\}$, of a vector u whose coordinates in the basis $\{v_1, v_2\}$ are (100, 85). A vector with coordinates of this magnitude could not be constructed could not be constructed on the Cabri screen and, consequently, its coordinates in the other basis could not simply be read off the screen. It was necessary to think in terms of linear combinations of vectors, and to use analysis: the vector u had to be written in two ways, as a linear combination of the vectors v_1 and v_2 with coefficients 100 and 80, and as a linear combination of the vectors w_1 and w_2 with unknown coefficients, x and y. Then these two representations would be equated. Using the relation between the vectors v_1 and v_2 and w_1 and w_2, and the independence of the vectors v_1 and v_2, a system of linear equations in two unknowns x and y would be obtained.

$$u = 100v_1 + 85v_2\ ,\ u = x\ w_1 + y\ w_2,\ w_1 = .5\ v_1 + .3\ v_2\ ,$$
$$w_2 = .8\ v_1 - 2.3\ v_2 \qquad (*)$$

$$(.5x + .8y - 100)\ v_1 + (.3x - 2.3y - 85)\ v_2 = 0 \qquad (**)$$

$$\begin{cases} .5x + .8y = 100 \\ .3x - 2.3y = 85 \end{cases} \qquad (***)$$

whence $x \approx 214.39$ and $y \approx -8.99$

The leap from the first to the second task was conceptually quite big, and all students experienced some difficulties with the latter. Some students solved the problem with the help of a hint from the teacher. The main topic of discussion with these students was why would one have to refer to the linear independence of the vectors v_1 and v_2 in solving the problem. For the students, the uniqueness of the representation in a basis was something obvious. They would naturally conclude from (**) that the coefficients should be zero, on the grounds that v_1 and v_2 are non-zero. But a few other students were directing their conversations with the teacher so that she tells them 'how to start', 'what to do'. One of these students found the correct coordinates for u, writing equations (*), (**), and (***) and

solving the last one, without any justifications between them. He then substituted these coordinates into the equation (**) obtaining '$v_1(0) + v_2(0)=0$'. His concluding statement was: 'v_1 and v_2 are linearly independent'. The reason why the student wrote this 'conclusion' could be that he overheard the teacher discuss the importance of the condition of linear independence of v_1 and v_2 in solving the problem with other students. He thus knew that this fact must be included in the solution; it was not important for him that putting it where he did, did not make sense from the point of view of the question in the problem. 'Making sense' was not his main concern; 'surviving the course' was.

In spite of the fact that three out of the nine students in the class were perceiving the situation as based on a social rather than on a cognitive contract when working on this task, we are willing to claim that the situation is a candidate for a QFS; not a QFS for the awareness of the importance of the condition of linear independence for the idea of basis, however, but a QFS for understanding the notion of coordinates of a vector in a basis. Some of the students' diary entries for this class give support to our conviction.

There were also other types of situations in our design with a strong potential to evolve into QFSs. One of them was based on the principle of sustained intellectual engagement in not just a simple task, but a series of related problems, whose solution requires the overcoming of some deeply entrenched obstacle. The series of problems which required students to extend a transformation of a basis to a linear transformation of the whole plane, belonged to this kind. Students had serious difficulties in solving these problems because they tended not to think about linear transformations analytically, in terms of the axiomatic definition, but synthetically, as a term referring to a kind of proportional change, or a name for transformations such as reflections, rotations, dilations etc. A description of the evolution of students' thinking in confrontation with one such problem can be found in Sierpinska et al. (1999). In the third experiment, not all students engaged in the intellectual challenge that these problems presented. But, those who did, achieved an understanding rarely encountered in the ordinary linear algebra courses.

~ * ~

The third experiment confirmed the inevitable character of some interpretations of the Cabri representations in students, but it has also pointed to the limitations of observations about the learning process that can be done in tightly controlled teaching experiments, limited in time and based on a small number of tasks. In particular, the time spent in the lab with the teacher could account for only a small part of the process of understanding the defining condition of linear transformations in the whole class experiment. Students were given a large variety of problems to work on between the sessions. The students reported being engrossed in some problems for the whole week between the sessions, working alone and with their peers, and even dreaming the solutions. Three weeks after the problem of extending a transformation of a basis to a linear transformation of the

whole plane was given in class, one student suddenly exclaimed: "It's been three weeks now that we have been working on it, and it's only today that it clicked into place. Now I don't even understand why I didn't see it before. Now it's so clear. And so beautiful". But the whole class experiment has also brought forth the fragility of the cognitive contract and the difficulty of maintaining it in an ordinary course, where the question of 'survival' in an academic program (as one of the students put it) may easily become more important than that of understanding.

We find the chosen direction of research promising because it leads to results which are relevant at the level of theory and methodology of research while making some products of the research (adapted descriptions of the didactic situations, with caveats concerning the possible unintended interpretations of the representations) accessible to those instructors of linear algebra who are not engaged in research themselves.

Finding the Student's Voice vs. Meeting the Instructor's Expectations

Uri Leron

Technion – Israel Institute of Technology

Reaction Paper to:

"Teaching and Learning Linear Algebra with Cabri"

by Anna Sierpinska, Jana Trgalová, Joel Hillel and Tommy Dreyfus

The topic under discussion can be decomposed into four levels, which I list from the bottom up:

A. Linear Algebra (LA);

B. The teaching and learning of (A);

C. The use of technology (specifically, dynamic geometry software; more specifically, Cabri II) in (B);

D. Research on (C).

In my reaction I will say something on each level. The remarks on the first two levels build up towards the last two levels, where the teaching and research issues raised by authors are explicitly discussed. It is convenient to arrange my observations around pairs of dual views that exist at each level.

Note: I use the abbreviation STHD to refer to both the paper and the authors.

A. Linear Algebra: Global-Geometric View vs. Local-Arithmetic View.

LA consists of a tight and powerful synthesis between two ubiquitous parallel threads: The Global/Geometric View (GGV) and the Local/Arithmetic View (LAV). GGV is a generalization and an abstraction from geometry of the 2-dimensional plane and the 3-dimensional space, especially in its vector representation. LAV is a generalization and an abstraction from the theory of linear equations in 2 and 3 unknowns. The LA synthesis is a generalization and an abstraction from analytic geometry, that is, the synthesis of geometry and algebra (of linear equations) developed by René Descartes in the 17th Century. The objects of GGV are usually given abstractly by postulating their defining properties; they include scalars, vectors, vector spaces, bases, dimension, linear transformations and the like. The objects of LAV are given concretely by specifying their form; they

include real numbers, linear equations, n-tuples and matrices over the real numbers (the restriction to real numbers is for convenience only). The synthesis is achieved by choosing a basis (analogous to coordinate system), and representing vectors by n-tuples and linear transformation by matrices relative to that basis. The power of the synthesis stems from the fact that this representation is an isomorphism between the two systems, preserving the corresponding operations (n-tuple or vector addition, multiplication by a number or scalar, and multiplication of matrices or linear transformations); thus all 'abstract' statements that are true in one system are automatically true in the other. [1]

B. Teaching and Learning Linear Algebra: Conceptual Understanding vs. Computational Facility.

Understanding linear algebra involves conceptual understanding (especially manifest in GGV), computational facility (especially manifest in LAV) and facility with the synthesis – the ability to move smoothly between the dual views, utilizing their complementary strengths and weaknesses: Some problems or theorems are much easier to solve or prove in one of the views than in the other, and some require clever combination of methods from both. Unfortunately, it is not easy to teach both views at the same time. Moreover, computational facility has traditionally been much easier to teach -- and test! -- than conceptual understanding; consequently, traditional lecture-based LA teaching has been much more successful with LAV than with GGV, even in classes where the instructor did aim at conceptual understanding. One reason for this unfortunate state of affairs is that students find computations with numbers and their derivatives (such as n-tuples and matrices) much easier than reasoning with abstract entities (such as vectors and linear transformations). Since in the early stages of learning LA students must work with some more-or-less concrete representations for the abstract entities, the traditional lecture-room instructor didn't really have much of an alternative.

C. Technology in Teaching and Learning of Linear Algebra: Finding the Student's Voice vs. Meeting the Instructor's Expectations

Modern technology has changed all this, since it has introduced new intermediate (computational) objects, new representations and new *interactive* ways to manipulate these objects. STHD give a beautiful example of these new possibilities, in using Dynamic Geometry software to enable students to manipulate 'pure' geometrical vectors, thus bypassing their 'arithmetical' representation via

[1] The last two sentences require some modification in case several vector spaces are involved

bases and coordinates.[2] Thus technology in principle enables STHD, in their role as teachers, to promote conceptual understanding, relative to what can be achieved in traditional LA teaching. The benefit of such a change is obvious – we all want our students to have a better and deeper understanding of mathematical concepts. But, as I explain below, this advantage does come with a price, and the instructor who aims for such understanding must be willing to pay the price.

First, learning for conceptual understanding is more time consuming than the usual more 'instrumental' learning, since students must go through a lot of *interaction*, socially and with the computational-mathematical environment, to allow for the necessary mental constructions to take place. Secondly, and for the same 'constructivist' reasons, conceptual understanding must come gradually by *successive refinement* [Leron & Hazzan, 1998] and, in intermediate stages along the way, students will inevitably form 'misconceptions' and 'mispractices' when judged by standard mathematical criteria. In particular, their computational facility and their performance on standard tasks and tests may be expected to temporarily lag behind. This should be no cause for alarm; on the contrary, students' urge to 'debug' their computational products can be a powerful engine for ascending to the next stage in the sequence of successive refinements. This urge can come about spontaneously or by appropriately designed activities, as seems to be the direction STHD have aimed at in the third phase of their research. Indeed, the authors' *Quasi-Fundamental Situations* may be just that – a situation which affords students feedback on their computational constructions in such a way that they can find and eliminate bugs in their software products and in their thinking (signaled by a feeling of surprise which results from a clash between their expectations and the feedback from the computational environment). The need to pay this price forms in my experience a major obstacle in practical implementations of such computational environments and the attendants teaching methods, since most undergraduate math faculty, who do not usually subscribe to 'constructivist' beliefs on learning mathematics, will not be willing to pay it.

With this background, it seems to me that STHD in their second experiment, having clearly aimed at conceptual understanding of their LA students, and having designed a beautiful computational environment for achieving it, were not fully ready to pay the necessary price. My (admittedly tentative) reconstruction of the educational situation, based on the description in section 5.1 of the STHD paper, consists of the following observations.

[2] Other examples of using of technology in teaching undergraduate algebra, utilize student activities in a Computer Algebra System such as Maple [Dreyfus and Hillel, 98; Hazzan *et al.* 98], or a programming language such as ISETL [Meunch, 93; Leron & Dubinsky, 95].

- By emphasizing GGV via the Cabri environment, STHD have in effect chosen to promote more conceptual understanding of their students (relative to computational facility) than conventional LA instructors do.
- The total duration of the teaching episodes in the second experiment was too short to expect a solid conceptual understanding to emerge, except for very bright students.
- In the intermediate stages, the students should have been *expected* to temporarily be less facile with computational procedures and to form 'misconceptions' concerning the mathematical objects and operations involved.
- STHD's research agenda has got the better of their teaching agenda, leading them to an over-pessimistic view of their students' achievements and preventing them from exploiting the full potential of their innovative teaching design. This claim is based on their research results and is explained more fully in the next section.

D. Research on Technology in Teaching and Learning Linear Algebra: Clean Research vs. Messy Reality

The educational researcher, in trying to describe the messy reality of teaching, learning and the classroom, is pulled in opposite directions by two ideals: producing clean, solid, 'scientific' research on the one hand, and giving a *faithful* (or *viable*) description of the educational situation under study on the other. Since clean research cannot faithfully account for messy reality, there really *is* a conflict between the two ideals, and striking an appropriate compromise is basically a *value* choice, not a scientific one. Since this is a matter of values, I cannot really argue with the authors, only state my own preference, which leans a bit more in the 'messy' direction.

I believe that the authors by choosing an epistemological, not psychological or social definition of mathematical objects, and by choosing to compare the intended objects with those constructed by the students, rather than to look at the *process* of construction, have obtained a relatively clean and solid research, but one that gives (to my taste) a not quite satisfactory view of the educational situation. Instead, I'd like to offer an alternative interpretation of their data.

The different analysis stems from three sources. First, I take a psychological and social view of mathematical objects (similar though not identical to Hersh's [97] *humanist* philosophy of mathematics), rather than the authors' 'purely' epistemological one. Secondly, I focus on the *process* involved in students' constructions, rather than comparing endpoints (the researchers' intended objects vs. the student-constructed ones at a fixed point in time). Thirdly, and most importantly, I bring in an interpretative approach to students' productions as

described in [Confrey, 94]: "It recognized that students' views are not simply inadequate or incomplete adult views, and it allows for the reconceptualization of the mathematical content of the expert in light of student invention." Indeed, this approach enables me to see in the students' constructions a source for *new mathematical insight*, rather than a cause for disappointment. I will now go into some detail in order to explain and substantiate my claim.

STHD present a very clear and insightful analysis of the kind of understanding (enabled by the Cabri environment) that the students *did* form. They describe the students' 'elastic' view of scalar multiplication, which has led to the "concept of linear combination as '*a set of all vectors* v_1+v_2, *with* v_1 *and* v_2 *having fixed direction, but variable length*'"(italics in the original). I claim that the students' intuitions in fact were very much in line with a mature mathematician's intuition: the elastic view and the resulting interpretation of linear combinations is pretty much the intuition behind the powerful notion of *decomposing a vector space as a direct sum of two subspaces*. In this view each vector in the 2-dimensional space is represented (uniquely) as a sum of two vectors, each taken from one of the 1-dimensional subspaces. It is quite natural then, and quite powerful too, to view the first vector as a variable vector, with variable components ranging over the respective subspaces. This is the GGV version of the LAV version of representing a vector as a linear combination of two vectors. Since the teaching design used Cabri to promote GGV, it is quite natural -- and welcome! -- that this view indeed emerged in student's intuitions. A mature mathematician can of course easily see the equivalence of the two representations and shift from one to the other as needed. Given the limited time of the experiment, the students simply didn't get there *yet*. But with proper planning, enough time, and a different set of expectations, I see the STHD approach and the result of their experiment as very promising in ways which are very hard to achieve with traditional tools and methods.

Interweaving the Training of Mathematics Teacher-Educators and the Professional Development of Mathematics Teachers

Orit Zaslavsky and Roza Leikin

Technion – Israel Institute of Technology

In this paper we present a study conducted within the framework of an inservice professional development program for junior high and secondary high school mathematics teachers. The focus of the study is the analysis of powerful processes encountered by the staff members, which contributed to their growth as teacher-educators. We offer a conceptual framework to think about becoming a mathematics teacher-educator.

The Setting

In the past decade there have been several calls for reform in mathematics education that are based on the assumption that well prepared mathematics teacher-educators are available to furnish opportunities for teachers to develop in ways that will enable them to enhance the recommended changes. Unfortunately, there are hardly any formal programs that provide adequate training for potential mathematics teacher-educators, let alone research on becoming a mathematics teacher-educator.

The work described in this paper was conducted within the framework of a five-year reform-oriented inservice professional development project ("Tomorrow 98" in the Upper Galilee) for junior and senior high school mathematics teachers. The goals and design of the project were very much along what Cooney (1994), Cooney and Krainer (1996), Comiti and Ball (1996), and Borasi, (1999) suggest as essential components for teacher education programs. They were inspired by *(a)* Constructivist perspectives of learning (von Glaserfeld, 1991; Kilpatrick, 1987; Davis, Maher, & Noddings, 1990). *(b)* Jaworski's (1992, 1994) teaching triad. *(c)* theories of reflective practice, which are addressed by Jaowrski (1994, 1998), Calderhead (1989), Gilbert (1994), Krainer (1998), Simon, (1994) and Borasi (1999); and *(d)* theories on social aspects of teaching and learning (Adler, 1998; Lave and Wegner, 1991; Rogoff, 1990; Leikin and Zaslavsky, 1997; Winbourne & Watson, 1998).

Thus, the project goals included the following:

- Facilitating teachers' knowledge (both mathematical and pedagogical) in ways that support a constructivist perspective to teaching;
- Offering teachers opportunities to experience alternative ways of learning (challenging) mathematics;
- Preparing teachers for innovative and reform oriented approaches to management of learning mathematics (particularly, the kinds with which they have had very limited experience);
- Fostering teachers' sensitivity to students and their ability to assess students' mathematical understanding;

- Promoting teachers' ability to reflect on their learning and teaching experiences as well as on their personal and social development;
- Enhancing teachers' and teacher-educators' socialization and developing a supportive professional community to which they belong.

The teachers who participated in the full program took part for four consecutive years in weekly professional development meetings, six hours per week, throughout each school year. In the first year there were two groups of about 20 teachers each, one group of junior high school teachers and the other group of senior high school teachers. In the second year most of the teachers continued and another two new groups began. In the third year again another two groups began. By the fourth year some teachers switched from full participation to monthly meetings. Altogether, about 120 teachers participated to some extent in the program. The meetings consisted of a wide range of activities led by the project team. Some of the teachers gradually became more involved in the program and towards their third year assumed responsibility for many of these activities. As the program progressed, the location of the activities shifted from a central regional location into the schools in the region.

The project team consisted mainly of experienced and highly reputable secondary mathematics teachers. The team members varied with respect to their expertise and experience. None of them had any formal training (such as the Manor Program reported by Even (1999)). Some did not have any previous experience in mentoring or teaching other teachers. Consequently, the project was designed to enhance the development of the project team hand in hand with the development of the inservice teachers who participated in the program. The design of both the staff enhancement component of the project and the research that focused on the staff members' professional growth stemmed from the project's goals, and was based on two main assumptions: *(a)* Similar to the ways in which teachers learn through their own (teaching) practice (Mason, 1998; Steinbring, 1998; Brown & Borko, 1992; Leikin, Berman, & Zaslavsky, forthcoming), teacher-educators learn through their practice. *(b)* There are learning aspects that are fundamentally inherent to the structure and nature of the community of practice which the project team constitutes (Adler, 1998; Lave, 1996; Roth, 1998; Winbourne & Watson, 1998).

This paper focuses on the professional development of the staff members as teacher-educators within the context of the project. We analyze some powerful processes in which the project team engaged as they became more proficient, and the conditions that contributed to their training and professional growth as a community of teacher-educators.

Conceptual Framework

The design of the program of the project as well as the research that accompanied it, were driven by constructivist views of learning and teaching. According to this perspective, learning is regarded as an ongoing process of an individual or a group trying to make sense and construct meaning based on their experiences and

interactions with the environment in which they are engaged (von Glaserfeld, 1991; Kilpatrick, 1987; Davis, Maher, & Noddings, 1990). The constructivist view applies to any learner regardless of age and context. It follows that teachers and teacher-educators can be seen as learners who continuously make sense of their histories, their practices, and other experiences.

In order to prepare teachers to teach in reform-oriented ways (such as suggested by NCTM, 1989, 1991, 1995), there is much they need to "unlearn" (Ball, 1997). The reform of mathematics teaching requires that teachers play an active role in their own professional development (Grant, Hiebert, & Wearne, 1998). Grant et al. raise the issue that until now teachers were only told about the new ways in which they are expected to teach, but did not experience these ways of learning and teaching. Thus, "teachers must make sense of proposed changes in the context of their own prior knowledge and beliefs about teaching, learning, and the nature of the content being taught" (p. 218, ibid.). In order to help teachers see new possibilities for their own practice they must be offered opportunities to *(a)* learn challenging mathematics in ways that they are expected to teach; *(b)* engage in alternative models of teaching (Cooney & Krainer, 1996; Ball, 1997; Grant et al., 1998; Malone & Taylor, 1992; Brown & Borko, 1992). Thus, the main task of the project staff members was to offer such opportunities for the participating teachers.

Providing the above kinds of experiences for teachers is not sufficient. It is also necessary to emphasize "a reflective component of inservice programs in which teachers explicitly consider the implications of their own learning experiences for their teaching and for creating contexts in which pedagogy and content are intertwined in a reform minded way" (Cooney and Krainer, 1996, p. 1162). Taking the stand that reflection is a key issue in teachers' and teacher-educators' learning, many elements of the program were incorporated in order to enhance reflection and self-analysis of both the participating teachers and the project staff. Similar to aspects of reflection such as those that Simon (1994), Krainer (1998), Borasi (1999), Tzur (1999) discuss, and depending on the situation, reflection in our study involved various aspects, e.g., the mathematics in which the teachers or teacher-educators were engaged, pedagogical considerations, implications for students' learning, or accounts concerning one owns practice and growth.

Jaworski (1992, 1994) offers a teaching triad, which is consistent with constructivist perspectives of learning and teaching. The triad synthesizes three elements, which are involved in the creation of opportunities for students to learn mathematics: The management of learning, sensitivity to students, and the mathematical challenge. Although quite distinct, these elements are often inseparable. Jaworski claims that "this triad forms a powerful tool for making sense of the practice of teaching mathematics" (1992, p. 8). We borrow the idea of this teaching triad for describing in a general way the tasks of the different groups of mathematics educators who were involved in the study, as well as for analyzing and discussing our findings.

In the current study, there were three different groups of mathematics educators: The teachers who participated in the program, the project staff members who were the teacher educators, and the project-director/leading-researcher (the first author of this paper), who can be seen as a teacher-educators' educator. We describe some similarities and differences between mathematics teachers (MT), mathematics teacher-educators (MTE), and mathematics teacher-educators' educators (MTEE), with respect to two aspects of their work: ***Task*** and the ***Context*** within which they carry out their Task (see Table 1). By Task we refer to the teaching triad relevant to each group.

Group of Mathematics Educators	**Task**			**Context**
	Manage Learning of:	**Be Sensitive to:**	**Provide Challenging Content in:**	
Mathematics Teachers (MT)	Students		Mathematics	Classroom Settings ...
Mathematics Teacher-Educators (MTE)	Teachers (MT)		Mathematical Challenge Management of Students' Learning ⟷ Sensitivity to Students	Classroom Settings **Workshops for MT** Individual Mentoring Staff Meetings of MT University Courses ...
Mathematics Teacher-Educators' Educator (MTEE)	Teacher-Educators (MTE)		Mathematical Challenge Management of Teachers' Learning ⟷ Sensitivity to Teachers	**Workshops for MT** **Workshops for MTE** **Staff Meetings of MTE** **Individual Mentoring** University Courses ...

Table 1: Tasks and Contexts of Different Groups of Mathematics Educators

The main task of all three groups has to do with managing learning, being sensitive to the learner and providing challenging content. The intended learners are different for each group. For a MT's task the learners are students, for a MTE's task the learners are teachers (or prospective teachers), and for a MTEE's task the learners are teacher-educators (or prospective teacher-educators).

The target learning content for which challenges should be provided also varies from one group to another. The task of MTs requires challenging mathematics. The task of MTEs requires challenges regarding the three components in Jaworski's teaching triad (see second row in Table 1). However, with respect to challenging mathematics, they need to address the needs and interests of both MTs and students. The task of MTEEs

requires challenges regarding the contents that MTs and MTEs should challenge (first and second row in Table 1), and in addition, they need to provide challenges concerning a similar triad. This triad consists of challenging mathematics for MTEs, sensitivity to MTs, and management of MTs' learning (third row in Table 1). This conveys the hierarchical nature of the content that plays a role for each group. It should be noted that the content relevant for a particular group is accumulative and includes the contents of the groups in the previous rows.

All tasks are influenced by the context in which the learning is managed. Table 1 presents the most commonly recognized contexts for each group. Those that were central to the current study are in bold.

Similarly to the ways in which teachers gain expertise in teaching as a result of their own teaching practice, an important element in becoming a mathematics teacher-educator entails experiences in facilitating the learning of mathematics teachers. Table 1 conveys this learning-through-teaching process that teachers often encounter (Mason, 1998; Steinbring, 1998; Brown & Borko, 1992; Leikin et al., forthcoming). A teacher (MT), by teaching (students) mathematics and reflecting on it, may develop his or her awareness and knowledge with respect to the teaching triad. Similarly, a teacher-educator (MTE), by gaining experience in providing opportunities for teachers to develop their knowledge in the three domains comprising the teaching triad (in the second row), is likely to become more knowledgeable of the three domains with respect to teacher learning (in the third row). Thus, learning-through-teaching is reflected in Table 1 by moving from one row to the content in the subsequent row.

Steinbring (1998) suggests a model of teaching and learning mathematics as autonomous systems. According to this model, the teacher offers a learning environment for his or her students in which the students operate and construct knowledge of school mathematics in a rather autonomous way, by subjective interpretations of the tasks in which they engage and reflection on their work. The teacher, by observing the students' work and reflecting on their learning processes constructs an understanding, which enables him or her to vary the learning environment in ways that are more appropriate for the students. Although each system is autonomous, the students' learning processes and the interactive teaching process, the two systems are interdependent. This interdependence can explain how teachers learn from their teaching.

We adapt our interpretation of Steinbring's model to help us think about and offer explanations to some ways in which mathematics teacher-educators may learn through the learning offers which they provide for teachers. It should be noted that mathematics teacher-educators interact with mathematics teachers in many different ways and settings. Thus, this model does not equally apply to all settings. It applies mostly to those that are structured as workshops for teachers and resemble to a certain extent the learning settings in school. According to the modified model, mathematics

teacher-educators offer learning experiences for mathematics teachers. As shown in Table 1, the content of these learning experiences includes many aspects of teachers' professional knowledge, in which mathematics is one of the components. The teachers work on the learning tasks, make sense of them and construct meaning in subjective ways. The problems that they solve may be mathematical, pedagogical or both. By reflecting on and communicating their ideas, teachers develop their professional knowledge. The teacher-educators, by observing the teachers and reflecting on the teachers' learning processes become aware of subtle aspects of their own knowledge, assumptions and practices and of the teachers' interpretations and needs. Consequently, they modify the learning offers for the teachers.

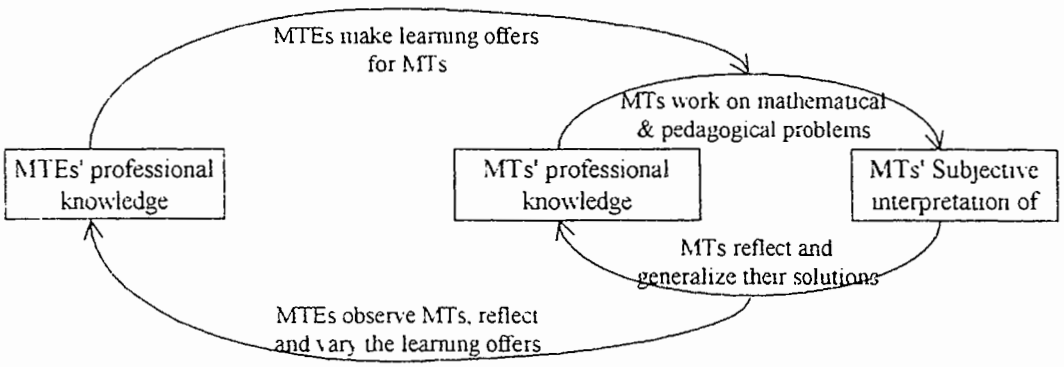

Figure 1: A Modification of Steinbring's Teaching and Learning Model (1998, p. 159)

As mentioned above, the model presented in Figure 1 may account for some ways and aspects of teacher-educators' growth. There are other aspects of the development of teacher-educators that can be better explained in terms of their participation in a community of practice (Lave & Wenger, 1991; Lave, 1996; Adler, 1998; Roth, 1998), where members learn from each other's expertise in an apprenticeship manner (Rogoff, 1990): "Vygotsky's model for the mechanism through which social interaction facilitates cognitive development resembles apprenticeship in which a novice works closely with an expert in joint problem solving in the zone of proximal development. ... Development builds on the internalization by the novice of the shared cognitive process appropriating what was carried out in collaboration to extend existing knowledge and skills." (ibid., p. 141). As mentioned earlier, the community of teacher-educators in the project was heterogeneous with respect to their prior experience and expertise. Thus, similarly to the mechanism, through which cognitive development is facilitated in social contexts, there are aspects of professional development of (teachers and) teacher-educators which resemble apprenticeship. Consistent with this perspective, the design of the project incorporated, for example, many opportunities for staff members to observe, participate in, and reflect on learning activities offered to teachers by more experienced staff members including the project director.

Methodology, Data Collection and Analysis

The methodology employed in the study followed a qualitative research paradigm in which the researcher is part of the community under investigation. It borrows from Glaser and Strauss's (1967) *Grounded Theory*, according to which the researcher's perspective crystallizes as the evidence, documents, and pieces of information accumulate in a dynamic process from which a theory emerges. The methods, data collection and analysis grow continuously throughout the progressing study. The researcher acts as a reflective practitioner (Schön, 1983) whose ongoing reflectiveness and interpretativeness are essential components of this type of research (Erickson, 1986).

The project was carefully documented. In order to investigate the development processes of the team members, and to be able to draw connections to the development of the participating teachers, a number of means and sources of documentation were employed. It should be noted that some of the means contributed in themselves to these processes (e.g., responding to the written questionnaires and being interviewed stimulated reflection and influenced the awareness to many aspects of their professional and private lives).

The documentation included:

- Interviews with the team members and with the participating teachers fostering their reflection on their personal professional growth and its connection to the project's goals and to the various activities in which they engaged;
- Written questionnaires for the staff members addressing the influence of their work in the project on various aspects of their lives, and the characteristics of the environment to which they attribute such influence;
- Self and peer reports on and analyses of the activities with the teachers;
- Videotapes of workshops with teachers;
- Videotapes and protocols of the project team's meetings and mini-conferences;
- A documentary film about the project;
- Resource materials developed by the project members.

Based on Bell & Gilbert's (1994) findings indicating that professional growth (i.e., developing ideas and actions) is interconnected to personal growth (i.e., attending to feelings) and social growth (i.e., developing collaborative ways of relating to colleagues) we looked for indications of these three aspects of growth. Other researchers have found similar evidence (Even, 1999; Halai, 1998). In addition to the three aspects of growth which Bell and Gilbert identify, they also point to three main stages in teachers' growth, which are consistent with more detailed stages that Jones et

al. (1994) describe. These stages were helpful in interpreting the data, particularly with respect to the differences between the group of teachers and the staff members.

Our conceptual framework guided our analysis of the professional growth of the staff members. We looked for evidence of growth associated with mathematics challenges, sensitivity to teachers, and management of teachers' learning. In addition, we looked for indicators of professionalization and professionalism in Nodding's (1992) terms.

The Project Team

As mentioned earlier, the project team consisted of people with diverse expertise, which is one of the characteristics that Roth (1998) considers essential to a community. Although there were altogether over 20 team members, only 14 were involved in the project from its early stages until its completion. The latter formed the focal group for our study. All members had experienced teaching mathematics for a number of years (they varied between 4 to 30 years of experience). Ten members continued teaching junior high or senior high school mathematics in addition to their work in the project. Of the above 14 members, at the beginning of the project there were only 6 members who had had some previous experience in managing inservice professional development activities for mathematics teachers. Three of the members had had experience in incorporating technology in innovative ways in the mathematics classroom. One member was competent in implementing cooperative learning methods in mathematics classrooms and inservice workshops for teachers. One member was particularly knowledgeable about new trends of assessment in mathematics education. Two members had had experience in curriculum development. One member was a practicing mathematician. Thus, it was expected that as a team, many elements underlying the calls for reform would eventually be addressed, although at the initial stage only 3 members were familiar with the NCTM Standards (1989, 1991) or similar calls for reforms. It should be noted that at the early stages of the project most of the project team members seamed to hold a transmission metaphor of the teaching-learning process. In addition, they found it hard to reflect on their work, let alone elicit reflection of the teachers.

In the first three years of the project, the tasks of the staff members were mostly directed toward designing and carrying out inservice workshops (see the second row in Table 1). Some were in charge of the inservice activities with the teachers, and others facilitated the activities by participating in the weekly inservice meetings or by assisting in the preparation of resources that were required for the inservice meetings.

It should be noted that at the beginning of the project there were many staff members who were not very confident of their qualifications as teacher-educators, and expressed a need for guidance by the project director or other relatively experienced members. From the very beginning it was clear that it would be a long term project. Thus, the staff members expected to gain expertise as teacher-educators within the framework of the project, in order to become more capable in their work. It was only

towards the end of the project that several staff members considered assuming the role of mathematics teacher-educators within other frameworks.

As mentioned earlier, the project director assumed the role of teacher-educators' educator (MTEE) in various ways (in later stages, an expert mathematics teacher-educator shared this role with the project director).

Components Designed to Contribute to the Development of the Team Members

As mentioned earlier, the main task of the staff members was to design and carry out weekly workshops and related activities with the inservice teachers. Contrary to the task of a mathematics teacher, who teaches according to a rather specific mathematics curriculum, there was no readily available and agreed upon curriculum for inservice programs. From the start, the stated goals of the project called for considering the teaching triad (Jaworski, 1992, 1994). The decisions regarding the mathematics, the teaching strategies, and the aspects of students' learning that should be addressed required analysis and self-reflection of the staff members with respect to their teaching experience in school. Translating these (content-oriented) decisions into powerful activities for teachers entailed considerations with respect to: *(a)* teachers' backgrounds and interests; (2) appropriate ways to manage teachers' learning and foster their development. All workshops were accompanied by resource material, which was developed or adapted by the staff members.

Although there was an overall plan for each year, the staff members had to attend to the constant need for (unexpected) adjustments and changes in plan and to be flexible in carrying them out. This approach was often seen as an obstacle for the staff members, however, it conveyed the need to listen - in the broad sense - to the teachers and involve them in the plan.

The teachers were grouped according to the grade levels they taught (junior/senior high grades) and the year in which they enrolled in the program. Thus, in the third year of the project there were 6 groups of 15-20 teachers in each group. There was a staff member in charge of each group. Some activities were conducted separately within each group, and some were conducted in different groupings (e.g., with all junior high school teachers, or all teachers who had been participating for a given number of years). For each workshop there was at least one staff member in charge. As part of their working load, staff members were required to observe their colleagues' workshops, to take part in the workshops' activities when they felt comfortable to do so, and to provide written and oral reactions to their colleagues. In the first stages of the project the project director would suggest for each member which colleague to join. Her considerations were based on her knowledge of the different domains of expertise of the staff members. The intention was to create situations in which less experienced members would learn from more experienced ones in an apprenticeship like manner. Along the same lines, when the project director was in charge of a workshop for the teachers, she invited all the staff members who were not

simultaneously engaged in other responsibilities to take part. The hope was that through such workshops a constructivist perspective to teaching would be conveyed and some forms of reform-oriented learning environments would be modeled.

In order to foster reflection and self-analysis of the staff members they were required to give written accounts of the workshops for which they were in charge (Borasi, 1998, reports the significance of writing for enhancing reflection). In addition, mutual peer (written and oral) evaluation and teachers' (written and oral) feedback were provided on a regular basis.

There were regularly scheduled staff meetings (Even, 1998, stresses the importance of such meetings), in which staff members could reflect on their work, share their experiences, consult with their colleagues, and negotiate meaning with respect to the goals and actions of the project. Small groups of staff members, who had common tasks, initiated additional meetings according to their specific needs and interests.

Staff members were continuously encouraged to initiate ideas and suggest new directions and actions within the project. Members' personal interests and enthusiasm drove many of the activities of the project. The underlying assumption was that ownership and responsibility, which are indicators of professionalism (Nodding, 1992), would contribute to their position in their community of practice.

All staff members (and teachers) had access to an electronic network (in their native language). The network served for informative communications, as well as for sharing, reflecting, and debating.

Special professional meetings and mini-conferences for the project team (2-3 times a year) were scheduled. These meetings were designed to address the evolving needs and interests of the staff members (this exemplifies one aspect of the MTEE's triad, as presented in the third row of Table 1). In these meetings staff members had the opportunity to conduct workshops and various activities for their colleagues. In addition, experts who were not part of the project team were invited to elaborate on their expertise.

To summarize this section, it seems worthwhile to note that the above components address all four dimensions which Krainer (1998, 1999) considers as describing teachers' professional practice: Action, Reflection, Autonomy, and Networking.

Professional Growth through Cooperative Learning and Learning to Cooperate

Overall, the findings indicate that the staff members encountered powerful experiences, which led to their professional, social, and personal growth (Bell & Gilbert, 1994). As we reflected on our experience we noticed a few patterns of development that seemed to emerge. The analysis of the accumulating data kept supporting these patterns and provided numerous pieces of evidence confirming them.

In order to convey the nature of the growth of the project members along the professional development of the participating teachers, we begin with a story (as

Krainer (1999) advocates). This is a story of a theme -- *cooperative learning* -- that evolved within the context of the project in many different layers by individual and groups of participants.

At the initial stage, there was only one staff member, Tami, who was an expert in managing cooperative learning experiences for students and teachers. Tami had strong beliefs regarding the significance of fostering cooperative learning settings in mathematics, based on her prior experience as a secondary mathematics teacher and a research program which she conducted (Leikin & Zaslavsky, 1997, 1999). Thus, she felt the need to incorporate in the teachers' workshops activities that would facilitate their appreciation of the potential of this approach for their students. In addition, Tami was very eager to convince her (project staff) colleagues to adopt this approach in their workshops. In staff meetings when planning the workshops, Tami always offered to conduct "cooperative learning" workshops. These workshops were very structured and were managed in one of five cooperative learning methods, which she had developed for her students, prior to her participation in the project. Several staff members observed her workshops and often took part in them as learners. Since the main purpose Tami set forth was "to convince the teachers to use *these* methods in their classrooms" she treated the challenging mathematics in the workshops mainly as a vehicle for promoting her goal.

In the first year of the project Tami conducted several cooperative learning workshops with the teachers, who were asked to adjust appropriate mathematical challenges for their students and to apply cooperative learning methods in their teaching. The teachers made some adjustments in the mathematics, however, used the cooperative methods exactly as they had experienced in the workshops. When sharing their experiences with their colleagues in the project some claimed that it was not realistic to expect a teacher to apply this approach regularly because of many constraints in school. Towards the end of the year, Tami encouraged a small group of teachers to adapt the material adjusted by their colleagues and themselves and to produce a booklet including a collection of resource materials for cooperative learning of school mathematics. This collection was restricted to one particular method. Following the teachers in their second year, Tami found out that those who applied cooperative learning methods in their classrooms used mostly the specific activities in the booklet without any modifications or additions. One of the reasons they gave for this was that in order to fully apply a cooperative approach to learning they needed to collaborate with other teachers in their schools. In fact, in schools from which a number of teachers participated in the project, Tami realized that collaboration began and more flexible ways were employed to facilitate students' cooperative learning. Of the small group of teachers that collaborated on the production of the booklet, some became rather competent and began preparing workshops for other teachers in cooperative approaches. Eventually, two of these teachers became teacher mentors in schools.

Parallel to the teachers' increasing appreciation of cooperative learning, staff members also started seeing its potential for teachers. They gradually began incorporating in their workshops elements that facilitate cooperative learning. However, unlike the teachers, they did not stick to the structured methods that Tami had developed. On the contrary, they

objected to the given constraints of each method. Each member adapted his or her own interpretation of what constitutes conditions for cooperative learning. Yet, some staff members felt they needed more theoretical background with respect to the principles underlying and research findings supporting cooperative learning in mathematics. Thus, Tami was invited by the project director to give a presentation to the staff members on cooperative learning in mathematics. Following the rather theoretical presentation, the staff members were asked to design cooperative learning experiences for the teachers to be included in the program of the following year. As a result of this request, a group of four staff members decided to collaborate on this task. This began a whole new story.

This group of four staff members encountered a unique experience in collaborating on this task. They devoted enormous time developing their ideas in ways that neither Tami nor the project director anticipated. Instead of planning a workshop for a period of an hour and a half, they expanded it to twice the time. They tried to incorporate many of the aspects of learning, for which they developed an appreciation, such as, connecting the mathematics to real life situations, addressing subtle issues of graphing and scaling, designing tasks that are open and engaging, in a way that inherently encourages full cooperation among learners. They applied all the principles they had learned on ways to facilitate cooperative learning of challenging mathematics. As they became more and more engaged in their task, they wanted to share their ideas with the staff members before conducting the workshop with the teachers. Thus, a special meeting for the staff was scheduled, in which the group of four staff members tried out their ideas with all the rest (including the project director). During this workshop, their colleagues were truly acting as learners, which turned out somewhat painful for the four, since they were confronted with some unforeseen problematic mathematical and pedagogical issues. They then returned to revise their plan and the resource material, and in the following year conducted one of the most exciting workshops with the teachers.

This story illustrates some of the dynamics, which the project fostered, as portrayed in Figure 2. In many other cases a similar pattern was identified. Staff members with an area of expertise provided learning experiences for teachers associated with their expertise. Consequently, the teachers started to appreciate the potential of this kind of learning experience for themselves as learners, and began -- often as a given assignment -- to try out very similar approaches with their students in rather limited ways. At the same time, staff members who did not have any expertise in this area, by observing and taking part in the offers for teachers, gradually began -- by their own initiative -- to incorporate various aspects of this approach in the activities they provided for teachers. Although both groups, teachers and staff members seemed to be empowered by these interactions, we suggest that there are differences in the extent and nature of these empowerments.

These differences can be explained mainly by the differences in the time and opportunities staff members had, in comparison to the teachers, to reflect and share their experiences, which are key elements in professional development (e.g., Borasi, 1998; Krainer, 1998; Jaworski, 1994). Another explanation can be seen in the

differences in the nature of the task for which each group was responsible (see Table 1).

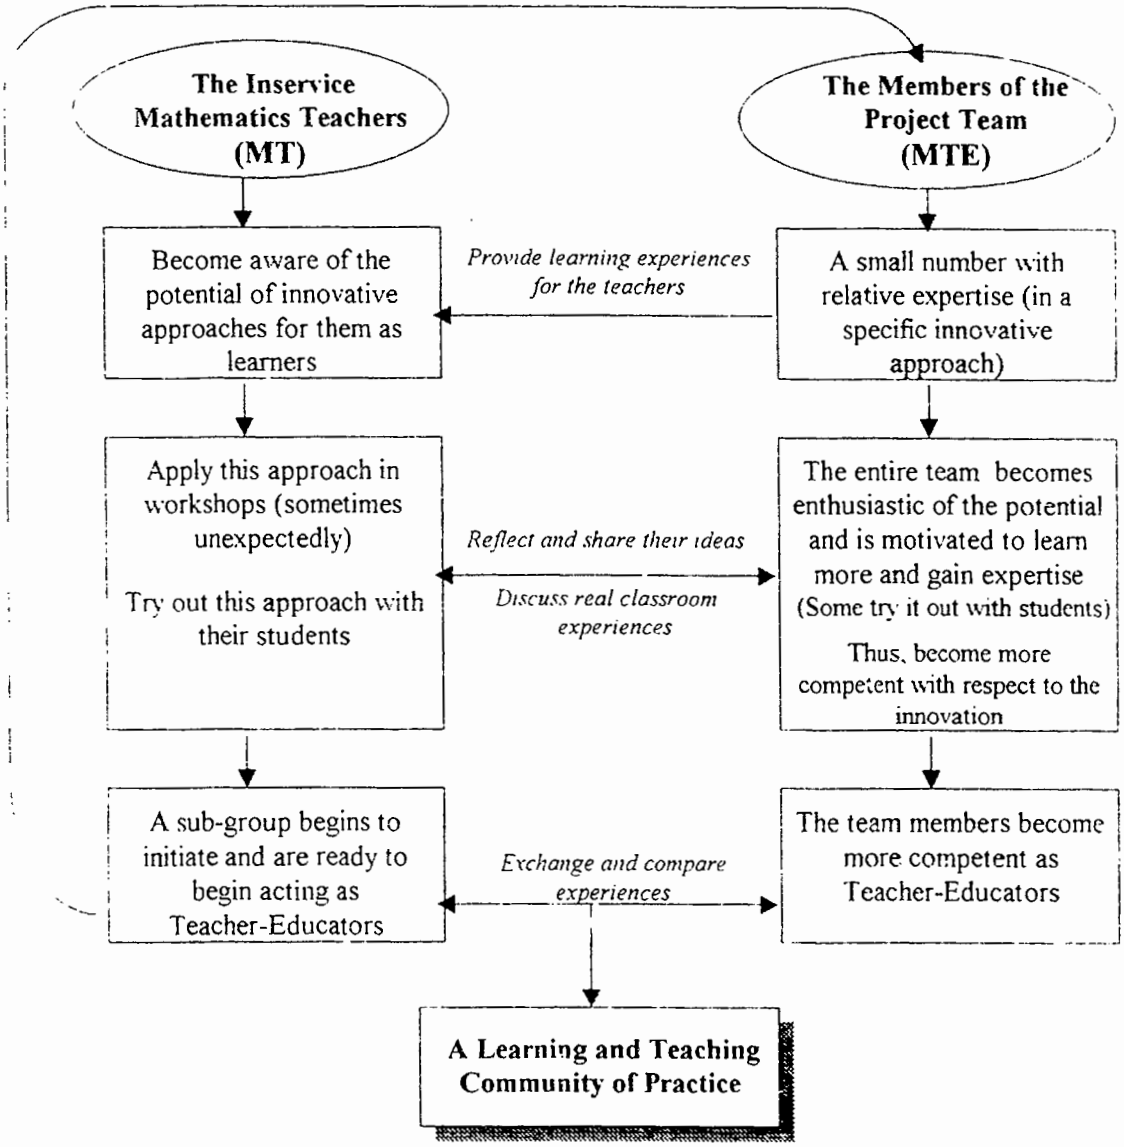

Figure 2: The Learning Dynamics within and between the Two Groups (MTs & MTEs)

The mere planning of the workshops for teachers entailed considerations of a teacher-educator triad in addition to a teacher's triad (see Table 1). There were also different kinds of constraints. The staff members had much more freedom and flexibility in terms of the "curriculum" they had to address and time allocated for the different activities. Finally, for the staff members, the project was their working place, thus their commitment to carrying out their task was inherently connected to their positions. However, teachers enrolled in the program for various reasons, and for the most, felt less committed and accountable for their role in the project. It should be noted that some of the above differences can be seen as reflecting a different phase in

BEST COPY AVAILABLE

the development of the teachers and teacher-educator (Bell & Gilbert, 1994; Jones et al., 1994).

To better understand the processes, which the staff members encountered, we bring excerpts from an interview with Ronit, one of the members of the "group of four". In this interview she reflects on the group's work:

"I think we all felt that after the first two hours, in which we sat and worked on the task and decided what to do, we thought that this is it, that we finished the work and there is not much more work. It was clear to us, that we have the idea and we know what to do. So there were a few doubts, maybe from the mathematics aspect it isn't so new, but it was clear to us that we have the idea and only have to sit and write and it would take another three hours and that would be it. But, like many things, it turned out that there was much more to it and needed more investment. But since each of us already invested a lot, and I, I don't know, I liked what we were doing, I found myself, not having a problem to invest the time. I found myself constantly thinking about it, even, you know, when I did other things. It kept bothering me, what can be done and how can it be improved. I enjoyed the group and the collaboration, and I think I really learned a lot".

"I thought we produced something good and that we would benefit from it. I found myself dealing with questions that interested me, because I asked the questions, I wanted to see if they could be answered and how they could be answered. So I sat and solved and thought: How can they be answered, then maybe in different ways, and I tried to see what could be done with it and I hoped it came out good. I still want it to stand a test, others judgement, because, maybe, I am too involved and not objective, like a mother to her child ... Yes, this was really a process of giving birth".

The above excerpts express the professional, personal, and social aspects of Ronit's development, which are interconnected.

We argue that the dynamics portrayed in Figure 2 influenced the growth of the more expert staff members as well. We conclude with some of Tami's reflections on her own development. Tami, who was considered by herself and her colleagues as a rather competent teacher-educator to begin with, reflected on her own development at the end of the project: "Today, I am much more open to many different ways of facilitating teachers' and students' cooperative learning in mathematics. I now accept and use methods that are not very structured, that seem to give way for many different kinds of cooperation to different extents."

In the beginning stages Tami was reluctant to conduct reflective discussions with the teachers. She had many debates with the project director on the need and ways to foster such reflections. Today she reflects: "When I first observed the project director conduct a reflective discussion with the teachers I told myself that I would never be able to do so myself. I wouldn't know what to ask, and would be insecure if the teachers would not react right away. Silence was a threat to me. Having observed over and over again in many different situations ways in which the project director conducted such sessions, with the teachers and with us -- the staff members. I began to try it myself. Slowly, I began to listen.

I no longer felt uncomfortable waiting for responses. I reached the extent that my colleagues often accuse me of waiting too long for replies".

Promoting reflection and networking as an intervention strategy in professional development programs for mathematics teachers and mathematics teacher educators

A reaction to the paper "Interweaving the Training of Mathematics Teacher-Educators and the Professional Development of Mathematics Teachers" by Orit Zaslavsky and Roza Leikin

Konrad Krainer

University of Klagenfurt, IFF, Austria

0 Introduction

"I found myself dealing with questions that interested me, because I asked the questions ...". This quotation stems from Ronit, a mathematics teacher educator engaged in the five-year professional development program *"Tomorrow 98"* in Israel, led by the first author of the above mentioned paper. Ronit's words give a first impression of the *freedom* enjoyed by the teacher educators in this project to define their own ways to grow professionally when working with teachers and when reflecting on their work as teacher educators, i.e. using their teaching as a basis for their own learning. In addition, the quotation indicates that the program fostered teacher educators' *investigative attitudes* in order to achieve a better understanding of their role in the interaction process with the teachers.

Following this first impression, it seems appropriate to sketch a broad picture of the value of the paper of Orit Zaslavsky and Roza Leikin before going into closer detail. One essential strength of the paper is the description and reflection on an apparently really successful project that creatively combines the professional growth of mathematics teachers and mathematics teacher educators within the framework of a *"supportive professional community"*. It demonstrates the dynamics and power that heterogeneous learning groups achieve through *building on the specific strengths* of individual learners (in this project teachers and teacher educators). The paper sometimes would gain additional value through more deeply linking the described processes in the project with the different theoretical considerations indicated in the text. However, the paper represents a variety of powerful ideas and interpretations that need to be highlighted and appreciated. It yields a good learning opportunity for our scientific community to reflect on the process of becoming a mathematics teacher educator, an issue that needs far more consideration in the future.

The paper of Zaslavsky & Leikin mainly considers the interaction between *mathematics teachers* (MTs), *mathematics teacher educators* (MTEs), and the *project director* who – among others – has the role of a *mathematics teacher educators' educator* (MTEE). In a broader sense all the MTEs can also be seen as having the role of MTEEs when providing workshops for their MTE colleagues. Figure 1 indicates the authors' explicit interest in their analysis of the paper, namely the professional growth of the MTEs.

The data collected mainly come alive to the reader through some brief insights into one teacher educator's, namely *Tami's* (individual, social, and) professional growth, and partially through reflections of her colleague *Ronit*.

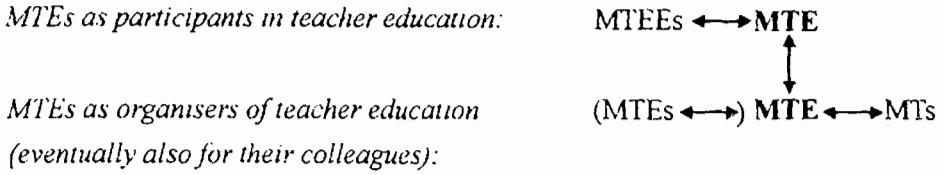

Figure 1

The methodology used in the study follows the paradigm of *"Grounded Theory"* (Glaser and Strauss, 1967) and refers to several theoretical considerations by other researchers, primarily to Jaworski's *teaching triad* (1992), Krainer's *four dimensions of professional practice* (1998), and Steinbring's *model of teaching and learning mathematics* (1998), for which links to the program are made.

The following analysis firstly aims at finding *common ground* between Jaworski's, Krainer's and Steinbring's considerations. Next, the *story of Tami*, an MTE in the program, is reflected upon in greater detail through the lenses of the four dimensions of teachers' professional practice, namely *action, reflection, autonomy, and networking*. Finally, this paper sketches some *future challenges* for similar professional development programs.

1 Searching for common ground between the main theoretical perspectives

Let us start with Jaworski's *teaching triad*, which Zaslavsky & Leikin use for *"describing in a general way the tasks of the different groups of mathematics educators [MTs, MTEs, MTEE] who were involved in the study, as well as for analyzing and discussing our findings"*.

The teaching triad used by Jaworski (1992, p. 8) *"as a powerful tool for making sense of the practice of teaching mathematics"* can be regarded as a possible concrete form of the classic *"didactic triangle: teacher – student – content"*, insofar as it puts three major *tasks of the teacher* in the foreground (see Figure 2).

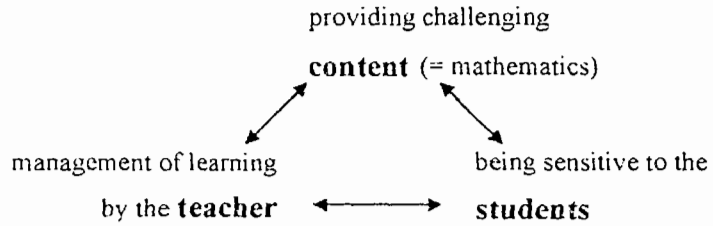

Figure 2

One benefit of this triangle – as used by Zaslavsky & Leikin – is its variable use in different contexts, for example, in the versions *MTE – MTs – mathematics teaching* or *MTEE – MTEs – mathematics teacher education*.

We must always bear in mind that the *didactic triangle* can be realised in a variety of different models, expressing different norms, values, beliefs, philosophies, ... behind learning and teaching, influenced by the teacher's explicit or implicit views on mathematics, education, society, world, sense of life, etc. and the explicit and implicit socially constructed views etc. in the context he or she lives in.

Zaslavsky & Leikin refer in their paper to two perspectives of learning and teaching, namely the *"constructivist view"* and the *"transmission metaphor"*, as representing opposite perspectives. The authors highlight the notion that the project is driven by a constructivist view where *"learning is regarded as an ongoing process of an individual or a group trying to make sense and construct meaning based on their experiences and interactions with the environment in which they are engaged"*, while at the same time also noting that *"at the early stages of the project most of the project team members seem to hold a transmission metaphor"*, finding it *"hard to reflect on their work"*.

This difference between the philosophy of the project and the starting perspectives of most team members (the MTEs), and, in addition, the explicitly stated project goal *"Facilitating teachers' knowledge ... in ways that support a constructivist perspective to teaching"*, leads us to assume that the project goal mentioned above was extended, tacitly at least, to the team members. All in all, this apparently indicates that the project intended to promote teachers' and teacher educators' change from the transmission metaphor to the constructivist view.

Referring to the didactic triangle, we can visualise the intended change as a transfer from a *Model T* to a *Model S* as illustrated below (Figure 3). The use of such opposites as *"top vs. bottom"* and *"indirect vs. direct"* is intentional and aims to amplify – and to some extent to exaggerate – the differences between the two models:

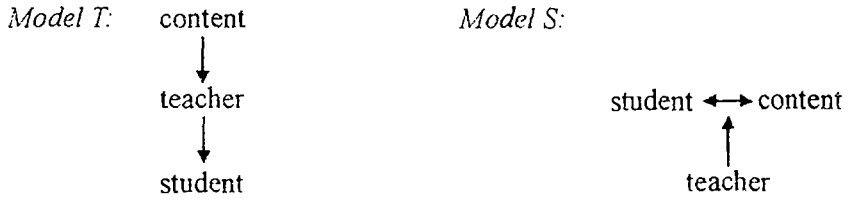

Figure 3

Whereas in *Model T* the teacher is transmitting the top-positioned content down to the students, thus providing them with only an indirect access to the content, *Model S* sees the students' direct and partially self-organised confrontation with the content as the major goal, with the teacher supporting and facilitating this process.

The *"transmission metaphor"* versus *"constructivist view"* distinction is one concrete form of the difference between Model T and Model S. Other authors, for example, use the difference *"teacher-oriented"* (or *"content-oriented"*) versus *"student-oriented"* (or *"process-oriented"*). We would need more discussion of what constructivist views, student-orientation, process-orientation, and other perspectives have in common or how they differ. We should also take into consideration *other versions* (than models S and T) of the didactic triangle in order to avoid the trap of uniformly painting everything black & white. In addition, we need to consider the question of to what extent the everyday practice of teaching students, student teachers, teachers, teacher educators, ..., influenced by general conditions like curriculum, assessment system, class sizes, etc., fosters or hinders these perspectives. Furthermore, we should ask how we could describe, for example, a teacher educator's position with regard to these models (whereby the position might change from context to context), or describe (aspects of) change in a teacher educator with regard to these models.

When Zaslavsky & Leikin bring Steinbring's *model of teaching and learning mathematics* (1998) into play in order to look more deeply into the *MTE-MT base line* of the *didactic triangle*, their bigger cycle (Figure 1 in their paper) has – slightly modified – the following structure (Figure 4):

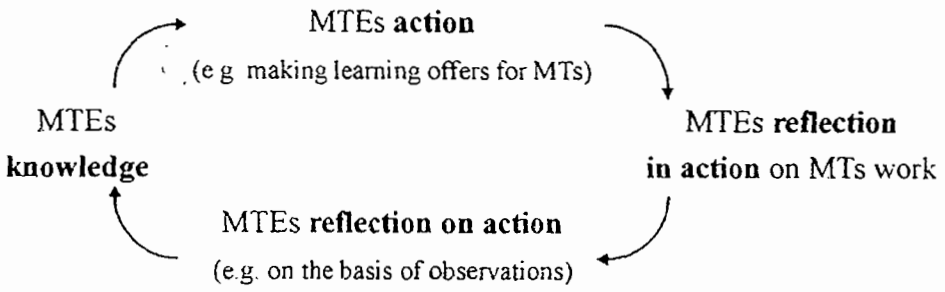

Figure 4

With reference to Figure 4, we can highlight *two additional features* of the "Tomorrow 98" program. Firstly, the program not only puts an emphasis on MTEs actions and reflections when working with MTs, but also strongly initiates and promotes *joint actions and reflections* among MTEs, for example, through internal workshops where MTEs (or the project director) work as MTEEs for their colleagues, through workshops where MTEs take part in workshops that experienced colleagues conduct for MTs, or through joint reflections among the MTEs. Secondly, experience in this program (as well as in general) shows that in addition to MTEs knowledge, their *beliefs*, *world views*, *etc.* also play an important role. Taking into account these two extensions, Figure 4 might be extended as follows (Figure 5):

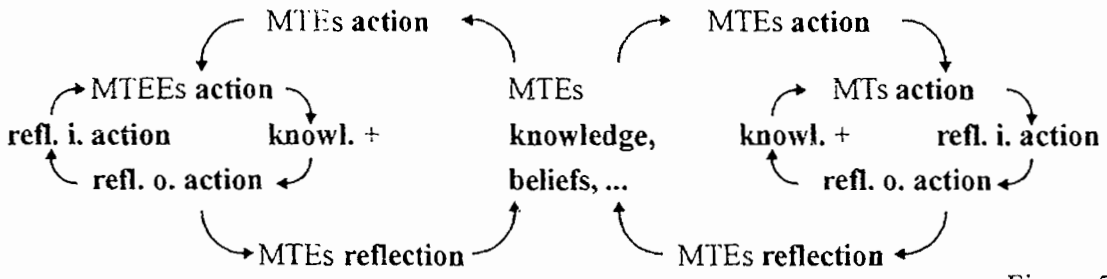

Figure 5

Figure 5 makes the connection to Krainer's *four dimensions of teachers' professional practice* (1998), to which Zaslavsky & Leikin refer in their paper. It is apparent that in the "Tomorrow 98" program the dimensions of *action* and *reflection* play an important role for the MTEs (as well as for the MTs). In addition, if we examine the difference between the right and the left circle, the dimensions of *autonomy* and *networking* also come to the fore: whereas the right circle mainly refers to MTEs autonomous inservice work with the MTs, the left one mainly refers to situations where the MTEs share their ideas and experiences with other MTEs. The two circles, the autonomy and the networking circles, meet in MTEs professional knowledge, beliefs, etc.

From this point of view, *MTEs professional knowledge, beliefs, etc.* can be seen as influenced by the four dimensions and visualised by the following schema (Figure 6):

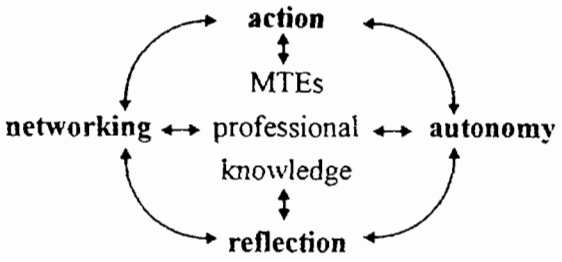

Figure 6

All in all, looking at Zaslavski's & Leikin's use of the models of Jaworski, Steinbring and Krainer, we can see *common ground*. Jaworski's teaching triad is used in order show the different *tasks* the MTs, MTEs and MTEEs (the project director and MTEs when leading workshops for MTEs) have in the project. Steinbrings' model of teaching and learning is brought into play in order to allow a closer look at the *interaction process* between MTEs and MTs. Finally, Krainer's dimensions of action, reflection, autonomy and networking can be used as lenses to look at *promoting and hindering factors* that influence MTEs professional practice, highlighting that a crucial part of MTEs growth is sharing experiences within the group of MTEs.

Before using these *four dimensions* in the next section in order to reflect on the story of Tami, I shall briefly describe how action, reflection, autonomy, and networking are interpreted in this model:

Action: The attitude towards, and competence in, experimental, constructive and goal-directed work;

Reflection: The attitude towards, and competence in, (self-)critical work that reflects on one's own actions systematically;

Autonomy: The attitude towards, and competence in, self-initiating, self-organised and self-determined work;

Networking: The attitude towards, and competence in, communicative and co-operative work with increasingly public relevance.

Each of the pairs, "action and reflection" and "autonomy and networking", expresses both *contrast and unity*, and can be seen as complementary dimensions which have to be kept in a certain balance, depending on the context. The interplay between these dimensions seems to be of great importance: in general, more reflection contributes to a higher quality of actions, and the sharing of experiences enriches one's own view; furthermore, a higher quality of action and autonomy promotes the quality of reflection and networking, etc. Experience shows that teachers' practice is usually characterised by *a lot of action and autonomy* but *less reflection and networking*, in the sense of critical dialogue about one's teaching with colleagues, mathematics educators, the school authority, the public, etc., and, linked with that, by putting an emphasis mainly on the dimensions of action and autonomy in their classrooms (see e.g. Krainer, 1999). Therefore, it is a great challenge for teacher education programs to foster particularly the dimensions of *reflection* and *networking* in order to support teachers' flexibility to generate and to keep an adequate balance between the four dimensions in their practice.

2 Looking at the story of Tami through the lenses of the four dimensions action, reflection, autonomy, and networking

The description of Tami, *"who was considered by herself and her colleagues as a rather competent teacher-educator to begin with"*, by Zaslavsky & Leikin in the early stages of the "Tomorrow 98" program can briefly be interpreted with regard to the four dimensions as follows (I can only refer to the data presented in their paper).

Tami in the early stages:

Tami is an *"expert in managing cooperative learning experiences"* (CLE), and she has a *"strong belief regarding the significance"* of CLE. Tami is *"eager to convince"* otner colleagues to adopt her CLE approach and to use the same methods she uses. Within the project she offers to conduct CLE workshops for MTs and MTEs. She even encourages *"a small group of teachers to adapt the material ... and to produce a booklet"*. Tami's workshops are *"very structured"*, she is *"reluctant to conduct reflective discussions with the teachers"*, *"silence"* is *"a threat"* to her.

Concerning the four dimensions, Tami has clear strengths with regard to *action and autonomy*. She is an expert in CLE and practices it with conviction. It seems that around CLE she constructs a considerable domain of autonomous action with strict rules where she feels competent and secure. It seems that Tami has some weak points in *reflection*. She avoids reflective discussions with teachers, and the use of very structured designs decreases the chance of such reflections. She is very convinced by her CLE approach and seems to feel not much need to reflect on modifications. Concerning *networking* the situation seems to be more complex. On the one hand, she is interested in spreading her knowledge to other teachers. She practices CLE in her workshops, initiating cooperative learning among her inservice teachers, thus promoting networking among them. On the other hand, she is reluctant to conduct reflective discussions with the teachers and avoids departures from her given workshop structure (which decreases the chance that the teachers themselves generate new ideas and ways), thus hindering networking among teachers.

Tami at the end of the project:

By the end of the "Tomorrow 98" program, Tami seems to have changed a lot. Again, we refer to the four dimensions of professional practice. Tami made great progress with regard to *reflection* and *networking*, as her reflection on the program shows: *"Today, I am much more open to many different ways of facilitating teachers' and students' cooperative learning in mathematics. I now accept and use methods that are not very structured, that seem to give way for many different kinds of cooperation to different extents."* Tami now no longer feels *"uncomfortable waiting for responses"*, having learned *"to listen"* to her participants' voices. She succeeded in supporting a small group of teachers writing a booklet about CLE, and in convincing other MTEs of the potential of CLE, in particular through motivating a small group of team members to collaborate on designing CLEs for workshops with teachers. This progress in reflection and networking also improved the dimensions of *action* and *autonomy*. She gained further expertise in CLE and in leading CLE workshops.

She increased both her flexibility and her self-confidence in taking autonomous decisions: *"I reached the extent that my colleagues often accuse me of waiting too long for replies."*

What made this *progress*, in particular with regard to *reflection* and *networking*, possible? Let us look at the program's effort to foster these two dimensions.

Zaslavsky & Leikin regard *reflection* as a *"key issue"* in their program and incorporated several elements of it *"in order to enhance reflection and self-analysis of both the participating teachers and the project staff"*. A considerable part of the reflection was organised as *joint activities* by MTEs, thus promoting exchanges about their experiences at different levels, for example, experiences from workshops they led for MTs or their MTE colleagues, or from participating in workshops led by the project director or other MTEs. Examples of other essential elements that strengthened the *combination of reflection and networking* were:

- The MTEs were *"required to give written accounts of the workshops for which they were in charge"*
- *"mutual peer (written and oral) evaluation and teachers' (written and oral) feedback were provided on a regular basis"*
- *"regularly scheduled staff meetings, in which staff members could reflect on their work, share their experiences, consult with their colleagues, and negotiate meaning with respect to the goals and actions of the project"*
- team members were *"continuously encouraged to initiate ideas and suggest new directions and actions within the project"* (thus promoting participants' ownership and responsibility for the project)
- *"special professional meetings and mini-conferences for the project team ... were scheduled"* where also *"external experts"* were invited to share their expertise
- the project was accompanied by a systematic documentation, for example including interviews, questionnaires, self and peer reports, written analyses, videotapes and protocols, thus enriching the reflection and networking processes
- all staff members (and teachers) had *"access to an electronic network"* that *"served for informative communications, as well as for sharing, reflecting, and debating"*
- a project director who apparently was really successful in coordinating this complex task and in taking a considerable amount of responsibility for the whole project, being involved intensively, professionally and socially.

All these factors (and more) together seem to have generated a fruitful and dynamic *project culture*, as it had been intended by those responsible for the project, as articulated in the project goals, for example: *"Enhancing teachers' and teacher-educators' socialization and developing a supportive professional community to which they belong."* Nevertheless, this supportive professional community cannot be the full explanation of Tami's growth, although it surely promoted her efforts extraordinarily. There was an interplay between the project's challenging *network* of actions and reflections and her *autonomous* struggle for growth. In particular one situation seems to have played a very *critical role* in her development, namely the one where a group of four MTEs, who had been motivated by Tami to collaborate on designing CLEs, conducted a workshop for the project team and were *"confronted with some unexpectedly problematic mathematical and pedagogical issues"*.

However, in this network of "critical friends" it apparently was possible for the group to appreciate the criticism as a learning chance and they *"returned to revise their plan and the resource material, and in the following year conducted one of the most exciting workshops with the teachers"*. This challenging situation seemed to hav greatly influenced Tami's way of making her CLE approach more open and flexible. We can assume that the openness and flexibility of the whole project, for example, with regard to MTEs freedom to define their own ways to grow professionally within the project was a supporting factor. This is, for example, expressed by Ronit who was one of the group of four MTEs that conducted the CLE workshop for the project team: *"I found myself dealing with questions that interested me, because I asked the questions ..."*. Such a motivation for developing oneself further, accompanied by colleagues who have similar goals and ambitions, and based on a project culture that provides challenging learning environments, is a good starting point for professional growth.

The "Tomorrow 98" project reveals some crucial features of promoting professional growth of teachers and teacher educators, with the particular strength that it combines their learning into a whole framework. It might be interesting to get an even closer view on Tami's development, possibly indicating how she dealt with other (critical) situations that challenged her. It would also be valuable to look more deeply at the growth of the four MTEs that collaborated on CLE, a group, which became a *professional mini-community* of its own. And, in addition, we could benefit from hearing a story about an MTE who was not so successful in his or her further development, even though he or she was involved in the project's rich learning environment.

3 Some future challenges for similar professional development projects

The paper of Zaslavsky & Leikin shows a *unique project* that combines the professional growth of mathematics teachers with mathematics teacher educators. The short story about the professional growth of Tami gives a brief insight into the processes that influenced her development. It is worth writing *data-rich stories* about mathematics teacher educators' and participants' development which allow us also to compare their growth.

One main feature of the uniqueness of the "Tomorrow 98" program is its *complexity*, as the following aspects demonstrate:

- The challenge of *interweaving* the professional development of MTs and MTEs.
- The *size* and the *structure* of the project with regard to the people involved: 1 project director (only supported by an MTE in the latter stages of the project), (a big group of) 20 team members, and about 120 participants.
- The *heterogeneity* of the *team members'* competence and experience (only 6 out of 14 *"had some previous experience in managing inservice professional development activities"* and *"were not very confident of their qualifications as teacher-educators"*, which means that many team members apparently were really busy with their own learning process, and thus did not have all their energy for taking some responsibility off the project director, or for looking more closely at mathematics teachers' growth).
- The *heterogeneity* of the *participants' background* (junior high school and high school teachers, the different length and intensity of their involvement).

- The *variety* of *activities* and *meetings* in the program.
- The *variety* of *data gathered* (observations, interviews, questionnaires, videos, ...).

It is astonishing that the complexity of the project – given its low personnel resources – seemed to have been mastered so successfully. On the one hand, this is due to a high degree to the work of a *project director*, who clearly is a highly skilled in leading projects and is prepared to take more responsibility than usual. On the other hand, we can imagine that *more resources* (people, time, money) for this project could provide the responsible people with more freedom to concentrate on specific development and research questions.

In the following I confine myself to some challenges for *similar professional development programs*, in particular looking at the *differences in MTs and MTEs growth* as reported in the paper by Zaslavsky & Leikin.

Regarding the MTs and the MTEs further development in the "Tomorrow 98" project the authors highlight *differences* in the *extent* and *nature* of their growth. Whereas the progress of the MTEs is stressed through expressions like *"entire team becomes enthusiastic"*, *"is motivated"*, *"become more competent with respect to innovation"* or *"become more competent as Teacher-Educators"*, the progress of the MTs is described far less spectacularly, for example, through expressions like *"become aware of the potential of innovative approaches"*, *"apply this approach"* or *"a sub-group begins to initiate and is ready to begin acting as Teacher-Educators"*. Zaslavsky & Leikin also point out that the MTs felt *"less committed and accountable for their role in the project"* than the MTEs. Besides the fact that, of course, MTs and MTEs had different starting points and tasks within the project, it is interesting that the relative effects, professionally and atmospherically, seem to be stronger in the case of the MTEs. Zaslavsky & Leikin explain it mainly by the *"differences in the time and opportunities staff members had, in comparison to the teachers, to reflect and share their experiences"*. This is certainly a very important point. However, I would like to bring into play some *additional hypotheses* that might explain the difference:

- The MTEs had more *freedom* to define their own ways to grow professionally, whereas the MTs had more the role of *applying* the approaches introduced by the MTEs. Connected with that, the MTEs were able to build their workshops on their individual strengths (as e.g. CLE in the case of Tami), whereas for the MTs these approaches often apparently meant the need to cope with situations that were really new for them (e.g. alternative ways of learning). Both factors have an impact on one's energy to reflect on one's own practice and on one's commitment with the project.
- The authors' assessment that at *"the early stages of the project most of the project team members seemed to hold a transmission metaphor of the teaching-learning process"* demonstrates the deep learning process of the MTEs. According to that, a lot of the *project's energy* was covered by promoting the growth of the MTEs who really were challenged in reflecting on their own learning process.
- The *research* mainly built on investigations into MTEs and MTs growth from the perspective of MTEs involved in the project. To some extent, the MTEs systematically investigated their own practice (mainly following a research question that arose from

their own interest), wrote down their experiences and shared it with their colleagues, and thus practised a form of *action research* (see e.g. Jaworski, in press). The MTs, too, were invited to reflect on their practice, however, it seems that their investigations were not mainly aimed at giving answers to their self-defined questions, but more towards informing the MTEs about how successful of their – the MTEs – interventions in promoting a constructivist view of learning and teaching had been.

- The *project director* had a complex task and took a considerable amount of responsibility for the whole project. She was very active in different roles, for example, through leading the project, defining and reinforcing further its philosophy and its conceptual framework, being the chief researcher, conducting several workshops, giving feedback and guidance to individual people, writing reports and research papers, and through keeping all the things together (being supported by a colleague only in the latter stages of the project). She seems to have been a focal point in the further development of many MTs and MTEs. This is shown, for example, in Tami's reflection *"Having observed over and over again in many different situations ways in which the project director conducted such sessions, with the teachers and with us - the staff members, I began to try it myself."* It can be assumed that the project director's competence and support reached the MTEs more intensively than the MTs.

Finally, some *brief suggestions* with regard to *future professional development programs* that might have similar goals and general conditions like the "Tomorrow 98" project:

- Given a complex project like above, it is worth considering getting enough resources in order to enable a team to share a *fairly balanced responsibility* from the very beginning, i.e. to differentiate between *different roles* (research, management, coaching, workshops, evaluation, ...), and to initiate other elements of a project structure that allow the project director to concentrate on important strategic and research-related activities.
- With regard to the challenge of *interweaving teacher educators' and teachers' professional growth*, it is worth considering putting more emphasis on teachers' investigations into their own practice, thus also providing the teacher educators with additional authentic reflections by the teachers.
- Referring to Zaslavsky's & Leikin's interesting statement, *"In fact, in schools from which a number of teachers participated in the project, Tami realized that collaboration began and more flexible ways were employed to facilitate students' cooperative learning."*, it is worth indicating that the organisational aspect of teachers' and teacher educators' professional growth needs more consideration, both with regard to teacher education programs and research on teacher education.

BECOMING A MATHEMATICS TEACHER-EDUCATOR: CONCEPTUALIZING THE TERRAIN THROUGH SELF-REFLECTIVE ANALYSIS

Ron Tzur

The Pennsylvania State University

Abstract: My purpose in this paper is to contribute to the conceptualization of the complex terrain that often is indiscriminately termed mathematics teacher educator development. Because this terrain is largely unresearched, I interweave experience fragments of my own development as a mathematics teacher educator and reflective analysis of those fragments as a tool to abstract notions of general implication. In particular, I postulate a framework consisting of four stages of development that are distinguished on the basis of the domain of activities one's reflections may focus on and the nature of her or his reflections. Drawing on this framework, I present four themes that contribute to thinking about and conducting research in the terrain of mathematics teacher educator development.

During the third year of my work as an assistant professor I encountered a problem that is not uncommon. A prospective doctoral student canceled her participation in the program, thus we needed an instructor for a mathematics education methods course for preservice teachers. I asked Kelly, a graduate student who has been working for two years as a research assistant in the mathematics teacher development (MTD) project if she would take on the responsibility. On the *intuitive* (unformulated) basis of knowing Kelly as a developing researcher and as a student in courses I taught, I expected that she would be able to take on the responsibility, and that this would promote her development. Yet, while talking with Kelly and my colleagues it soon occurred to me that I had never before articulated the perspective underlying my practice as a mentor of developing mathematics teacher educators, nor did I articulate my own development as a novice teacher educator. To my surprise, in searching for research literature I could find many generic studies on development of teacher educators (Denemark & Espinoza, 1974; Diamond, 1988; Ross & Bondy, 1996; Wayson, 1974) or on such development in other disciplines like English teaching (Farrell, 1985), but only one (Onslow & Gadanidis, 1997) that focused on development of mathematics teacher educators. Therefore, in this paper I attempt to begin conceptualizing the terrain of mathematics teacher educator development through self-reflective analysis.

My interest in mathematics teacher educator development is rooted in my work of studying mathematics teacher development (Simon, Tzur, Heinz, Kinzel, & Smith, 1998b; Tzur, Simon, Heinz, & Kinzel, 1998). I became convinced that mathematics teacher educators can, and should, construct clearer (a) conceptions of desired teaching practices that can serve in setting goals for the development of preservice and inservice mathematics teachers (Simon, Ball, Dekker, & Russel, 1998a), (b) explanations of mathematics teachers' development toward such practices (Tzur & Timmerman, 1997), and (c) ways in which teacher educators might think about, and promote, such development (Cooney, 1994). It seems as important that mathematics

teacher educators construct clearer (a) conceptions of desired teacher-educating practices that can serve in setting goals for the development of mathematics teacher educators, (b) explanations of mathematics teacher educators' development toward such practices, and (c) ways in which mentors of teacher educators might think about, and promote, such learning processes.

I organized the paper as follows. Following Guilfoyle, Hamilton, Pinnegar, & Placier (1996) writing, I first interweave narratives and analyses of experience fragments of my own development. Then, I present my way of thinking (conceptual framework) about learning and teaching processes, stressing the critical role that reflection plays in learning. This is followed by my conception of mathematics teacher educator development in terms of four interconnected foci of reflection—learning mathematics (student), learning to teach mathematics (teacher), learning to teach mathematics teachers (teacher educator), and learning to teach mathematics teacher educators (mentor). In this context I present four themes for further research and conversation.

Reflecting on Experience Fragments

In this section I interweave narratives and analyses of experience fragments that greatly impacted my current praxis[1] as a teacher educator and a mentor of teacher educators. The experiences are ordered according to my understanding of the developmental sequence in which the four foci mentioned above are interwoven. I will elaborate on relationships among those foci later. However, it is critical to note that I view the four foci as highly interconnected, and distinguish among them on the basis of what issues (activities) serve as "material" on which the learner reflects and on differences in the nature of the reflective process (awareness, rigor, depth).

Learning Mathematics

I learned mathematics at my kibbutz elementary and high schools. The kibbutz is a small community operated by its members on the basis of socialist ideas such as equality, cooperation, and mutual aid. To educate the young toward realization of those ideas, the kibbutz school is operated as a mini-community in which adult educators and students negotiate social norms and practices (notions borrowed from Yackel & Cobb, 1996) to guide students toward gradually taking responsibility for academic, social, and physical aspects of their life. In particular, capable students are expected and encouraged to tutor their peers or younger students. Below, I present a fragment pertaining to my learning through peer tutoring.

> My peers knew of my affection for mathematics, and frequently asked me to help them in doing their homework. My usual technique was that I worked one or two problems step-by-step, then asked my peers to try the next problems, which for me seemed "just the same." However, my peers usually got stuck. To help them, I explained what I saw as the reasons behind what we were told or asked in class, and how all the pieces

[1] I use the term praxis in Dewey's (1938) sense of the combined conglomerate of theory and practice that characterizes the teacher's work.

> "clicked together" in the process of solving the problem. Often, the struggle to figure out how to explain the matter brought about new insights *in me*. Sometimes, my peers "got it" and I experienced a feeling of accomplishment; other times they did not and I felt dull and disturbed. In both cases, I was curious about their understanding. These experiences were related to my decision to take several courses in education during my junior and senior years in high school, where I was first introduced to the educational and psychological thought of Dewey and Piaget. However, in spite of the courses, at that time I continued to use the same tutoring techniques.

In reflecting on this fragment, I notice three significant aspects—the social context in which I learned, the advancement of *my* mathematical understanding, and the lack of change in my ways of tutoring. Regarding the social context, it seems that my tutoring was encouraged and affected not only by the generic social norm of helping others, but also by our classroom sociomathematical norms (Yackel & Cobb, 1996) of being expected to justify a solution and to make connections between results of different problems. Regarding my learning, it seems that my continual reflection on activities I used to explain my solutions *to others* played a key role in advancing my mathematical understanding.. While I repeated the process of interpreting the information provided in the problem, setting some image (goal) as a solution, carrying out activities to work to the solution, and relating the effects of my activities to the solution image, I noticed new regularities in activity-effect relationships. Regarding the lack of change in my ways of tutoring, I did not understand that many of my peers could not see what I saw because their mathematical conceptions were different than mine (Cobb, Yackel, & Wood, 1992). Thus, my reflection was focused on my own understanding of the (obvious to me) mathematics, not on others' thinking and how it might be changed via *their* activities and reflective processes. Simply put, I used activities in an attempt to promote others' mathematics, but I did not reflect on the relationship between those activities and the effects in terms of my peers' learning.

Learning to Teach

I started my formal education as a mathematics teacher in 1982, at the kibbutz branch of Haifa University School of Education ("Oranim"). My development continued while I taught mathematics at the kibbutz high school and while I studied (1990-92) toward a master's in mathematics education at the Technion - Israel Institute of Technology. While at "Oranim," I became friends with a small group of students who not only prepared themselves as teachers in different disciplines, but who also participated in the creation of a new program focusing on social education issues. At the kibbutz high school, although I taught all grade levels (7-12) and tracks, I worked mainly with the older, failure-experienced (non-college bound) students who struggled to understand basic mathematical ideas and to not drop out of mathematics courses. At the Technion, I focused on the role of assessment in students' mathematics learning. I created an alternative assessment method in an attempt to facilitate failure-experienced students' learning of mathematics and

studied the impact of using this method on students and teachers (Tzur & Movshovitz-Hadar, 1998). Below, I present fragments pertaining to my learning to teach mathematics through teaching students and teachers, and researching.

> A few years after high school I decided to realize my dream of being a mathematics teacher at the kibbutz high school. I vividly remember how my teacher educators encouraged me to give voice to my thoughts about how my (often painfully) growing understanding of higher level mathematics would help (or impede?) my abilities to make a difference in my future students' understanding of mathematics. They also encouraged me to conduct several mini-research projects on diverse issues (e.g., the development of the Cartesian coordinate system, gender differences in the kibbutz, drug abuse impact on the brain). Most important, they supported my decision to begin teaching full-time while completing my studies as a part-time student. Teaching failure-experienced students was challenging and rewarding. I was engaged in taking apart mathematical ideas that an expert might consider rather simple and unproblematic, and continually searched for a variety of activities that might promote the students' learning. I was pleased when their work indicated progress and felt somber when they were frustrated and stuck.
>
> The master's program was a breeze of fresh air, but it was not because I stopped teaching—I deliberately continued full-time teaching (cf. Halai, 1998) while joining a research and curriculum development project (Movshovitz-Hadar, 1992). The project team focused on developing learning materials to provide non-college bound students with enjoyable, meaningful, and successful learning experiences. Besides using those materials in my teaching, I also traveled every week to one of 6 high schools and met with teachers to promote their *understanding and use* of the materials. During those visits, I collected data (observe, interview, survey) for my thesis. The teachers' use of the curriculum indicated (to me) misunderstandings on their part. By communicating how I thought of the materials and demonstrating ways I would use them, I tried to encourage the teachers to not only use the materials as given, but also to understand the underlying educational reasoning and to adjust teaching activities to students' work. In working with the teachers, I had many insights into teaching my students, but rarely did the teachers' indicate the intended understandings. In writing my thesis, I struggled to formulate commonalties I noticed in the teachers' use of the alternative method and students' cognitive and social-emotional development. Consequently, I reconstructed my conception of Piaget's and Vygotsky's theories, emphasizing the key theoretical construct of interaction and applying it to the case of assessment.

In reflecting on these fragments, I notice three significant aspects besides the obvious continuation of my learning mathematics—the institutional norm to conduct research; my learning to teach as a result of integrating activities of teaching, research, and course work; and the lack of significant changes in my attempts to promote other teachers' reasoning about teaching-learning processes. Regarding the first two aspects, it seems that both my undergraduate and master's programs stressed a view of learning to teach that is compatible with Schön's (1983, 1987)

notion of the reflective practitioner, and with recent trends of teacher action research (Cooney & Krainer, 1996; Crawford & Adler, 1996; Jaworski, 1998; McEwan, Field, Kawamoto, & Among, 1997). My teacher educators expected me to actively engage in doing research, to integrate my diverse learning experiences, and to figure out how to make my research available to others. Being simultaneously engaged in the activities of teaching mathematics, conducting research, taking courses, and guiding teachers provided me with many situations in which to reflect on my own teaching. For example, in teaching the high school classes, I actively experimented with activities in an attempt to promote my students' understanding. That is, I looked for tasks and problems in the learning materials that had been developed in the project or that were in research articles, or I created new tasks on the basis of my interpretation of learning theories. When the activities did not bring about the intended learning I felt responsible for adjusting them, and the adjustment process focused my reflection on relationships between my teaching activities and their effects (students' learning). A similar focus was also evident in my work with other teachers. I shared with these teachers activities that promoted my students' learning, which again engendered my own thinking about why the activities were useful. Simply put, I was actively exploring and transforming my own mathematical and educational praxis (my students would say "improving as a teacher").

An important reason for the lack of change in my work with teachers seems to be that I did not understand the teachers' praxis—the conceptions of mathematical knowledge and learning underlying their teaching. In retrospect, I think that both my own mathematics teaching and my attempts to promote teacher development were rooted in a perception-based perspective (Simon et al., 1998b). That is, I *implicitly* viewed mathematical (or pedagogical) knowledge as a well connected web of concepts that exist independent of the knower, and thought of learning as the essentially unproblematic process in which a learner comes to see a growing portion of the web by connecting pieces he or she can already "see" with new pieces, connections that take place through learners' active, first-hand experience. What I lacked was an elaborated epistemology (Steinbring, 1998) that would provide an explanatory mechanism as to how one can "see" a mathematical or pedagogical concept in particular situations, let alone how one might develop new concepts.

Learning to Educate Teachers

In 1992, three years after the publication of the first National Council of Teachers of Mathematics (1989) *Standards* document, I started my doctoral program at the University of Georgia. Although my previous work as a high school teacher and as a guide of teachers included influencing others' mathematics teaching, it was then that I began to seriously consider issues of teacher education. Besides doing course work in mathematics, mathematics education, psychology, and philosophy, I participated in two research projects: a teaching experiment focusing on children's construction of fraction knowledge and a teacher enhancement program focusing on teachers' use of alternative assessment. After two years of working mainly as a research assistant,

I added a teaching role to my program. Moreover, I was asked to let a new doctoral student (Lori) who had little teaching experience join me in teaching a mathematics course and two methods courses for elementary preservice teachers as a means of assisting *her* learning to be a teacher and a teacher educator. Upon graduation (1995), I assumed an assistant professor position in the School of Education at the Pennsylvania State University. Here, I am currently developing as a teacher educator through: reforming and teaching methods courses for teachers, creating and teaching new graduate courses, promoting and researching mathematics teacher development, and mentoring novice teacher educators. Below, I present fragments pertaining to my learning to teach teachers and teacher educators.

> Entering a doctoral program in the USA was a major cultural transition (e.g., language difficulties, organization of teaching). My mentors encouraged my desire to articulate relationships between several theoretical approaches and the real-life experiences of students and teachers. I clearly remember how I was stuck when Les Steffe asked me: "When interacting with children, how do you know that you met a scheme?" Such questions sparked periods of intensive thinking, reading, and conversations with my peers and mentors that led to focusing my dissertation on both children's construction of fraction schemes and the teacher-learner interactions that might promote this process.
>
> From day one, Lori and I were excited to team-teach. We shared full responsibility in planning, implementing, and reflecting on our teaching reform-oriented mathematics and pedagogy to the prospective teachers. Having excitedly worked with the students throughout the course, I was startled when I received their low rating of my teaching. Their feedback threw me into an intensive period of reflection. I painfully recognized my failure to understand *the teachers'* experience (conceptions) as a critical first step to teaching them anything. When discussing those issues with Lori, I also realized that team-teaching with her enhanced my understanding of teaching and helped her to experience activities of teaching, but it did not seem to be as useful in terms of Lori's conceptualization of teacher education.
>
> At Penn State, my learning about teachers' experiences and how I might build on them to promote their development is taking a new form while I am integrating teaching teachers and researching teacher development. As I supervise the graduate students who teach methods courses, I try to inspire them with the kind of cooperative, inquisitive, and creative work I enjoy in my research team. I cherish and contribute to that kind of culture as a deliberate effort to confront the pressures of academia. I try to translate the "aha" experiences of my research into new or revised methods courses for teachers. In the last four years, I have been struggling with Marty Simon's question, 'Do you have a way of thinking, a theory, about graduate students' learning processes?" For example, half way into a graduate seminar I realized that just reading and conversing about children's mathematics resulted in superficial understandings. Consequently, I engaged the graduate students in interviewing a child as a means to make sense of the child's mathematical conceptions. Such adjustments in my teaching intensified the question I came to view as preliminary to Marty's question: "What are

graduate students' perspectives of mathematics education and, in particular, of mathematics teacher development and the ways one might promote such development?" It is this question that provoked my work on this paper.

In reflecting on the last three fragments, I notice three significant aspects: how contextual features impact one's learning; how one's explicit ways of thinking about the development of teachers and teacher educators empowers her or his acting as a teacher educator or a mentor; and how it is difficult to translate such explicit ways of thinking into daily planning for or reflecting on teaching, let alone adjusting (on the spot) one's interactions with teachers and teacher educators. Next, I elaborate on each of these three aspects.

The first aspect seems to be a case of the general notion of situated learning (Lave & Wenger, 1991). Three examples in my personal experience seem to highlight this notion. First, culture change intensified my learning by pushing me to see "old" experiences in new light, hence to abstract new ideas about teaching and learning to teach. Second, team-teaching also intensified my learning because of the need to constantly reflect on my teaching in the context of observing Lori's teaching and receiving her feedback on my teaching. Third, there is a mutual impact between my research and my teaching (Jaworski, 1994) while I continually struggle with the inherent tension between expectations and reward structures in academia (e.g., prioritizing writing or teaching, cf., Collins, 1997; Guilfoyle, 1995; Guilfyole et al., 1996). It seems reasonable to expect that my development as a teacher educator would differ from the learning of leader-teachers (Zaslavsky, this volume) whose tenure and promotion are not determined by conducting and publishing systematic research. As my experience indicates, the activity of writing serves as a main vehicle for constant, rigorous, and deep reflection on and reorganization of thinking about teaching and teacher educating.

The empowering impact that constructing explicit conceptions of teaching had on my work was indicated in two shifts: from teacher to teacher educator and from teacher educator to mentor. I now realize how the lack of such conceptions limited the repertoire of plans and interactions that I, or other teacher educators and mentors, could generate and use. For example, Lori could carry out most of the teaching activities we planned for our students. However, her contributions indicated that she had not yet constructed a global perspective about mathematics teaching that allows one to generate or adjust teaching activities, let alone translate learning from research with children into opportunities for teachers. Or, in teaching doctoral students, I frequently found myself adjusting plans and activities after noticing new regularities in their participation. Those adjustments were rooted in my perspectives of the roles that students' conceptions play in their learning and indicate the limited nature of my understanding of their conceptions. In all, it seems that formulating explicit ideas about teaching-learning processes is a necessary (though not sufficient) condition if one is to promote others' teaching or teacher educating.

With respect to the translation of theory into practice, I came to distinguish between reflective and anticipatory states of knowing with respect to my understanding of the learning of students (children, teacher, or teacher educators). Being able to notice students' learning while I reflected on concrete experiences with them is different from being able to form anticipatory ideas as to how students might develop. The latter allows for flexibility and creativity in planning or for adjusting one's interactions on the spot. Moreover, I propose that developing one's ability to construct reflective and anticipatory understandings at a specific enough level is a long and difficult process. My experience (e.g., the negative feedback from prospective teachers in my early methods courses) indicates that the process of reconstructing for oneself a theoretical stance and applying it first to teaching children, then to teaching teachers, then to teaching teacher educators, requires reflective work on various "local" issues before abstracting and connecting the local pieces into an integrated, well articulated praxis. Such a process involves the development of new understandings of mathematics, its learning, and teaching.

Conceptual Framework

The previous section highlights the following seven main areas of potential development of a mathematics teacher educator and a mentor: mathematical knowledge, perspectives on the nature of mathematical knowing, how mathematics is learned, how mathematics is taught, perspectives on the nature of mathematics teaching, how mathematics teaching is learned, and how mathematics teaching is taught. In this section I briefly describe my conceptual framework with respect to these areas. This framework affects what I notice, what I consider important, and what challenges my current understanding.

A foundational component of my conceptual framework is the emergent perspective (Cobb & Yackel, 1996). Using this perspective, I regard the relationship between social and individual aspects of human experience as reflexive (inseparable) in nature. To account for human experiences such as knowing mathematics or educating mathematics teachers, I try to understand both social and psychological aspects of human beings' (inter)activities in their social-cultural-physical milieu. I assume that people learn as they participate in, and *reflect on*, the continual negotiation of norms, practices, and taken-as-shared meanings concerning their (inter)activities in various communities of practice. I also assume a constructivist epistemological stance and theory of learning (Piaget, 1980; von Glasersfeld, 1991) that stress the inseparability of a person's history of (inter)activities in her or his milieu and what she or he knows and feel.

I conceive of knowledge (e.g., mathematical, pedagogical) as a person's conceptions that are used to make sense of (organize) her or his experiential world. Accordingly, I view learning as the adaptive process in which people, while participating in their communities of practice (e.g., a mathematics classroom), transform their current conceptions via *reflecting* on the relationships between their activities and the effects of those activities. In this context, I emphasize two key

to teach mathematics—differentiating plausible explanations of learning processes that afford mathematics teachers' advancement from lower to higher stages, and (*3c*) how someone's activities promote others' learning of mathematics teaching—differentiating plausible relationships between teacher educators' activities and teachers' learning. In this sense, being teacher educators themselves, mentors of teacher educators can develop their mathematical and pedagogical knowledge through such experiences as teaching mathematics to students, teaching pedagogy to teachers, or teaching epistemology to teacher educators.

Fourth Focus: Mentors of mathematics teacher educators develop ways of thinking about and intentionally participating in others' learning to educate mathematics teachers. Through reflection (indicated by arrows 1, 2, 3, 4, 5, & 6 in Figure 4);

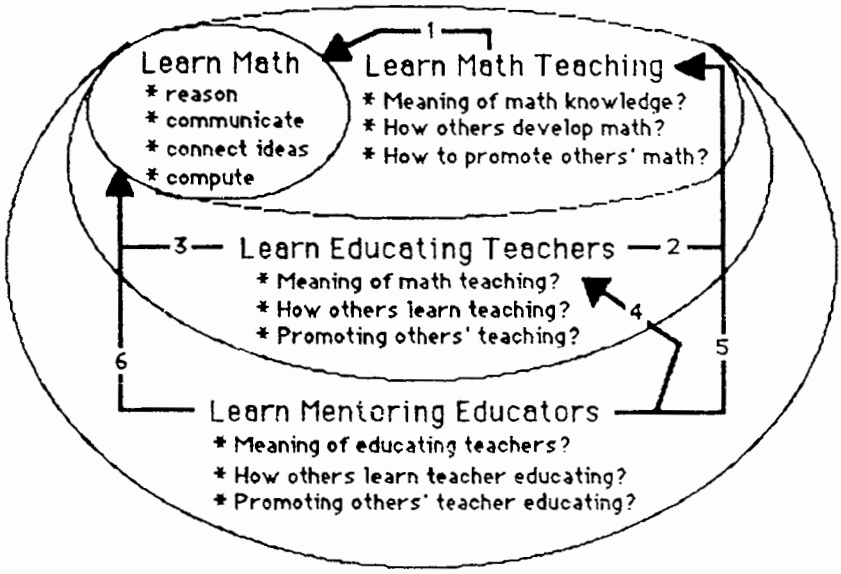

Figure 4: A four-Foci model of Teacher Education.

mentors may become aware of the perspectives that underlie their practices in terms of: (*4a*) what it means to educate mathematics teachers—elaborating one's own perspective of *3a* (hence *1a*, *1b*, *2a*, *2b*, and *2c*), *3b*, and *3c* above and differentiating levels and stages in mathematics teacher educators' practices, (*4b*) how someone comes to know how to educate mathematics teachers—differentiating plausible explanations of learning processes that afford teacher educators' advancement from lower to higher stages, and (*4c*) how someone's activities promote others' learning of how to educate mathematics teachers—differentiating plausible relationships between mentors' activities and teacher educators' learning.

A key to understanding this four-foci model is that development from a lower to a higher level is not a simple extension (i.e., doing more and better of the same thing). On the contrary, development entails a "conceptual leap" resulting from making one's *and others'* activities and ways of thinking at a lower level the *explicit focus of reflection* (cf., Cooney & Krainer, 1996; Edwards, 1996). Through such

reflection, the developing teacher educator (or mentor) may construct *anticipatory conceptions about learners and learning at the lower level(s)*, conceptions that become the theoretical ground for one's praxis. One may question this distinction by noting that all four foci include mathematical thinking. However, I emphasize that even in the case of mathematical thinking, let alone pedagogical and epistemological thinking, each focus is qualitatively different from the previous foci in that it embodies the lower level as an explicit way of thinking abstracted via reflecting on lower level ways of interacting in communities of practice (cf., Schifter, 1998). This is why, for example, proficient mathematics teachers often feel limited in their ability to teach pedagogy to other mathematics teachers on the basis of what they came to experience as empowered understandings of mathematics or students' conceptions and learning (i.e., being a good teacher does not necessarily imply being a good teacher educator).

Themes for Conversation and Research

As the four-foci model indicates, we learn through reflecting on our experience regardless of whether we are pupils, teachers, teacher educators, or mentors of teacher educators. In this context, I delineate 4 themes significant to the mathematics education community that can spark conversations and research.

1. Research Sites and Subjects: Graduate programs seem to be a good site to study teacher educator development, because such programs may promote critical shifts of foci and understandings. For example, one may study the interconnected nature of doctoral students' development of anticipatory perspectives of mathematics, mathematics learning, and mathematics teaching, as they teach mathematics teachers. In doing so, researchers will have to consider the impact of graduate students' motivations and backgrounds (e.g., beliefs about mathematics) and the political-cultural contexts in which they learned (e.g., collaboration vs. competition) on continual changes in their understandings (Acker, 1997; Diamond, 1988; Ryan, 1987). Moreover, it seems important to study development of novice teacher educators after their graduation, and to study groups of teacher educators who were not doctoral students, such as teacher-leaders or principals (Clemson-Ingram & Fessler, 1997; Collins, 1997; Hord, 1988; LeBlanc & Shelton, 1997; Levine, 1997; Rowley, 1988; Simon & Schifter, 1993; Talmage & Monroe, 1970; Zaslavsky, this volume). I anticipate that this last point may become an issue of debate, because mathematics educators may very greatly in their idea about "Who is considered a mathematics teacher educator?" (Cooney & Krainer, 1996).

2. Research Focus/Scope: It seems useful to study both general trends and personal shifts. Obviously, individuals in different communities of practice reflect on very different experiences as they construct (anticipatory?) perspectives of mathematics teaching (third focus) that underlie their shift from teacher to teacher educator. Thus, researchers may be interested in identifying regularities in teacher educator development that are unique to a specific sub-group (or political-cultural context), or regularities that characterize the majority. Additionally, as my story and the

four-foci model imply, teacher educator development is a very long and complex process. Thus, longitudinal studies seem most appropriate, but I think that short-term studies can contribute to conceptualizing specific aspects of new foci and how they are developed on the basis of previous foci.

3. Research Questions: A few fruitful questions highlighted by my story as possible research problems are: "How can models be developed for conceptualizing professional development and what would they look like?" (cf. Cooney, Grouws, & Jones, 1988) "What is important mathematics and mathematics pedagogy that teachers need to learn and how do mathematics teacher educators develop anticipatory perspectives of such learning in teachers?" "What specific shifts of focus occur in teacher educators and how do political-cultural contexts and the educators' perspectives about mathematics, mathematics learning, and mathematics teaching impact such shifts?" (Kinzer, 1972) "How can teacher educators promote bridging the gap between knowledge about students' thinking and teachers' learning to teach, or how does teaching/researching impact focus change in teacher educators?" (Cooney & Krainer, 1996; Denemark & Espinoza, 1974; Hudson-Ross & McWhorter, 1995) "How can mentors be involved in teacher educators' development and what models of teacher-learner interactions can inform the mentors' activities?" (Rahal & Melvin, 1998; Simon & Schifter, 1991) "How do teacher educators assimilate professional experiences into their praxis; what dilemmas do they confront?" (Cherland, 1989).

4. Explicating Teacher-Educating Models: Along with research on teacher educator development, it seems important to clarify the community's understandings of what constitutes teacher education consistent with principles of reform (Wilson & Ball, 1996). This is analogous to Simon et al.'s (1998a) plea to clarify models of teaching as a central means to explicate goals for teacher education. In the last 4 years, my struggle to conceptualize models of mathematics teaching through focusing my reflection on other teachers' development proved very *difficult and useful* to my understanding of and involvement in teacher development. I therefore anticipate that mathematics teacher educators will find it very difficult and useful to study developing teacher educators as a means to construct models of teacher-educating.

Closing Comments

The four-foci model presented in this paper is a work in progress and it is certainly far from being formulated and used in an anticipatory way. However, it highlights the long process required to reflect upon components at one level and develop, first locally and then globally, a new, higher level, integrated praxis. In particular, the model captures a primary goal for teacher educators and their mentors—to promote teacher educators' appreciation of the different foci of reflection. Key to this appreciation is that moving from the teacher's classroom to the teacher educator's classroom requires much more than a shift in the curriculum; it requires a shift in the kind of reflective analysis in which both parties engage. In both cases, such a shift calls into question the context of teaching and its impact on students' learning.

This paper is but an incomplete, self analysis of one teacher educator's story. Thus, it is limited to an individual's evolving perspective of teacher educator development, including recent learning resulting from reflecting on literature and reviewers' feedback while preparing the paper. Guilfoyle et al. (1996) suggested that self-reflective analyses should not be underestimated as a way to research teacher educator development. Although they stressed the need to extend studies of the meaning that teacher educators give to their development beyond this method, they saw this kind of research as appropriate because it provides access to important aspects of the teacher educator's past and current experiences (Ayers, 1988; Kaufman, 1996). In this sense, the hope is that the paper provides stimulating and relevant material for further collective and individual reflection among mathematics educators about the phenomenon loosely called teacher educator development.

WHAT DOES IT MEAN TO PROMOTE DEVELOPMENT IN TEACHING?

A response to Ron Tzur's paper: *Becoming a mathematics teacher-educator: conceptualising the terrain through self-reflective analysis*

Barbara Jaworski – University of Oxford

Through a process of 'self-reflective-analysis' Ron Tzur sets out towards conceptualising mathematics teacher-educator development. He presents a deep and searching account of his own growth of knowledge as a teacher-educator on which he bases a four-focus model to 'conceptualise the terrain'.

In this response I shall focus firstly, and briefly, on two aspects of Ron's theory and methodology that are of significance to his substantive focus: (i) his use of fragments as a methodological tool for self-reflective analysis; and (ii) his juxtapositioning of the individual and the social as a foundation for discussing growth of knowledge in becoming a teacher-educator.

Secondly, and at slightly greater length, I will then respond to the substantive material of Ron's paper to discuss the main elements of his analysis and the resulting model, and to raise an issue which seems implicit in the paper but not extracted explicitly or subjected to critical scrutiny. This, I believe, raises questions central to much mathematics teacher education as it exists currently.

Fragments as a tool for self-reflective analysis

Ron begins by reflecting on 'fragments' from his own experience, anecdotes, narratives or stories which carry in the them the essence of the concepts he seeks to extract. John Mason (1988a) has suggested a *fragment* is

> a temporarily continuous recallable incident whose content can be negotiated and agreed. It is generally of short duration because it must be recallable ... and since its content can be agreed, it must be detailed enough not to require extensive interpretation.

Mason uses the phrase "brief-but-vivid" to capture the two essential ingredients of a fragment. A working group of the Mathematical Association in the UK expounded a theory of the use of *stories* or *anecdotes* to develop professional practice - the Anecdoting Process (Mathematical Association, 1991). The notion of *narrative* as a source of theoretical grounding is now well developed in the educational literature through the work of, for example, Connolly and Clandinin (1995), acknowledged by Bruner (1986, 1996) as taking its place alongside nomothetic and ideographic forms of evidence and demonstrated in the mathematics education literature in the work of Deborah Schifter (1996) and Leone Burton (in press). Ron himself refers to the work of Guilfoyle et al (1996) in the use of narratives and analyses of experience to present their work.

As a methodology leading to emergent theory, however, fragments must be seen as more than unsubstantiated personal reflections from which generalisation is dubious. The importance of such stories, narratives or fragments lies in their offering particularities which resonate so strongly with the experiences of others in a community that general principles can be extracted. The notion of 'essence' is a key idea, since the fragment is chosen to carry

this essence, to be generic rather than particular. It is not that we can generalise from the one example, but rather that the one example points paradigmatically towards the principles we wish to expound or issues to extract. The *essential* nature of the story is resonated in experiences of its audience, who are able to recall similar instances of their own, and thus enter into the general principles involved.

Ron's choice of fragments is done selectively and succinctly to point to the key stages in his development and bring his readers, effectively, into the terrain he seeks to analyse. The levels of generality or particularity in the fragment seem central to its effectiveness in convincing its audience of the ideas or issues to be extracted. I should have liked to see rather more *specific* instances of Ron's experience in some cases. For example, in his first fragment, where he talks of his mathematical learning from peer tutoring, he says,

> "Often the struggle to figure out how to explain the matter brought about new insights *in me*. Sometimes my peers "got it" and I experienced a feeling of accomplishment; other times they did not and I felt dull and disturbed."

I can enter into this experience, knowing myself of occasions when I as teacher learned more from a situation than the students I was trying to teach. Thus the fragment has important face value reflected in my experience. How much more powerful this might have been had we been presented with a specific occasion in which something mathematical suddenly was crystalised for the teacher while seeming not to be appreciated by the peer. Similarly, in subsequent fragments, it could have been valuable to be given a glimpse of a particular issue discussed with Lori, and its differences for Ron's and her development. While a general description might resonate with a reader's own experience, such generic particularity has an intrinsic power to convince, thus providing powerful evidence for a theoretical conjecture. Mason (ibid) writes, "It is essential that a fragment be known by what people experience, and not by some interpretation or generalisation of their experience".

As a research tool, the use of fragments can be extremely valuable in analysing incidents or situations leading to general articulations or characterisations. A brief-but-vivid account of an incident which manages to capture its essential nature becomes data for analysis. Analysis looks critically at the issues raised by the fragment and the particular circumstances in which it occurred. For example, in a *particular* case of team teaching with Lori, in which Lori's learning appeared not to be what Ron might have hoped, what were the key circumstances and issues? How do these relate to circumstances and issues in other fragments? Such identification across a range of fragments could start to provide insights into the practices described and to a theoretical account of their problematic nature. In this way, reflection shifts into research, and research provides clearer evidence on which further practice can be more knowledgeably designed.

Reflection and Reflexivity: the individual and the social

Ron's position on knowing and the growth of knowledge influences overtly his conceptions of himself as a learner. He acknowledges this position as a *constructivist* one in which "people, while participating in their communities of practice (e.g., a mathematics classroom), transform their current conceptions via *reflecting* on the relationships between

their activities and the effects of those activities"(emphasis in original). He sees a reflexivity between individual and social aspects of human experience, assuming that "people learn as they participate in, and *reflect on*, the continual negotiation of norms and practices, and taken-as-shared meanings concerning their (inter)activities in various communities of practice (emphasis in original).

This reflexivity between the individual and the social is no simple matter. It involves a complexity of theory which depends on assumptions about the growth and status of knowledge and is lengthily articulated by theorists in psychological and sociocultural domains in the mathematics education literature and beyond. It is understandable that Ron did not include a critique of such theoretical positions in the short space allowed for his paper in this forum. However, such critique is now well-known in the public domain. See for example the excellent juxtapositioning by Jere Confrey of elements of Piagetian and Vygotskian theory in Confrey, 1995. She, along with Jerome Bruner (1996, in his key address in Geneva, bridging the conferences celebrating the centenary of the births of Piaget and Vygotsky) points to the incommensurability of these theories where the origins and growth of knowledge is concerned. The debate in mathematics education, between constructivism and socio-cultural theory, continues currently between Les Steffe and Stephen Lerman in JRME (forthcoming).

My point in mentioning this debate is to emphasise the complexity of the theoretical arena in which learning is conceptualised, and the problematic nature of 'giving the nod' to both constructivist and socio-cultural positions as supporting a conceptualisation of learning. Ron speaks of "the social and psychological aspects of human beings' (inter)activities in their social-cultural-physical milieu", and "the negotiation of norms and practices, and of taken-as-shared meanings concerning [people's] (inter)activities in various communities of practice". He views learning as an adaptive process in which current conceptions are transformed via people "reflecting on relationships between activities and the effect of those activities". As he indicates, this is undoubtedly a *constructivist* position. However, it uses terminology from a number of paradigms (for example, 'communities of practice' from social practice theory (e.g. Lave and Wenger, 1991) and 'taken-as-shared meanings' from social interactionist theory, (e.g. Bauersfeld, 1988) to explain communication of knowledge.

There have been many attempts to explain, from a constructivist position, apparently 'correct' understandings by one person of the thoughts or actions of another, or apparently 'mutual' understandings between one or more people – what might be called 'common knowledge', or intersubjectivity. Les Steffe and colleagues' *second-order models* offer one persuasive example (e.g. Steffe, in press; another is Cobb , Wood and Yackel's focus on developing *taken-as-shared meanings*. in classroom interactivity (e.g., Wood et. al., 1993). It is nevertheless hard to explain intersubjectivity in constructivist terms. The communication and 'sharing' of knowledge is central to consideration of social norms within classrooms, yet, often, the problematic nature of such sharing, from a constructivist theoretical perspective, is not addressed.

Socio-cultural theory, on the other hand, is *based* on a position of understandings being in the community *first*, and individual learning being derivative of social practices, or even

embedded in those practices. Reflexivity could be interpreted, in Vygotskian terms, as the shifting between social and individual planes, with the social plane having pre-eminence. Where reflection is concerned, it seems unclear whether its transformative nature is a construct relating to the individual, or whether (and how) it leads to transformations within a community. From a sociocultural view, learning is an enculturative process in which learners grow into the intellectual life of the community in which they engage. What the community espouses and practices (for example, critical reflective practice in teaching), it is likely that participants in the community will develop as a result of participation (Lave and Wenger, 1991). However, if such practices are not central to the community, it is unlikely that they will be developed through a process of enculturation. In terms of the Vygotskian construct of Zone of Proximal Development, by engaging with a learner in the learning process, the more experienced other can interact to support learning within the ZPD. Whether the outcomes would be those desired is far from certain.

These various theoretical positions (treated very sketchily here) depend on epistemological assumptions regarding the nature and status of knowledge. It is dangerous to interpret constructive intersubjectivity, participative enculturation, or supported learning as promoting *desired* learning without examining critically such assumptions. Thus, in trying to *promote* learning, we find ourselves in ambiguous positions theoretically. It is perhaps not surprising therefore, that promoting *desired learning* in practice is so difficult, as Ron's paper shows.

Another issue concerns the nature of the community in the mathematics classroom, where negotiation of norms and practices may be central to achieving goals, for example goals of mathematical described by Wood et al.,(1993) where it was clear that a *changing* of norms was central to the success of their programme. When we set out to negotiate, or change, the social norms of the classroom community, we have to look beyond mathematics and the immediate institutional environment to the wider sociocultural influences on relationships within the classroom: whether the practices being nurtured are compatible with *societal* norms – issues of equity for example, and the implications of changes in the classroom power structure. Does reflection and negotiation include addressing these wider (and potentially stronger) influences? If so, is this an individual or a collective act; constructive or enculturative? How is it achieved and what are its consequences for participants? Ron sidesteps these issues by acknowledging what he calls the "non-academic issues", but deciding for this paper to leave them "in the background". I believe they are too central to all levels of development, including the academic, for this to be a real option, and this raises issues for teacher educators as well as theoreticians and researchers.

The Teacher-Educator's Dilemma

Teacher-educator Development

The main theme of Ron's paper is the drawing of a conceptual model of teacher-educator development based on deep reflections on, and critique of, his own development over a lengthy time period. Ron describes his learning through reflection on his own activities, starting with early experiences of peer tutoring leading to his own enhancement of mathematical understanding, and continuing through a critique of teaching practices leading

to adaptations to his teaching. The key notion here is that the reflective activity needs to relate to a learner's own experiential domain, so that the learner tackles and finds solutions to his own problems.

Ron has taken the questions from his own mentors (Steffe and Simon, for example) and, through working on those questions relative to his own previous knowledge and experience, has adapted his approaches to teaching, educating teachers and mentoring teacher educators. He points to the importance of cultural changes , of the need to reflect on his experiences, and of the mutual impact between his research and teaching leading to his own enhanced awarenesses of growth of knowledge in teaching and educating teachers. In the terms of Jaworski and Watson, 1993, Ron has an extremely well-developed 'inner mentor'.

The developmental path that Ron traces for himself resonates strongly with my own experiences of developing as a mathematics educator: for example, the recognition of key stages in one's own learning of mathematics; the realisation that, in trying to teach another person, the teacher's own mathematical knowledge grows; the value of reflecting on experiences in order to be more consciously aware, and critical, of aims and outcomes. I believe that most educators will be able to produce their own fragments of experience to speak to the stages of development described and conceptualised. It is quite clear that the reflective process so clearly articulated is a compelling way to characterise effective growth of knowledge both of mathematics and of the complexities of the learning and teaching of mathematics for the critically conscious[1] teacher educator.

Ron outlines a four-focus developmental model based on his own experiences. This model offers a clearly articulated and convincing conceptual account of the inter-related stages of teacher-educator development, taking in learning of mathematics, learning of teaching mathematics, learning of educating teachers of mathematics, and finally learning of educating mathematics teacher-educators. It is an account which characterises the development of an aware teacher educator. It also fits with other articulations in the same terrain (e.g. Jaworski, 1999). However, it is an account in which it is not clear how any student, teacher or educator comes to engage in this process. It is also not a model of how educators promote the engagement of others in the process. A critical question, given that the process is clear and convincing and well evidenced in the experience of many educators, is how can educators use this conceptualisation to promote the learning of others at any level within it? Or does it just *describe* a developmental process?

Educator centrism

In his clarity of articulation, what I found especially outstanding, and poignant, were Ron's references to occasions in which, despite his own evident growth and development, his teaching ambitions had not been realised in the learning he observed. For example, Ron says

> Often the struggle to figure out how to explain the matter brought about new insights *in me*. Sometimes my peers "got it" [something mathematical] and I experienced a feeling of accomplishment; other times they did not and I felt dull and disturbed.

[1] In using such terminology I draw on a substantial literature relating to critical reflective practice, most seminally represented for me in the works of Dewey, Kemmis, and Schön See for example Jaworski, 1994

> In working with the teachers, I had many insights into teaching my students, but rarely did the teachers indicate the intended understandings.
>
> When discussing those issues with Lori, I also realized that team teaching enhanced my understanding of teaching and helped her to experience activities of teaching but it did not seem to be as useful in terms of Lori's conceptualization of teacher education.

As Ron acknowledges, in many of his teaching interactions the chief learner is himself. What the other participant learns is not clear, but, often, it seems not to be what Ron would ideally like to be learned, or at least there is no evidence that it is. Such situations are clearly recognisable to me, and I could find many similar ones in my own experience. I suggest this might be true for other educators. How does one build from such recognition to a clearer understanding of the problematics involved? Research consisting of a systematic analysis of fragments (mentioned above) might be one way to achieve this.

In particular, such research lifts reflective activity to a more objective plane. As teacher educators individually reflect on their development and ask questions about its problematic aspects, it is often the "I" which impedes progress in perceiving the nature of the problems - a sort of educator centrism. A caricature of the situation is, '*I* have learned this, or achieved this – how can *I* promote this in others?' The focus on the "I" both illuminates and obscures the essential nature of the developmental exercise in which the "I" has participated.

'Promoting' the learning of others

Ron makes it very clear that his own learning relates strongly to his cycle of raising his own questions and setting his own goals as a result of reflecting on outcomes of his own research activity. This recognition leads to questions of how he, or other educators, might *promote* such learning in others. I want to argue for some dichotomy between these aspirations. The poignant nature of the quotations above lies in the frustration of the experienced, aware and knowledgeable educator in trying to promote "intended understandings" in others. This might be typified as "the teacher-educator's dilemma", and it relates closely to dilemmas of the teacher, recognised for example as the *teacher's dilemma* (Edwards & Mercer, 1987) and the *didactic tension* (Mason, 1988b). Perhaps a key phrase is "intended understandings".

When Ron was faced with Les Steffe's question "When interacting with children, how do you know that you met a scheme?" his learning was enhanced. He himself knows how this question impinged on his experience at that time, and the subsequent effect of it. Could Les Steffe have envisaged this? Did he see, in Ron, his own intended understandings? Was he, perhaps, disappointed because of Ron's apparent understandings did not coincide with what he had intended in posing the question? Were there parallels between his perceptions of Ron's awareness and Ron's subsequent perceptions of Lori's awareness? Like Ron, Lori can be seen to have a personal learning trajectory, one part of which relates to her team teaching with Ron. Her learning relative to the team teaching is also relative to other parts of her experience in communities of practice to which, perhaps, Ron has little access. According to Ron's model of development, based on critical reflective practice, each person promotes

their own development relative to the issues they address. What is problematic is for some other person to try to direct that development.

A constructivist view is that the only person who can 'know' what has been learned – through reflection on experience – is one's self. Through attempts at reaching intersubjectivity, another person can gain insights to this learning, but can never be sure what has been learned. More importantly, the other person can only try to approximate to the desired learning, based on intersubjective experience. These issues are subject to the all the theoretical problems mentioned earlier.

Towards resolving the dichotomy

Ron's team teaching with Lori seems to have been especially powerful in Ron's learning. Here he was working *with* Lori, rather than (or as well as?) trying to promote her development. Of course we know nothing from Lori about this development, only Ron's perception of it. Lori's development can only be *her* development. It can never be Ron's. Also Ron cannot be expected to have insights into the cultural origins of Lori's experiential development. However, as two people conduct classes together, and work together on ideas and issues, their intersubjective understanding would grow. This would allow critical questions to be recognised and addressed jointly, albeit from different experiences and developmental levels. A form of co-learning, or co-mentoring would result, which would support the inner mentor of each of them. Thus reflexivity is interpreted as acting between the social plane and the individual plane for the individuals in a co-learning partnership. The idea of such a partnership is based on a typology of researcher-practitioner co-operation offered by Jon Wagner who writes:

> In a co-learning agreement, researchers and practitioners are both participants in processes of education and systems of schooling. Both are engaged in action and reflection. By working together, each might learn something about the world of the other. Of equal importance, however, each may learn something more about his or her own world and its connections to institutions and schooling. (Wagner, 1997)

I have proposed that Wagner's concept of co-learning agreements might be extended to work between teachers and educators in an enterprise of mutual development (Jaworski, 1999b). For any participant in the developmental enterprise this involves growth of the individual in practice through reflexivity between co-mentoring and the inner mentor. A co-learning agreement requires both participants to reflect on activities, jointly and separately, and to critique outcomes of activity. The aim of a co-learning agreement is to create learning situations in which all participants can be reflective partners, and through which ideas can be offered and issues and tensions addressed overtly. Such a partnership would remove the necessity for one person to 'promote' learning in others. Partners take responsibility for their own learning and development, but levels of mutual responsibility within the partnership offer and support development of ideas. There is no intention that partners should be equal, but more responsibility rests with the more experienced partners to ensure minimisation of power differentials and ease collaborative communication and critical reflection.

Of course there are many issues to address, not least the epistemological groundings of such a theoretical perspective, and the nature of relationships in an evolving praxis. These are addressed to some extent in Jaworski 1999a and b, but further research and more rigorous attention to theory is still required.

In Conclusion

In my response I have valued greatly Ron's articulate account of his own development, and his consequent four-focus model to describe development in the teaching and education process more generally. I have recognised what might be seen as a dichotomy in the aspirations of educators in valuing development through self-reflective analysis, while seeking simultaneously to promote particular development in others. In making a critique I have touched on the methodology of using fragments as an analytical tool, and the theoretical commensurability of constructivism with versions of sociocultural theory. It must be recognised the enormous issues in epistemology, cognition and pedagogy which are raised when we start to offer conceptualisations for teacher-educator development. Ron's four-focus model offers an important starting point in addressing these issues.

Visualization as a Vehicle for Meaningful Problem Solving in Algebra

Michal Yerushalmy, Beba Shternberg, Shoshana Gilead

University of Haifa and Centre for Educational Technology - Tel-Aviv.

Our experience with a new algebra curriculum has challenged us to identify both strengths and complexities of the variation function approach we take. Among a few noticeable effects of the approach, we learned that functions form an important basis for solving algebra word problems. The approach described here maintains that graphing is not necessarily an outcome of measurement and plotting points. This approach is supported by the use of a software environment. Already in the very first stages of the course, a natural language text turns into a script of events and processes, and then into qualitative graphs sketched using iconic notations; then it turns into a subject for qualitative analysis of the rate of change. This sequence forms a visual basis for modeling. In this article we discuss the relevancy of this approach to problem solving in algebra. We also do an exhaustive analysis of the major types of algebra word problems in order to point out the structural differences between various algebra rate problems and the possible interactions between the visual mental models and the symbolic equations involved in the solution process.

The use of various representations of functions offers new ways for supporting strategies of solving algebra problems (Chazan 1993, Heid 1995, Yerushalmy 1997). Most attempts offer the use of multiple representations as a means of bridging and deepening connections between areas assumed to be separated (e.g., symbolic manipulations in algebra and knowledge of functions). Other proposals call for democratizing the access to calculus using MBL and simulations that can help describe complex phenomena (Kaput 1994)without relying on formal algebraic symbolization. As a result of studying our students who were using the "*Visual Mathematics*" curricular materials and software that offer syntax and semantics for qualitative visual description of processes[1], we became interested in the link between the two; We wondered how we could use modeling attempts based on the concept of variation and on visual descriptions and analysis of rates, that naturally lead towards symbolization in calculus (e.g. simple differential equations

[1] "*Visual Mathematics*" is an algebra curriculum focused on the concept of function and organized around major ideas and representations rather than technical manipulations (Centre for Educational Technology CET 1995).

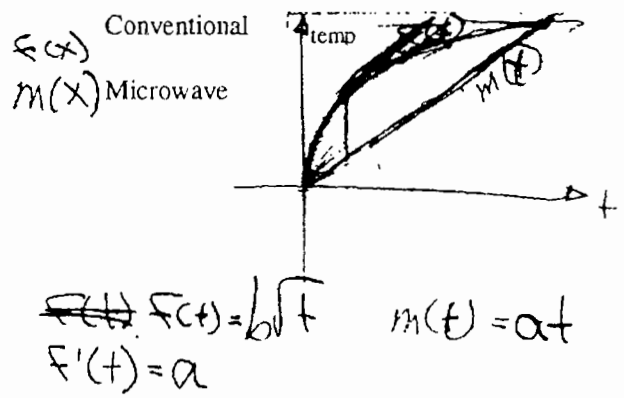
such as $f'(x)=Af(x)$), in order to introduce and establish an understanding of algebra.

To demonstrate a step within this exploration, we will look first at strategies and representations used by calculus students and 7th graders solving the same non standard modeling problem. Both groups were equipped with tools for solving the given problem, which requires a comparison of rates of two processes: the calculus students were familiar with derivatives and algebra, and the 7th graders have learned how to describe and analyze models using a basic set of iconic symbols. The analysis of these solution attempts offers some ideas about how to treat this gap between graphing and meaningful algebraic symbolization. From the non traditional modeling we will move on to look at the possible effects of the visual foundation on studying traditional algebra word problems. We will start by looking at attempts of solving a non trivial algebra problem prior to any teaching intervention; continue by identifying problems that were harder for students to solve, and finally suggest exhaustive classification of all linear-models algebra problems by the deep structure of their graphical models.

Part I: Coping with the Ovens problem

The Ovens problem requires skills that are not usually taught in algebra; it deals qualitatively with a phenomenon related to the lows of heat. It does not provide numerical data. Therefore, students who are not familiar with the physics involved nor provided with a simulation tool, can hardly benefit from the use of graphing technology while solving this problem. Thus, this was an appropriate activity for studying modeling and solving skills of both symbolically mature and immature students.

> The Ovens problem: A cook has to cook a large lamb as quickly as possible. The meat is at room temperature. The cook has a conventional oven and a microwave oven. In a cooking test it was found that during the cooking time, the temperature of the lamb in the conventional oven is always higher than the temperature in the microwave and that the cooking time required in both ovens is exactly 2 hours. In the microwave oven, the heat of the lamb increases at a constant rate, and in the conventional oven kept in constant temperature, the heat of the lamb increases at a changing rate. Could the cook use the two ovens to reduce the two-hours cooking time ? (adapted from Taylor, 1992, p. 20)



A symbolical approach

In order to learn about the contribution of formal symbolic knowledge to the construction of models using rate of change, we interviewed a group of 11th or 12th graders. The students took algebra, pre calculus and calculus courses. However, none of their courses was centered on modeling or realistic situations. We will demonstrate typical attempts taken throughout the interviews.

Ella started her solution by looking for specific information about the processes:
Ella: I think that some givens are missing...
Interviewer: Which one do you miss?
Ella: I think I need the temperatures...
Interviewer: So you'd like to have the measurements from the experiment?
Ella: Yes!
Interviewer: Why don't you make them up yourself?...

It was not easy for Ella to give examples of numbers which could fit the processes. She used constant differences to represent the constant rate condition for the microwave sequence. But she could not form any model of the collection of numbers she fabricated to represent the conventional oven. Nothing looked as mathematics to her in this sequence, and as a result she gave up trying to solve the problem. Ella was one of many students (12 out of 34 interviewees) who tried but failed to express their intuitions symbolically or in any other general way.

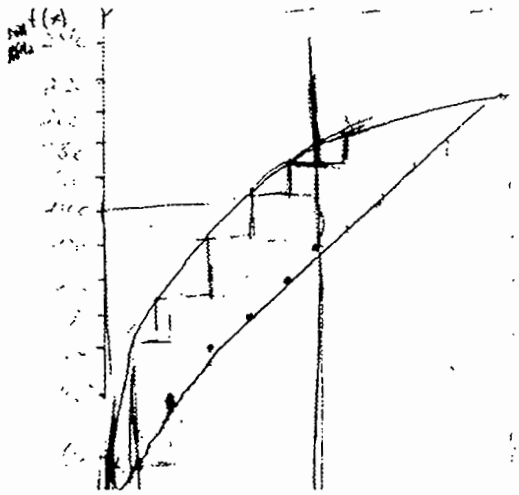
Yoni, on the other hand, immediately started by graphing and assigning symbolic descriptions:
Let's say that m(x) is the microwave and f(x) is the conventional oven.
He sketched the graphs and inferred that the cook should start by using the conventional oven:

.... it should stay there to a certain point, something like that (he pointed on the graph) and then... Intuitively, I would say that it should be at a point where the slope here (conventional oven) will be equal to the slope here (microwave), since from this point onward, the first slope begins to be smaller than the second one.... m(t) = at, f(t).... it doesn't matter for a moment what it is. We have to find the derivatives of m(t) and f(t).

Still, Yoni did not consider his answer to form a solution and continued his efforts:

I have to find the value of the t...

Here Yoni began to look for an expression that would fit the description of the curve. He offered the square root function but commented with great disappointment that there is no way to know:



I have a problem with curves which aren't parabolas and here I am not sure that it is a parabola...

So how do high achiever calculus students deal with a modeling problem that does not provide information to form an algebraic equation? Yoni belongs to the group (20 out of 34 students) that made an attempt to use known symbolic conventions of functions to formulate a model. Yoni's intention to provide a parametric description rather than a specific expression was exceptional. Only 6 interviewees out of the 34 reached a solution for the Ovens problem. Yoni, who was one of them, was unhappy with his answer. His disappointment stemmed from his inability to use rate as a tool for explaining the behavior of a curve (for Yoni, any non linear curve is a parabola) and was probably linked to the traditional sequence of an algebra course where the visual situation models are being established as an outcome of an algebraic equation rather than being a basic tool for description and analysis.

A qualitative approach

While technology usually serves for plotting data or performing computations symbolically (Heid 1995), we were interested in using technology to support the two qualitative stages: the recognition of typical graphical models (as demonstrated in curricular materials of the Netherlands and the UK [Swan 1982]), and the visual non-quantitative analysis methods. To do this, we developed a software environment, "The Algebra Sketchbook" (Yerushalmy , Shternberg 1992/4). We were interested in understanding how this environment supports evolution of visual and linguistic modeling capabilities and how these capabilities support the solution of problems of the Ovens problem type that the students were unfamiliar with. The interview of 16 7th grade pairs took

place right after the completion of this qualitative modeling unit. The students were intuitively using symbols as generalized numbers but did not yet deal formally with manipulating or solving any algebraic relations. The following is an attempt (made by Erez and Ilanit) to solve the problem by offering a graphical method to evaluate the rates of change of each of the processes.

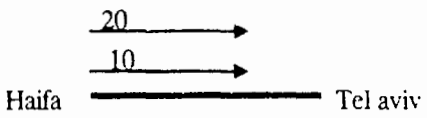
The graph above that these students sketched represents the general approach of students in this sample: they made a sketch, analyzed the two rates, and compared the stairs size of the two processes as a way of deciding if and how to use the two ovens. The modeling capability demonstrated by 7th grade students was not only convincing; we found, again and again, that it was a strong mathematical foundation which they were able to build their further knowledge.

Part II: Visualizing traditional algebra word problems

For decades, algebra students encountered word problem of the following kind :

> Problem 1: A biker left Haifa for Tel-Aviv riding at an average speed of 10 km/h. His friend left Haifa 4 hours later, took the same road to Tel-Aviv, and rode at an average speed of 20 km/h. How long after the first biker left Haifa did they meet?

The expectation has always been that students would assign symbols to variables such as distance or speed, arrange them in an algebraic relation. and solve the equation to discover the answer to the problem.



BEST COPY AVAILABLE

Organizing table for Problem 1

	time	speed	distance
Biker	t	10	$10t$
friend	t-4	20	20 (t-4)

$10t = 20(t-4)$

Traveling path in Problem 1

This translation from situation to symbols proved to be difficult for many students. Previous studies suggest that the re-representation of a situation by a symbolic expression requires the evolution of what is called "*the situational model*" and the use of graphs, tables, and diagrams of various sorts. With the function approach to algebra, this translation process takes a different direction. The following is a solution of the problem offered by Tal, an 8th grader of the "*Visual Mathematics*" curriculum prior to any formal instruction of word problems:

Tal was mostly interested in the connections between the formal functions expressions and the situation structure. At first, Tal described the functions properties. Then, he found the value of the intersection point. However, this numerical information from the graph and the table did not coincide with the information retrieved from the functions expression: "At $x = 2$ the function $g(x)$ assumes the value -40, but a negative distance does not exist, so there the function is zero but I still use the expression $g(x) = 20x - 80$ since I don't know how to find a better procedure". The negative values, which resulted from substitution in the

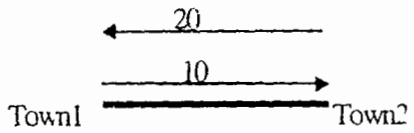
BEST COPY AVAILABLE

function expression, were inconsistent with his perception of the situation. But at that time, Tal did not know how to write symbolic descriptions of functions in multi intervals, and therefor gave up. A way to settle this conflict, one that we did not take at that time, was to follow Tal's thought about the meaning of the "negative" distance. One could do that by considering another situation having the same symbolic description and the same solution . For example, if the two bikers would have left at the same time from two locations 80 kms apart, then Tal's conflict would be set. Thus, a problem that we assumed to be a routine exercise turned to be a rich modeling activity for students who seek meaning in connecting the situation and its representations and are equipped to do so.

Do graphs always simplify problem solving?

Here is an example of another motion problem taken from the same set of practice problems as problem 1:

> Problem 2: A biker traveled from town1 to at an average speed of 10 km/h. Arriving at town2, she immediately turned back and traveled from town2 to town1 at an average speed of 20 km/h. The return trip was 4 hour shorter than the outward trip. How long took the trip in each direction?



In the traditional approach this problem is almost identical to problem 1.

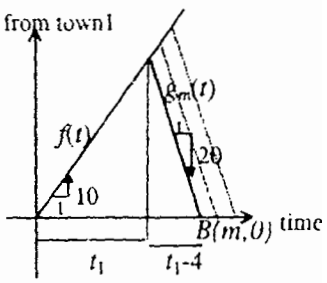
Organizing table for Problem 2

	time	speed	distance
out	t	10	$10t$
back	t-4	20	$20(t$-4)

$$10t = 20(t-4)$$

Traveling path in Problem 2

In the function approach, there are noticeable differences between the two problems.



Problem2

$f(t) = 10t$

$g(t) = -20(t-m)$

$f(t) = g(t)$

$10t = 20(t-m)$

The distance in the second problem cannot be graphed as a function of time but must be sketched. Distance can be evaluated only for the first

segment of the round trip, and the return point cannot be numerically determined by a comparison of the two functions. The function rule g is dependent on a parameter m to specify the x-coordinate of point B, and it represents a family of parallel lines with a slope of -20. The equation $10t = -20(t - m)$ represents a comparison between the function f and a family of functions g_m. Only one member of the family, for which $m = t_1 + (t_1 - 4)$, satisfies all the constraints defined by the given story problem. The solution requires substitutions that transform the original equation, that describes processes as a function of t, into a function of m. This function does not describe the situation structure as initially graphed by the distance-time graph.

Thus, two similar problems pose different challenges regarding the construction of symbolic semantics and the possible information that can be evaluated from the visual model. What might be the source of the different levels of complexity encountered while formulating functional expressions? Since the problems have the same givens and constraints (see table below), one may suggest the difference can probably be explained by their different situational context.

The givens in problem 1	The givens in problem 2
v_1= 10 km/hour, v_2= 20 km/hour	v_1= 10 km/hour, v_2= 20 km/hour
$d_1 = d_2$ (same distance until they met)	$d_1 = d_2$ (same distance in both directions)
$t_1 - t_2$= 4 hours	$t_1 - t_2$= 4 hours

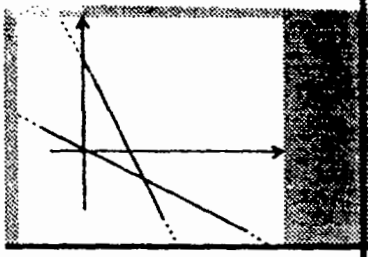
To contradict this assumption we will re-examine problem 2, but this time we will compare it to problem 3. Problem 3 describes a similar situational context as problem 2 but defines a different time constraint.

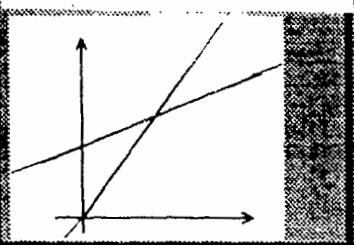
> Problem 3: A biker traveled from town1 to town2 at an average speed of 10 km/hour. Arriving at town2, she immediately turned back and traveled from town2 to town1 at an average speed of 20 km/h. The whole trip took 7 hours. How long was the trip in each direction?

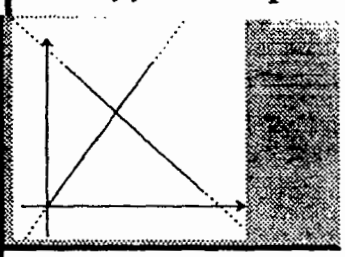
The givens in problem 2	The givens in problem 3
v_1= 10 km/hour, v_2= 20 km/hour	v_1= 10 km/hour, v_2= 20 km/hour
$d_1 = d_2$ (same distance in both directions)	$d_1 = d_2$ (same distance in both directions)
$t_1 - t_2$= 4 hours	$t_1 + t_2$= 7 hours

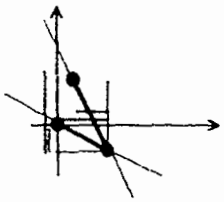
Problem 3 in contrast to problem 2 can be graphed (using a point and a slope for each of the two functions) and the expressions, the equation

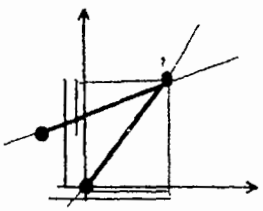
$10t=20(7-t)$ (or its equivalent equation $10t=140-20t$) and the solution values can be directly related to the visual situatuational model.

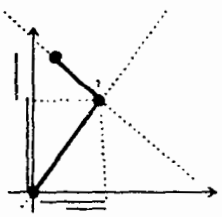


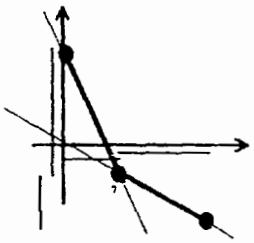


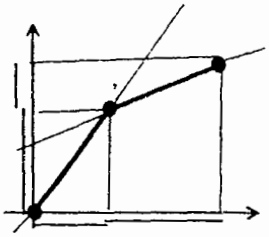


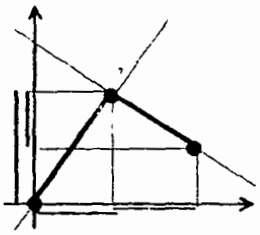


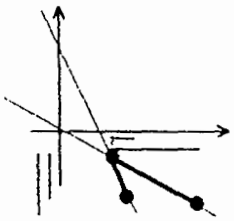


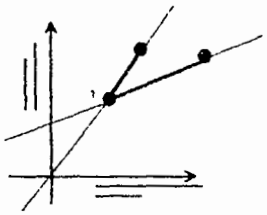


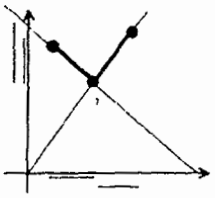


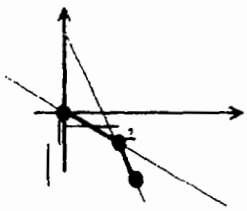


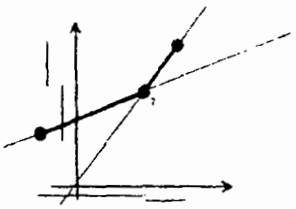


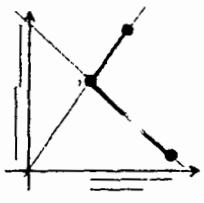








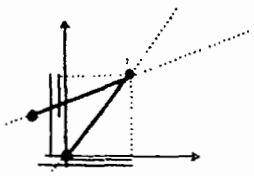




Use of visual models to classify algebra word problems

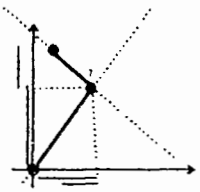
The different challenge each of problems 1 ,2 and 3 pose, suggests that neither the situational context (which problems 2 and 3 share) nor the set of givens and constraints (which problems 1 and 2 share) can each of them alone explain the differences between problems when taking the function solution approach. We conjecture that the interaction between the two is the crucial component and therefore can serve to analyze the deep structure of most algebra word problems. To systematically test our conjecture, we have chosen terminology drawn from cognitive research on arithmetic and algebraic word problems. Problem structure can be examined at two levels of abstraction: the *quantitative structure* describes arithmetic operations and relations among symbolic or numerical entities, and the *situational structure* describes relations among physical properties of the entities within a story problem. Both the quantitative and the situational structure of a problem can be described in different forms and representations. (Nesher and Hershkovitz 1994, Nathan, Kintch and Young 1992, Hall 1989). In this work, we describe the quantitative structure of constant-rate problems by the number and type of given quantities, the number and type of unknowns, and the constraints formed by arithmetic operations between pairs of unknowns (e.g. $t_1+t_2=5$ or $t_1-t_2=5$ or $t_1/t_2=5$). We describe the situational structure of constant-rate problems through sketches of linear functions that describe the change of the output (e.g., signed distance) in time where the rate is described by the slope of the line.

At this stage of the study, our main goal was to examine different structures of "algebra rate problems" as an outcome of all the possible interactions between the situational structure and the quantitative structure. The problems in this study consist of two processes that for some input share the same output, and the question in the problem asks about the value of this shared input, its shared output or both.



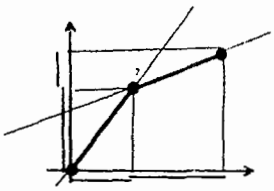
Defining a space of the situational structures: The basic elements of the functional language of rate problems in our work are two intersecting linear functions from R to R, the intersection point, and two other points (one on each line). There are three different possible combinations of the two intersecting lines (see table below): 1. slopes of negative signs (left column), 2. slopes of positive signs (middle column), or 3. slopes of positive and negative signs (right column). For any of the three combinations there are 4 different ways to create the set of the two

points on each line. The graphic representation provides a visual global perspective on the space of algebra temporal-constant rate problems.

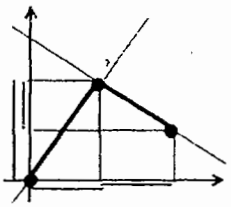


Two negative slopes	Two positive slopes	Two opposite slopes
		
		
Shared domain – Shared range	Shared domain – Shared range	Shared domain- Adjacent range
		
Adjacent domain - Adjacent range	Adjacent domain- Adjacent range	Adjacent domain- Shared range
		
Shared domain – Shared range	Shared domain – Shared range	Adjacent domain- Shared range
		
Adjacent domain- Adjacent range	Adjacent domain- Adjacent range	Shared domain- Adjacent range

Looking at the twelve situational structures in the table, four different types of relations between and within domain and range can be observed:



1. shared domain, shared range, 2. adjacent domain, adjacent range (both obtained by two lines of the same sign slope), 3. shared domain, adjacent range and 4. adjacent domain, shared range (both obtained by two lines of opposite sign slope). This organization allows the mapping of most algebra word problems onto one of the four types of situational structures.

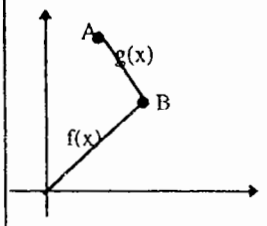


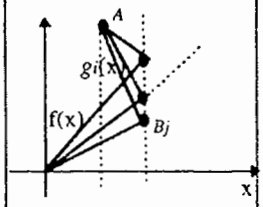
Shared domain – Shared range

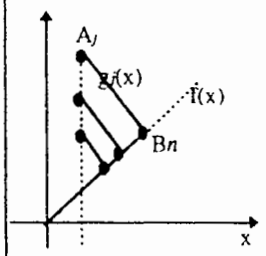
Shared domain- Adjacent range

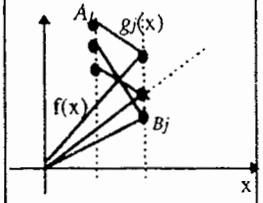
Adjacent domain- Adjacent range

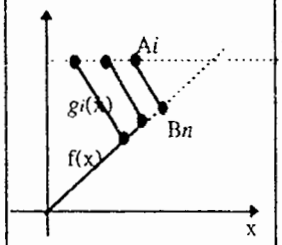
Adjacent domain- Shared range

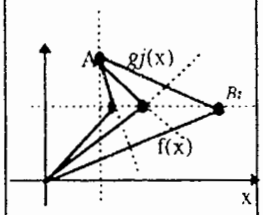


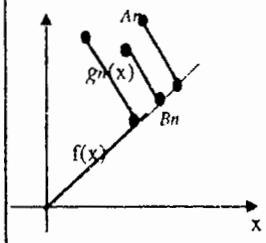


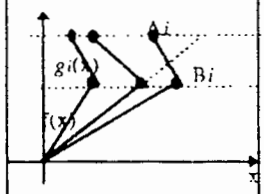












Definition of the space of the quantitative structures: Each of the situation problems classified above can also be determined by the following quantitative elements and relations:

1. Each problem deals with two triads of quantities, d, v, t, connected by a multiplicative constraint $d = v \bullet t$. Thus, there are exactly six elements involved in each problem.[2]
2. Only magnitudes of quantities are dealt with.

The problems which are normally called "algebra" problems describe additional two constraints, each of them linking two quantities of the same type by a binary operation (e.g., $t_1 + t_2 = c_1$ $v_1 + v_2 = c_2$, "One left 5 hours before the other", "His speed is 4 times larger", " They started at the same station and reached the same station"). There are always two known quantities and the unknowns are of a third quantity type (e.g. for given constraints about t and v, d is unknown). All possible combinations of two givens and two constraints produce a space of 24 different quantitative structures. The 4 situaitonal structure types and the 24 quantitative types produce 96 types of algebra problems. Our next step was to investigate the 96 interactions in order to reduce the number of different classes. To do so,

[2] The quantities referred to here, time, distance and speed, may be replaced by other quantities for non temporal situations or for work problems.

we considered again the differences between problems 2 and 3. The structure of the given situation and quantities in problem 2 allow to draw a unique graph. The structure of problem 3 allows to graph a family of possible graphs; the family is created by the parameter *m* which provides "freedom" to shift function *g* horizontally. Here is a demonstration of one of the four situation structures:

Information about slopes and points	Constraints and "freedom" of the situation graph	Information about slopes and points	Constraints and "freedom" of the situation graph
Class 1 v1(✓) v2(✓) B(? ,?) A(✓,✓)		**Class5** v1(?) v2(?) B(✓,?) A(✓,✓)	
Class 2 v1(✓) v2(✓) B(? ,?) A(✓,?)		**Class 6** v1(?) v2(?) B(✓,?) A(✓,?)	
Class 3 v1(✓) v2(✓) B(? ,?) A(?,✓)		**Class7** v1(?) v2(?) B(?,✓) A(✓,✓)	
Class 4 v1(✓) v2(✓) B(? ,?) A(?,?)		**Class 8** v1(?) v2(?) B(?,✓) A(?,✓)	

Analysis of all 96 structures according to "types and degrees of freedom" reduced the number of different classes to 32; eight types of "freedom" are repeated in each of the 4 situaitonal structures.

Part III: Directions for further research

Using images of rate to construct symbolic models

A covariational approach in analyzing a problem situation has been already suggested as more powerful than a correspondence approach (Confrey & Smith, 1994, Nemirovsky 1996). Even young children use rate of change as a way to explore functional relations (Nemirovsky and Rubin, 1991). A central question in our studies is whether the consideration of rate of change is a vehicle towards formulating models in algebra and calculus and whether the description of phenomena by their rate of change (rather than by dealing with values of specific events) can support symbolic understanding. We found that consideration of rate of change as a vehicle towards formulating and explaining symbolic models is absent in traditional algebra and calculus strategies. We conjecture that this absence could be a major obstacle of the 'modeling based' algebra curriculum designed to motivate the understanding of the mutual relations between phenomena and it symbolic models. It is even less clear how the qualitative visual covariation description of phenomena (and not of numerical values of discrete events) can support symbolic understanding or even create symbolic awareness.

Mathematics offers methods allowing the construction of symbolic expressions from given data; here is an example: Imagine a "stairs" graph that models a motion of a car that during an hour constantly accelerates from 50 to 60 miles/hour (adapted from Thompson 1994). The visual image of the rate can be translated and manipulated by the following procedure:

$$a(t) = 10\ mi/hr^2 \qquad v(t) = 50 + 10*t\ mi/hr$$

$$d(t) = 50 + (50 + 10) + (50 + 10 + 10) + \ldots + (50 + 10*t) =$$

$$= 50*t + (10 + 20 + 30 + \ldots + 10*(t-1)) = 50*t + \frac{10*(t-1)}{2}*t\ mi$$

In order to reach a symbolic model that describes the distance traveled at any instant along this hour, one should employ calculus methods:

$$a(t) = 10\ mi/hr^2 \qquad v(t) = 50 + \int_0^t 10\,du = 50 + 10t\ mi/hr$$

$$d(t) = \int_0^t v(u)\,du = \int_0^t (50 + 10u)\,du = 50t + \frac{10t^2}{2}\ mi$$

Although the first procedure yields information only about instants and suffers from inaccuracy, the sum expression is to a certain extent similar to the expression resulting from the continuous model computation.

The visual based covariation approach is successful in supporting complex non quantitative modeling. It also supports moving from graphs to symbols in the case of linear expressions. But for other algebra activities that involve quadratic (for example the acceleration -distance model described above) or exponential models it is yet unclear how to support the transition from graphs to the construction of symbolic expressions. Although the mathematics of sequences can be considered as a possible pedagogical bridge, it might be a too difficult task for algebra beginners; it cannot be easily generalized along various models and even more important, it must be accompanied by an intervention that would justify the swap between discrete and continuous views of the process. Acknowledging the benefits and the difficulties, we are seeking ways to study further the visual foundation for supporting symbolization.

The impact of the classification

Data obtained from problem solving studies indicate that novices tend to classify problems according to the surface structure of the problem and experts according to the deep structure. (Schoenfeld 1985). The analysis begun here identifies the deep structures of algebra rate problems. Clearly, other dimensions of the problem structure should be further explored by means of an exhaustive analysis of algebra word problem. Our underlying assumption is that explicit representation of the deep structure of a problem facilitates student's ability to recognize the properties of the problem and choose appropriate strategies. We propose that once problem structures are accurately defined, a tool of significant predictive power would be formed that could be examined empirically. The pedagogical implications of such an analysis will help us become more sensitive to the sequence of instruction and the types of strategies that should be adopted, and will also allow better understanding of the difficulties encountered by algebra students.

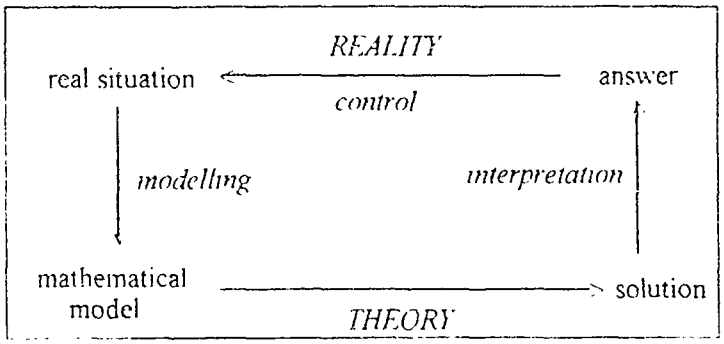
Visualization and Modeling in Problem Solving: From Algebra to Geometry and Back



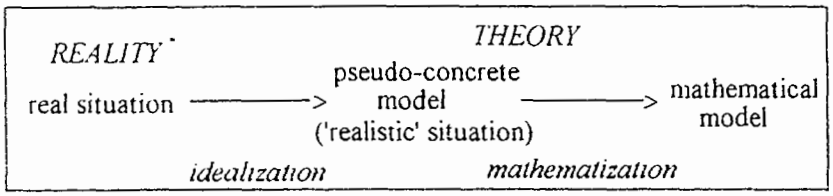
A Response to Michal Yerushalmy, Beba Shternberg, and Shoshana Gilead's paper:
Visualization as a Vehicle for Meaningful Problem Solving in Algebra

Bernard Parzysz
Equipe DIDIREM, Université Paris-7

When I was asked to react on M. Yerushalmy, B. Shternberg and S. Gilead's paper *Visualization as a vehicle for meaningful problem solving in algebra*, I was rather puzzled since I am not a specialist in algebra problem solving, my area being mostly geometry. But, as I came to reading it, I was brought to link some ideas developed in the paper with some I had met in my own field of research. I wrote them down as they appeared, as well as some questions, and then tried to organize the whole of them. So, you will not be surprised to see some references to geometrical situations.

1- The Modeling Process

The first question, which came to me, was: *What is a realistic situation?* I know that a teaching of mathematics based on 'realistic situations' has been developed recently in some countries [Hershkowitz *et al.*, 1996]. I believe it a sound idea, training students to start from a problem they might be confronted with in their everyday life, and undertaking to solve it with the help of a mathematical model that they elaborate themselves, or with one that they already know and think well fitted to the problem. This process -well known- can be described by the following diagram:



It appears clearly in 'double' statistics (regression) problems. This came to my mind from Yoni's behaviour in the 'ovens problem': he started by graphing; then, basing his choice on his graph, he got to a mathematical model (functions), looked 'for an expression that would fit the description of the curve' and finally chose a particular type (square root). Even if he could not go any further, he had undertaken a genuine mathematical process. On the contrary, Ella and other students were not able to

proceed because they clung to the wording of the problem (written in terms of changing rate) and were unable to associate it with a mathematical model.

2- Real or Realistic?

Let us go back to the above diagram. The starting point is a 'real' situation, that is to say a situation as it presents itself (or may present itself) to somebody in 'real' life. But the authors are in fact talking of 'realistic' situations, and we can at first take this term as meaning 'looking real'. It is the case with the 'ovens problem' as well as with the 'bikers problem'. For instance, in the microwave oven 'the heat of the lamb increases at a constant rate'. In fact, there is little chance of this actually happening: there would probably be some variations of the rate, due to various factors. But 1° it is impossible to determine these variations accurately and 2° it can be assumed *grosso modo* that they will be of small range. Hence, at the cost of a small 'twist' of the real facts, we shall suppose that 'the heat of the lamb increases at a constant rate'. This situation is 'realistic', although not real; one can say that it is a 'pseudo concrete' situation. It does not belong to a mathematical model, but it is does not belong to reality either; it belongs in fact to a kind of 'idealized reality', in Plato's sense:

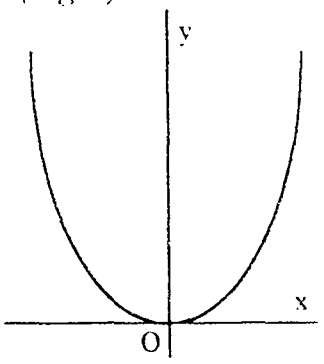
This 'idealized reality' is in fact a model, in the following sense: '*A model is an abstract, simplified and idealized interpretation of an object of the real world, or of a system of relations, or of an evolutive process, stemming from a description of reality*' [Henry 1997 p. 78, tr. B.P.]; hence, it belongs to theory. The difference between a 'pseudo-concrete' model and a mathematical model being that the latter is clearly included in a mathematical theory.

Many 'word problems' are of the 'pseudo-concrete' type, a type which can also be found in geometry and probability. Here are two examples:

1- *A box contains 5 red balls and 3 white ones, indiscernible by touch.*
Three balls are drawn from this box simultaneously, at random.
What is the probability for getting at least two red balls?

2- *A wooden stick is broken into three pieces.*
Is it possible to make a triangle from these pieces?

In the first problem, the situation is already idealized: the balls are 'indiscernible by touch' and 'drawn at random'; in fact, the function of such features is to indicate which mathematical model is to be used to solve the problem. In the second problem, the situation is described as a 'real' one ('wooden stick'), and the student has to imagine the pseudo-concrete model by him/herself, that is a 'straight' stick with 'no thickness'.



Now, if we look from this point of view at the two problems dealt with in the paper, we can say that the 'ovens problem' is a pseudo-concrete model of a real

situation, both from the qualitative data (changing rates) and the numerical datum (which, anyway, is of no use apart from giving the problem a 'realistic' touch). What's more, the data have already been selected; for instance, nothing is said of what 'cooking a lamb' consists of: is it reaching a given temperature? or being kept at a given temperature during a given time? As this piece of information is not useful, it is not mentioned. Nevertheless the authors choose not to give sufficient information to solve the problem completely; the wording says that in the conventional oven 'the heat of the lamb increases at a changing rate', but nothing is said about how it changes. So the mathematical model is to be built by the student him/herself. This explains, to some extent, the difficulty which the students were confronted with: they usually have nothing to choose in a mathematics problem (cf Yoni's disappointment); and in fact, when it is the case, they have the impression that some data are missing, and consequently ask their teacher for them (cf Ella).

In the 'bikers problem' the given situation is somewhat idealized (by the choice of the numerical data), but, as it is worded, it cannot be solved, since knowing the average speed of a biker is not enough to determine his position at any time. As a result, in order to solve the problem you have to make an extra hypothesis *(model hypothesis)*, the simpler one supposing that the speed of the bikers is constant during the whole ride. Whatever the hypothesis you choose, it is only at that stage that you get to a pseudo-concrete model.

3- Visualization and Modeling

Visualization can play an essential role in the modeling process, and especially by helping to choose an appropriate model. This is the case for Yoni, who refers the curve he has drawn to a parabola, and hence to the square root function. In that respect, it seems important to provide students with what can be called a 'herbarium' of functions, *i.e.* a collection of visual images of curves, each one of these being associated with a set of functions and a set of properties such as symmetry, tangents, asymptotes *(Fig. 1)*.

$y = kx^n \quad k \in R \quad n \in N$

$k \neq 0 \quad n$ *even*

$x = 0$ *tangent at point O*

$y = 0$ *axis of symmetry*

$y = 0$ *asymptotic direction*

Fig. 1

In such a 'herbarium' the connection *curve x functions x properties* has to be precise in order to be useful; the mental image of a curve, though essential (it acts as a starting point enabling one to choose a possible model) is not sufficient by itself, and neither is the symbolic relation. Fischbein's theory of figural concept seems quite

suitable to take this connection into account [Fischbein 1993]. The process is quite similar in geometry problem solving; here, the diagram constructed from the wording may help to find a 'key figure', *i.e.* a subdiagram related to a known and referenced situation, as in the following problem *(Fig. 2)*.

ABCD is a parallelogram.
E is the middle of [AB].
F is the middle of [CD].
(DE) intersects (AC) at M.
(BF) intersects (AC) at N.
Demonstrate that AM = MN = NC.

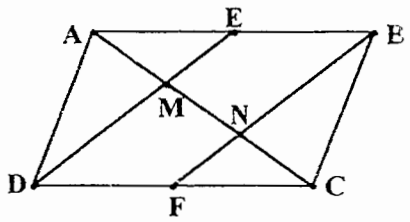


Fig. 2

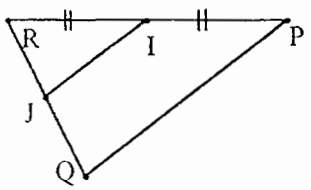

Fig. 3

The key of this classical problem lies in the spotting of the subdiagram shown on *Fig. 3*, which appears twice on Fig. 2. Since (IJ) is parallel to (PQ), one can assert that J is the middle of [RQ].

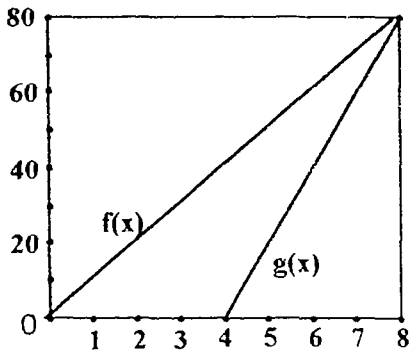
Once these two subdiagrams are identified, the solution becomes simple, on the condition that one can remember the associated property.

4- How to Solve It?

Tal's solution of the 'bikers problem', as it is described in the paper, appears to be most interesting, for two main reasons. The first one is that it illustrates, in a brilliant way, the control process which intervenes in modeling: having found that the distance, as a function of time, can be expressed by $g(x) = 20x - 80$, Tal undertakes to check if this makes sense, by testing some values of x. This is worth to be noted, for such a behaviour is not common among students, for whom 'mathematics is not reality', and hence it does not matter whether the result is plausible or not [Girard & Parzysz 1998]. However, such a behaviour as Tal's should be developed among students, since it is an essential component of the modeling process: indeed, what use can a model be if it does not fit with the real situation it is supposed to represent ? By the way, we can here get an insight into Tal's conception of a function (a most frequent one), which is mainly that of a functional relation between two variables; and a function defined by $g(x) = 0$ if $0 \leq x \leq 4$ and $g(x) = 20x - 80$ if $4 \leq x \leq 8$ is perceived as a juxtaposition of two functions, not as a single function. This narrow conception prevents Tal from overcoming his problem.

The second interest of Tal's behaviour is that he is able to establish relations between several 'frames' [Douady, 1986] and 'representation registers' [Duval, 1995]; in this case: numbers, graphs and symbols *(Fig. 4)*.

x	f(x)	g(x)	
0	0	0	
0.5	5	0	f(x) = 10x
4	40	0	g(x) = 20x - 80
4.5	45	10	
8	80	80	



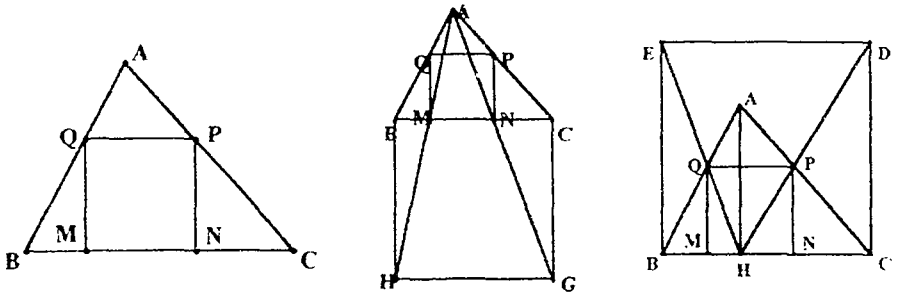


Fig. 4

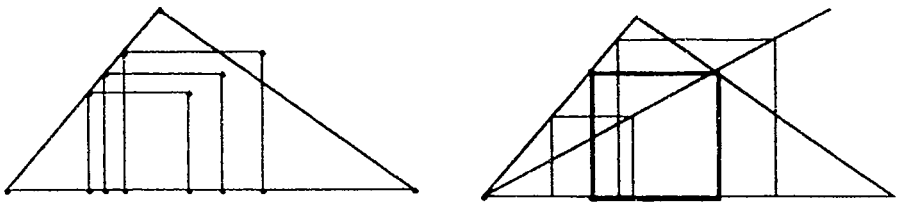
This ability to connect several areas of mathematics and/or several ways of expressing mathematical situations is most important in problem solving, because it enables the student moving to an area in which he/she will be more at ease, being thus in better conditions for solving the problem. Here, Tal was able to solve the problem with numbers (left column) and with graphs (right column), and he would have solved it with algebra (center column), had he not been upset by the 'negative distance'.

5- Towards Dynamic Problem Solving

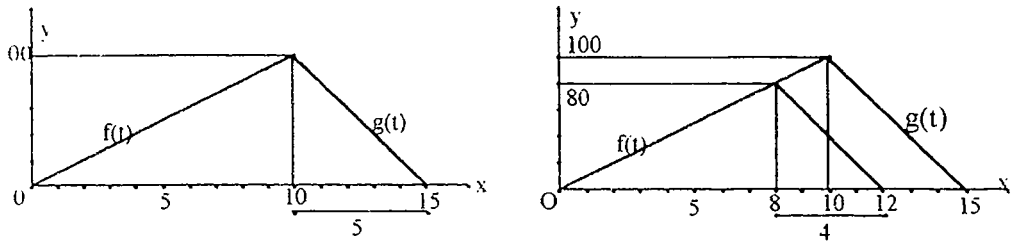
The second 'bikers problem', although looking similar to the other, confronts the students with quite a different approach, since one has to introduce a parameter (for instance the time when the biker is back to town 1, or the distance between the two towns). A consequence is that it becomes impossible to draw an accurate graph (one can only draw a sketch). The presence of the parameter defines, not a single function, but a whole family, and 'only one member of the family (...) satisfies all the constraints'. This problem reminded me another (classical) one *(Fig. 5. A)*:
A triangle ABC is given. Construct a square MNPQ so as M and N belong to [BC], P belongs to [AC] and Q belongs to [AB].



A **B** **C**

Fig. 5

In textbooks this problem is usually solved with the help of one of two diagrams *(fig. 5. B and C)*. But I have experimented that this is not how students proceed. In fact, they begin with a 'trial and error' process, drawing several squares successively



(Fig. 6, A). This process leads some of them to an accurate solution, by using homothecy, *(Fig. 6, B)*.

A **B**

Fig. 6

In fact, the various squares drawn in the first stage can be considered as 'snapshots' of a same square MNPQ growing from point O, the points M and N remaining on (CB) and Q remaining on (BA). This same 'dynamic' solution, in which visualization plays a essential role by suggesting the suitable geometrical transformation, may be used in the second 'bikers problem': supposing that the distance between the two towns is, say, 100 km, you can draw a first graph *(Fig. 7, A)*. By so doing, you can see that the return trip is 5 hours shorter than the outward trip (instead of the 4 hours requested). And then you can finally adjust the second line by using a homothecy, the center of which is O and the ratio 4/5 *(Fig. 7, B)*.

A **B**

Fig. 7

This type of solution can easily be put into play by using graphical software. In the above problem, for instance, the line representing the distance covered during the outward journey (y = 10x) can be graphed. Assuming now that the distance between the two towns is 100 km, the point A(10; 100) will also belong to the line representing the distance covered during the return journey. And, if the software makes it possible to move this line parallel to itself (by changing the coordinates of A with the constraint that it remains on the first line), a graphical solution of the problem can be found. Here, students do not have mere 'snapshots' of the situation, but they can see it moving, they have a continuous view of it. This gives sense to resorting to a homothecy and can also lead to the idea of replacing point A by any point of the first line: B(t; 10t), the question being then to determine the value of t for which the

difference between the lengths of time of the outward journey and the return journey is 4 hours.

The efficiency of such a move from a discrete to a continuous point of view can also be observed in phenomena such as radiocarbon dating. Knowing the value of the 'half-life' of C^{14}, and provided some model hypotheses are defined, one can study it by using a geometrical sequence, obtaining an interval of time, or one can solve a differential equation, which gives a -theoretical- date [Parzysz 1999].

Similarly, in the 'ovens problem' Erez and Ilanit -after having drawn a continuous curve- use a discrete graphical method *(Fig. 8)*: They compare the changing

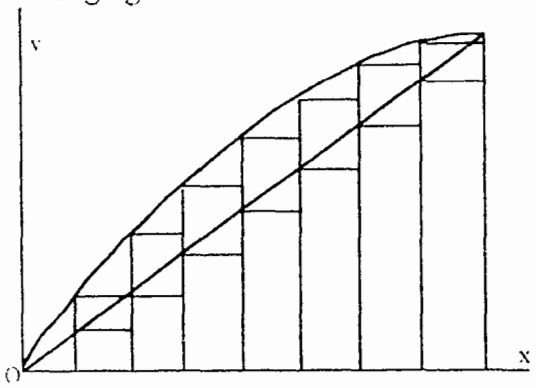


Fig. 8

rates of the two ovens in each time interval ('stair') and choose, for this interval, the oven with the highest rate. By so doing, they can conclude that, in the beginning, the conventional oven is better, but towards the end it is the contrary. But this process can only give them an interval during which the move from the conventional oven to the microwave one has to be operated; one cannot get a precise time.

On the contrary, Yoni's process, which is a continuous one based on the slopes of the curves, enables him -at least theoretically- to find this time: on the graph, it is the point where the slopes are equal. This 'superiority' of the second process over the first one, as regards the 'cost' and accuracy of the answer they can give, may be a motivation for the students to shift towards the concept of derivative.

6- Classifying the rate problems

The idea of classifying the rate problems (in which two lines intersect on the associated graph) according to 1° the signs of the slopes and 2° the unknown quantities seems interesting. The authors distinguish between the situations which have no degree of freedom, allowing to draw a unique graph (I should call them *static* situations) and those which have one degree of freedom or more, allowing to draw a family of possible graphs (I should call them *dynamic* situations). As we have just seen, this leads to different processes, from the point of view of problem solving.

Such a mapping of the 'deep structure' of the problems seems promising, because it can help teachers find problems in a more rational way, thus leading their students to explore the different types. It can also help researchers study the relation between the structure of a problem and the difficulties encountered by students, in order to have 'a tool of significant predictive power', as the authors say. Some questions could perhaps be answered, as for instance:

How can the surface structure of a rate problem obliterate the deep one?
Are there realistic situations, which prove to make the solving easier?
Can rate problems help students move from graphs to symbolic understanding?

How can students be helped to grasp the deep structure of a rate problem?
Can graphical software help students become aware of the similarity of structure between such algebra problems and some geometry problems?
Can the move from 'static' to 'dynamic' situations help students with the use of parameters for solving problems?
Can dynamic situations help students deal with qualitative problems? etc.

This list, far from being exhaustive, shows that there is still some work for the authors and other educational researchers to be done. I wish them good luck.

THE ROLE OF VISUALISATION IN YOUNG STUDENTS' LEARNING

Kay Owens

University of Western Sydney, Macarthur

The study draws together a number of research studies carried out by others and the author into a framework of early spatial mathematics learning. The emphasis is not only on conceptual knowledge but also on the role that visualisation plays in learning spatial mathematics. Several tasks were developed to assess students in primary school and the types of responses collated in terms of the framework.

Related Research Studies with Adults

There are several aspects of visualisation that I have explored with adults although my focus is on children's visualisation. Adult participants can articulate their thinking as we explore new ideas, and comparisons between adults and children have highlighted certain aspects of thinking. In one study (Owens, 1990), a comparison of the *order* in which adults and children made the different pentomino shapes (shapes made from five squares with sides exactly aligned) indicated that conceptualisations and associated images influenced decisions. For example, children were more likely to consider that shapes had to have a name or be symmetrical when making their first few pentomino shapes. For both adults and children, responding in the problem-solving situation was reliant on a range of cognitive processes including imagery, concepts, affect, and heuristics such as investigative tactics and self-monitoring. This responsiveness was idiosyncratic but an important part of problem solving (Owens, 1996b).

Another study (Owens, 1998) was an experimental study of adults asked to recognise equal angles in complex designs presented on computer screens. The adults responded to the training tasks in four different ways. During the training those who were in the *Doing* group could use acetate and pens to trace over angles to check size; those in the *Speaking* group were asked to explain how they were deciding; those who were in the *Listening* group listened to the researcher on earphones explain why angles were equal; while those in the *Looking-only* group could only read the explanation which was presented to all the participants. Learners were presented with both analytic reasons such as "vertically opposite angles are equal" and reasons such as "they just look the same and (another) angle is smaller". The computer was programmed to show the designated angle move to be positioned on the equal angle. Some of the adults were later asked what they were attending to, and how they were thinking during the tasks. There was significant variance between the scores of members of the groups who were speaking or doing. The lower variance in the Listening group suggested that this group had their attention more focussed. Overall there was no clearcut difference between responding groups nor support for the effect of cognitive load due to training responses. However, participants did refer to their use of visual imagery, their search for equal angles and how they used geometric knowledge to reduce their searches. A

significant effect of affective processes was noted in their retrospective comments. Responsiveness was also a key to learning through investigating when the children participated in the series of tasks that linked to angle conceptualisation (Owens, 1996b).

Studies on Children's Spatial Strategies

Relevant Findings from Earlier Studies

I have previously reported on a matched-group experimental study that showed that primary-school students engaging in spatial problem-solving activities improved in spatial thinking (Owens, 1992b). Based on the positive outcome of this experimental study, it seemed important to explore *how* spatial problem solving improved learning in classrooms. Over 180 problem-solving episodes were analysed. The role and diversity of visual imagery in problem solving was one key aspect that emerged in this grounded-theory investigation (Owens, 1994; Owens & Clements, 1998). The work of Presmeg (1986) was useful in classifying this diversity.

Students' apparent visualising was classified as concrete pictorial imagery, imagery associated with patterning, dynamic imagery associated with movement within the image structure, action imagery involving movement of body parts, and imagery that involved following a series of procedures. The examples of dynamic imagery in such young children were noticeable. For example, one child imaged a square becoming a rectangle and then becoming thinner as he developed his rectangle concept. Another dynamically changed a trapezium into a parallelogram. Action imagery was exemplified by one child who explained that she could see her hand moving around the line of four squares as she investigated new pentomino shapes. The fact that action imagery was associated with investigative tactics provided a further focus for the present study (Owens, 1994; Owens & Clements, 1998).

Pattern imagery was associated with students' developments in tiling areas. For example, one child explained how a triangle could be covered by smaller, similar triangles using the zig-zag pattern of one-up, one-down (Owens & Clements, 1998). Some students on the test, *Thinking about 2D Shapes* (Owens, 1992a), used in the experimental study, spontaneously drew tiles and grids to answer the questions on tiling. A comparison of their drawings and those of children in a study by Outhred (Owens & Outhred, 1997, 1998), and the earlier studies of Mansfield and Scott (1990) on young children covering shapes, suggested that young students can develop a sense that a particular shape could tile a given shape. Students were likely to do this by recognising certain attributes of the tile such as type of angles, size of tile, relevant pattern for filling with the tile, and recognition of gaps. The early ideas on tiling are part of the current study.

Students' responses to the items of *Thinking about 2D Shapes* on angles and the activities related to angles, showed that young children can recognise angles but relevant experiences are needed as well as an ability to "see" the angle (Owens, 1996a). Rosser, Lane, and Mazzeo's (1988) study indicated the importance of rotation

and visual memory in early spatial thinking. These two ideas also needed to be considered in exploring young children's spatial thinking.

The ideas of reseeing, seeing parts that fit, and completing images have been discussed extensively in the spatial abilities literature (see Eliot, 1988). Several tasks were developed by Del Grande (1988) and a succinct summary made by Tartre (1990). These seem to be important features of early spatial thinking. Students also increase their visual memory, and sequential use of perceptions. For example, young students can mentally fold a net of an open cube (Owens, 1992a).

Theoretical Framework Development

Reviewing the earlier studies resulted in the development of a theoretical framework that could be used to inform teachers of young students' early spatio-mathematical development. The framework was also designed to build on ideas developed by *The Count Me in Too* project (NSW Department of Education and Training, 1998) through which teachers became familiar with such terms as *emergent*, *perceptual*, and *figurative* (imagery) stages.

Orientation and Motion

Students need to recognise shapes in different orientations and to develop the skill of appreciating what an object or group of objects might look like from another perspective. These changes in perspective and orientation are related to motion. Motions with manipulatives (e.g. card cutouts and tiles) that represent two-dimensional shapes include flips, slides, turns, and folds. These motions assist students to develop concepts such as (a) reflection symmetry (flips in horizontal, vertical, and diagonal lines or folding), (b) area (slide repetitions associated with covering of areas), and (c) rotational symmetries.

Movement is imaged by students as they make associations between shapes. For example, they can image one triangular shape moving to become another triangular shape as a point slides along a taut string. They might see how a triangular shape becomes a quadrilateral by bending one side into two or how a square can be pushed over to make a rhombus.

Movement necessarily involves position concepts. Actions are described in conjunction with directions such as left, right, or straight ahead. A particularly important change of direction or turn is associated with the concept of angle. Early learning is often stimulated by action and this turning of one arm of an angle away from the other does seem to be one of the ways that children first begin to learn about angles. However, they also begin to notice angles on shapes.

Part-Whole Recognition

All shapes are made up of parts. When students notice the parts, then they develop their concepts about shapes. For example, a student might notice three corners on a triangle and decide that this is a defining feature of a triangle. The corners are at first

just considered as the pointy parts. Gradually, the parts become specific in their features and students notice right angles or equal sides.

Students might only notice dominant features of shapes such as a pointy part or they might only see the overall shape. It is important that students develop both skills. Noticing the parts requires students to see the part within the context of a shape or configuration of lines. This is the skill of *disembedding* and it has a counter skill of embedding by which a student is able to complete shapes imagined in the mind.

The ability to see angles on shapes, to see differences in angles, to see shapes within other shapes, and to complete shapes using imagery are necessary skills for students if they are to develop a repertoire of properties of shapes or to apply geometry in real examples.

Classification and Language

Students will realise that a variety of examples of a shape can be categorised as one particular shape. Students will begin to associate more and more properties of parts as necessary or not necessary for a shape to belong to a particular category. Verbal expressions are associated with visual imagery and help define it. As students group and regroup, they develop relationships between shape categories and properties of shapes and lines.

Students will associate particular words consistently with particular actions, shapes, and other spatial relationships. They can use words to represent their imagery. Students need to identify spatial features such as parallel lines, perpendicular lines, spatial patterns, slopes, shapes, and corners in their environment, and discuss what they see.

Through discussions, students begin to abstract concepts such as shapes, to describe comparisons between parts, and to recognise why certain shapes make patterns and tessellate.

Imagery Strategies

Each of the above aspects of spatial knowledge becomes evident in the way that students behave and respond to tasks. Their imagery strategies can be inferred from their actions and words. It is through student's language and the selection and use of objects (including recognition of spatial features of card cut-outs, pictures, and shapes in their environments) that decisions on children's learning will be made. By saying and pointing, students indicate that they notice parts and visualise their relationships.

Certain experiences may encourage the development of dynamic changes and patterning in their imagery. These can challenge and modify limited concept images. For example, a full range of triangles can be included for the concept of a triangle.

Nevertheless, students' abilities to represent shapes by drawing or using materials like sticks can have different influences on their thinking. For example, some think that their drawing of a square is not a square because it no longer matches their mental

imagery. They may then decide a problem cannot be solved because the square does not look right but other students will accept that they just had trouble with the drawing and their mental imagery dominates. In a similar way, when students are making shapes, they make decisions about whether gaps and overlaps are important or not (Owens & Outhred, 1997). It is important, therefore, for teachers to wait and probe during assessment tasks in order to recognise how the student is thinking.

There are five groupings of strategies:

- *Emergent strategies*. Students using emergent strategies are *beginning to* attend purposefully to aspects of spatial experiences, to manipulate and explore shapes and space, to select shapes like ones shown or named, and to associate words with shapes and positions.
- *Perceptual strategies*. Students using perceptual strategies are attending to spatial features and beginning to make comparisons, relying on what they can see or do.
- *Pictorial imagery strategies*. Students using strategies involving pictorial imagery are developing mental images associated with concepts, with increasing use of standard language.
- *Pattern and dynamic imagery strategies*. Students using strategies involving pattern and dynamic imagery are using pattern and movement in their mental imagery and developing conceptual relationships.
- *Efficient strategies*. Students using efficient strategies, are beginning to solve spatial problems and constructions successfully by using imagery, classification, part-whole recognition, and orientation.

These strategies are more or less likely to emerge and be used by children in the above order. Intuitive and incidental learning can influence these strategies in unexpected ways. The casual use of a spatial term can be picked up by a young child in such a way that a well developed understanding of the concept is formed earlier than expected. This might occur if a child realises that the term *triangle* is used over a number of different occasions to refer to shapes that are not all exactly the same.

Orientation and motion, part-whole recognition, and classification and language aspects of spatial thinking are described for each strategy group in Table 1.

Table 1
Framework of Imagery for Space Mathematics

	Orientation and Motion	*Part-Whole Relationships*	*Classification and Language*
	The student:	The student:	The student:
Emergent Strategies	recognises shapes that match the student's fixed image(s)	attempts to put pieces together to see what is obtained	matches shapes with everyday words e.g. ball for a circle
Perceptual Strategies	recognises shapes in different orientations and proportions, checking by physical manipulation	recognises whole shapes used to build a shape or picture	describes similarities and differences and processes of change as they use materials
Pictorial Imagery Strategies	generates images of shapes in a variety of orientations and with different features	disembeds parts of shapes from the whole shape, matches parts of different shapes completes a partially represented shape or simple design	discusses shapes, their parts, and actions when the shape is not present
Pattern and Dynamic Imagery Strategies	predicts changes by mentally modifying shapes and their attributes using motion or pattern analysis; represents relationships created by change and patterns by modelling or drawing	develops and uses a pattern of shapes or relationship between parts of shapes; plans and dynamically modifies a shape to illustrate similarities between different representations of the same concept	discusses patterns and movements associated with combinations of shapes and relationships between shapes
Efficient Strategies	selects effective strategies to make changes needed to achieve a planned product	assesses images and plans the effective use of properties of shapes and composite units to generate shapes	describes relevant use of properties of shapes to generate new shapes

Assessment Tasks

Associated tasks were specifically designed to assess students' thinking in terms of the framework and whether, in particular, students were developing pictorial imagery, pattern imagery and dynamic imagery, and associated concept images. Several tasks (e.g. Tasks 2 and 7) were developed from the concrete introductions and items used in the test *Thinking about 2D Shapes* used in the initial experimental study with children (Owens, 1992a) and from the above references (e.g. Task 2B is based on Mansfield & Scott, 1990; Task 5 from Rosser, Lane, & Mazzeo, 1988). The revealing shape task (Task 3) is an extension of a common task used in studies based on the van Hiele theory.

The development of the tasks has involved the assessment of over 50 students in the first three years of schooling (ages 5 to 7 years) by the researcher, curriculum consultants, and several teachers. Some students were video-recorded during the tasks, and discussions on viewing the tapes assisted in checking the validity of the framework and in improving the tasks.

Table 2 gives the details of some tasks and brief descriptions of the remainder. Task 1 emphasises the idea of context for learning. It also seeks to see what properties the student might know. Subtle changes were made to wording, (e.g., "tiles to *make* (not cover) a given shape" in Task 2), and tasks were modified so they were manageable by teachers and students (e.g. Task 6). The tasks were also devised to allow students to show they were visualising before they were given the opportunity to try with concrete materials (e.g. Tasks 2, 6 & 7). Several probes are suggested to help when students are having difficulties with the harder question or if they are not familiar with the language (e.g. Tasks 2C, 8).

The tasks require some equipment but it is kept to a minimum. The card cut-outs, are shown in Figure 1. Spare small rectangles and small squares and another large square, drawings of the square at a 30° slope (plus photocopies) and of an inverted equilateral triangle double the size of the right-angled triangle are needed. Nets for Task 7, 3 circles with tabs for Task 5, string, and sticks are used.

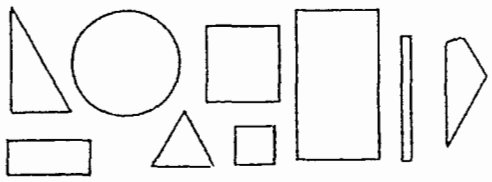

Figure 1. Card cut-out shapes required for the tasks.

Table 2

Selection of Tasks for Assessing Students Early Space Learning

Task 1A: Recognising shapes in the environment

Use card cut-out shapes, one of each type except the quadrilateral, (i.e. large square, circle, large rectangle, and both types of triangles).

Place the card cutout shapes on the table.

Ensure the layout of the shapes is not aligned horizontally.

- *Look around the room. Can you see a shape like one of these shapes?*

(Indicate the cut-out shapes on the table. Allow the student to nominate the shapes.)

- *How are they like each other?*

  Probe question

  If a student is unable to complete the task, point to the rectangle. (Push it away from the other shapes towards the student, turn it into horizontal alignment)

  - *Can you see a shape like this one?*

Task 1B: Sorting shapes and identifying properties

All the shapes shown in Figure 1 and the drawn shapes are to be sorted. Probes are used, for example, if a picture is made.

Task 2A: Recognising double tiling

The square is used and students asked to image another joined to it. They are asked if they can choose the shape it makes. If not, two squares are used to try. The squares are used to explain that they join without gaps or overlaps in preparation for the next two parts.

Task 2B: Imagining triangle tiles

The student is asked how many and how the right-angled triangle might cover the drawn equilateral triangle, and then given the tile if needed.

Task 2C: Imagining tiling of areas

Use card cut-out shapes, drawn square, photocopies of square, pencil, more square and rectangular tiles (if needed)

Display the card shapes and the drawn square on the table.

- *Which one of these cardboard shapes could you use to start making this drawn shape?*
- *How many of those would you need to cover this drawn shape?*
- *Show me how you would make it.*

Provide the student with the photocopy of the square.

- *Draw what it would look like.*

  Probe. If the student cannot show how to move the tile and cannot draw it on the diagram, give the student more of the same tiles to make the square. Cover it. Then ask

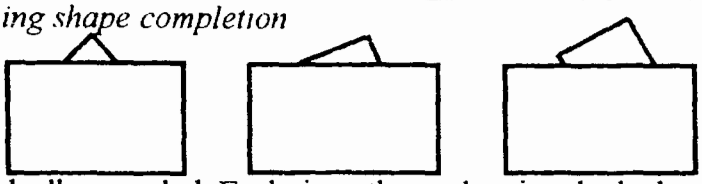
  - *Draw what they have made.*

Show me another shape to use to make this square.

If the student chooses an appropriate shape ask:

- *How many of these would you need?*

Provide a second photocopy of the square.



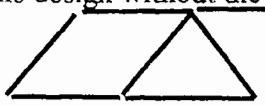
- *Draw what it will look like.*

  Probe. If the student cannot draw it, give the student the tile (rectangle or square) and say:

  - *Show me how you would make it.*

- *Please draw it.*

Task 3: Imagining shape completion



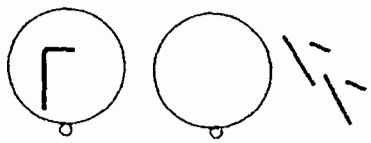
A square is gradually revealed. Each time, the student is asked what it might be and to trace where it might be. They are encouraged to give more than one answer.

Task 4A: Seeing shapes within shapes

Students use sticks to form 2 squares joined together and then 2 triangles. They are asked to draw the 2 triangles, preferably while covered.

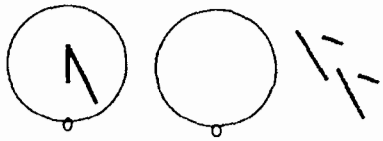
Task 4B: Seeing shapes within shapes

Use diagram of a trapezium, 7 equal-length sticks, sheet A4 paper.
Arrange the sticks to make this design without the student seeing.



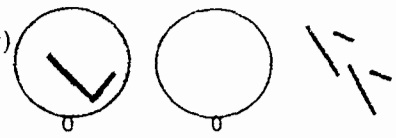
Show the outline drawing of the trapezium to the student. As you talk run your finger around the perimeter of the trapezium.

- *This is a drawing of a trapezium. Look at the design I made with the sticks.*
- *Do not touch the sticks but point to the sticks you would need to take away so that it is the same as the drawing of the trapezium.*
  Probe: If the student is unable to identify the correct sticks to be taken away, allow them to manipulate the sticks.

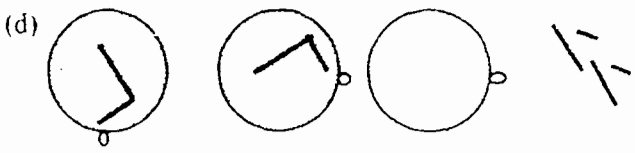


Task 5: Angle recognition, visual memory, and rotation skills

Make the following diagrams on a circle using long and short sticks or pipecleaners, point out the tab, let the student make the same diagram on their circle with tab mark aligned with yours. The first two are uncovered, the third is covered before the student starts, and the fourth is shown to the student, covered, and turned before the student starts.



(a)



(b)

(c)

(d)

Task 6: Dynamic imagery

Use 40 cm string, joined to form a loop, a firm stick
Place the loop of string on the table and hold two points firm, about 15 cm apart (the string needs to form a triangle when one side is shortened). Provide the student with the stick

- *Use this stick to pull the string tight and make a triangle.*

- *How would you describe the triangle you have made?*
- *Could you make other triangles?*
- *How would they change?*

  Probe: If the student cannot explain, let them use the stick to demonstrate and tell about the triangles they are making.

Point to one of the sides of the triangle.

- *Tell me what you would have to do to make this side shorter.*

Point to the other side.

- *As the first side is made shorter, what will happen to this side?*

Task 7: Imagining, folding and turning nets to make three dimensional shapes

Use nets of the open triangular prism and open cube. 

Show the net of the open triangular prism and fold it up to make an open triangular prism. Talk about how you folded up and turned the sides. Talk about how the 2D shape became a 3D shape. Let the student try to fold it. The word "box" may be used as well as prism.

Show the net of the open cube but do not let the student actually fold the sides

- *Tell me how you might fold it up and where each square will end up.*
- *What will it make?*

  Probe if the child cannot explain.

  - *Try to fold it up, and as you do, tell me what you are doing.*
  - *As soon as you know what you are making tell me.*

Task 8: Visualising turning three dimensional shapes

Place a square pyramid on its base in front of the student.

- *If I push this over and the point lands away from you, what shape will you see?*

After the student responds, push it over so the point lands away from the student and the square is facing the student

- *If I stand it on its point, where will the square be?*

  Probe: If the student is unable to say the square is on the top, tell them and indicate with your hand how the pyramid is turned up onto its point.

- Draw how the triangle facing you will look.

  Probe: If the student cannot draw it, hold the pyramid up on its point and indicate the triangle to be drawn.

Results

Our preliminary use of these tasks has indicated students portraying different strategies. Table 3 indicates the kinds of responses given by students and how they indicate different strategies within the framework. The efficient strategies were not well established by any of the assessed students in Kindergarten to Year 2 at school. It was possible to distinguish responses for the different categories of Orientation and Motion, Part-Whole Relationships, and Classification and Language. Clearly some tasks addressed one area more than another. More importantly, the tasks did provide a range of strategies to be observed by different students.

While students did not necessarily show the same type of strategy across all questions, there was a tendency for this to happen. That is, if a student tended to use perceptual strategies in one task, the student was likely to show these same strategies across all tasks. Some students were only showing the beginning of Perceptual

BEST COPY AVAILABLE

Strategies; for example, they seemed inexperienced with diverse shapes. It is also interesting that in some cases, one area such as Language and Classification assisted a higher strategy for another area such as Part-Whole Relationships. For example, students who learnt about quadrilaterals and that they had four sides were more likely to use pictorial imagery strategies for Part-Whole Relationships in Task 1B.

Results of some tasks are presented in Table 3. Task 1A on shapes in the environment and their properties shows how the students' responses may be best considered in terms of one of the main conceptual areas. Task 2B on tiling with the right-angled triangle shows the importance of the investigative tactic of flipping. Task 2C on tiling shows how the tasks can show a range of strategies. The idea of tracing and encouraging different responses in Task 3 was successful in drawing out responses of different kinds of strategies.

Table 3

Typical Responses for Space Tasks for Early Space Framework

Strategy	*Orientation and Motion*	*Part-Whole Relationships*	*Classification and Language*
1A: Recognising Shapes in the Environment			
Emergent		* Tries to match the rectangle	
Perceptual	◊ Selects much larger, differently oriented shapes		◊ Selects and names ○ □ ▭ △ ◺
Pictorial Imagery			⇒Readily selects and gives properties
2B: Imagining Tilings of Equilateral Triangle with Right-Angled Triangles			
Emergent		* Can't guess 2 and places triangle in centre of equilateral triangle	
Perceptual	◊ Eventually flips or turns shape into position	◊ Covers shape with triangles when both given	
Pictorial Imagery		⇒Quickly says 2, places and flips one triangle	
2C: Imagining Tiling of Square with Smaller Square or Rectangle Tiles			
Emergent			* Selects any shape and places inside square
Perceptual	◊ Turns tiles to be aligned with sides and corners	◊ Says 3 to 5 tiles, selects □ ▭ , covers square when given extra tiles	
Pictorial		⇒Says 4□ 3▭ rough	

Imagery		drawing, shows with 1	
Pattern , Dynamic Imagery		• Quickly says correctly, Uses grids in drawing	
3: Imagining Shape Completion by Tracing Possible Hidden Shapes			
Emergent			* Says any shape name
Perceptual	◊ Says square		◊ Says triangle or square but cannot trace where it might be
Pictorial Imagery		⇒ Traces for a triangle or square or rectangle	
Pattern, Dynamic Imagery		• Traces out several possible shapes	
Efficient Imagery		▪ Indicates tracings and various changes	▪ Readily explains how different shapes could be underneath
4B: Seeing Trapezium within Shape			
Emergent		* Tries to place sticks to make a shape	
Perceptual		◊ Can select a stick when allowed to try it	
Pictorial Imagery		⇒ Can select at least one stick to take away	
Pattern, Dynamic Imagery		• Can quickly point to all sticks to take away	
6: Dynamic Imagery Using a Stick to Move a Loop of String			
Emergent	* Moves stick but does not make or recognise a triangle		
Perceptual			◊ Knows a triangle will be made
Pictorial Imagery	⇒ Makes different triangles	⇒ Tells other side will get longer	⇒ Knows names and properties of different types of triangles
Pattern, Dynamic Imagery	• Automatically slides stick to make different triangles, commenting on them		• Explains why continuous range of triangles can be made in general and by type
Efficient Imagery	▪ Shows an arc of points to shorten side		

Task 4B shows how the skill of disembedding or re-seeing parts is manifested while responses to Task 5 indicated the development of orientation skills and noticing angles. Results for Task 6 on making triangles show how a carefully designed task can illustrate a full range of strategies. It was a particularly novel task for consultants and teachers. The turning of a face for the 3D shape in Task 7 was a critical step for pattern and dynamic imagery strategies under Orientation and Motion. Task 8 was an important task for 3D concepts, and responses to the task could be placed in most of the cells of the first four strategies.

Discussion

Task 1B was difficult to use if the idea of sorting and grouping was new to the students. Both Tasks 1A and 6, as well as Task 1B, encourage students to express their concept images. However, Task 1B may be very fruitful in ascertaining students' knowledge, and in helping teachers realise just how limited students' concepts can be due to the lack of mathematical ideas in the common language of the classroom. For example, the lack of language such as "a quadrilateral has four sides" often meant that students tended to group the quadrilateral with a triangle or turned square.

The tasks provide information about the students in the different areas of the framework. One task can be multifaceted and used for a range of outcomes. In this sense, the tasks are rich in informing the teacher about the students' learning. Not all possible responses or cells of the table have been completed. It is possible that further testing will assist in showing other common responses for different cells. Nevertheless, this is not expected.

The tasks allow teachers to know the strengths and weaknesses of different students. For example, Natalie in Year 2, mostly showed emergent strategies and seemed to have most difficulty in the classifying and language area. She was able to show perceptual or pictorial imagery strategies in Task 6, 7, and 8. These were novel questions for her and may have been less associated with her general struggle with learning. The assessment provided the basis to plan suitable activities for her. For example, she needed experiences in sorting and grouping many different kinds of triangles, squares and rectangles (two kinds at a time); talking about the reasons for grouping e.g. four sides or four corners; seeing shapes within shapes in matchstick type puzzles; doing more jigsaws and making geometric shape like squares with pieces.

On the other hand, Jack in the same class, generally showed pattern and dynamic imagery strategies and an ability to see shapes within shapes assisted by good general language. However, his recognition of diversity when referring to a shape like "a triangle" still needed extension. He needed activities like matching parts of different shapes in order to notice similarities and differences, and to develop properties. He also needed more language to describe the parts and types of shapes. Interestingly, he showed some hesitation in placing the position to shorten the side of the triangle in

Task 6, trying to indicate that it would be further away than the line of the string (tending towards efficient strategies). He was ready to use properties to establish that squares are rectangles and that the same names apply when the shapes are in turned positions (a problem that was exacerbated by the use of words like diamonds), and to use words like rhombus, trapezium, quadrilateral or four-sided shape.

The tasks can be used for individual assessment or for the basis of activities for the class. The questions and probes can be used by the teacher to assist in students' learning and assessment during class experiences. The technology may be as simple as card cut-outs but computer-generated tasks could extend learning from previous activities with concrete materials.

Further research is needed to assess how consistently students are showing the same type of strategies across each task. It was clear in modifying the tasks that slight changes could make a task more difficult so that students were not using the same strategy as on other tasks. Research is also needed to see how classroom experiences can encourage students to use more advanced strategies. Such longitudinal studies would give further evidence of the validity of the framework, and its value for classroom teachers.

Conclusion

The previous studies of the researcher and those of numerous other people working in the area of spatial mathematics have been drawn upon to develop a framework that is useful for teachers. Synthesising so much research into a framework is an important step forward in developing a theoretical base for early childhood education in Space mathematics. In particular, the framework shows how visualisation strategies are a key to development of spatial thinking (knowledge and skills).

The framework provides a basis for teachers to assess students' current learning and to plan learning experiences that will extend their students' knowledge and visual skills. The facets of the framework interlink to provide holistic learning experiences and assessment tasks for students. The tasks provide a richer forum for teachers' understanding of the framework.

Students' responses to the tasks have provided evidence that the various facets of the framework can be assessed. In particular, the tasks can assess more than one facet, and each can generate responses showing different types of strategies. For this reasons, some tasks are constructed to encourage students to visualise first, and probes are suggested to elicit an emergent or perceptual response.

Abstract

This paper is an invited response to the Imagery and Visualisation Research Forum of PME XX111. It takes as its starting point the keynote *paper The Role of Visualisation in Young Students Learning* (Owens,1999). The review attempts to consider the paper in the wider context of mathematical thinking. It addresses difficulties associated with the investigation of imagery and draws the conclusion that a reappraisal of the data could suggest the possible existence of a divergence in spatio-visual thinking similar to that in arithmetical/algebraic thinking.

Introducing a Perspective

Writing in 1996, Owens suggested that:

> Student's responsiveness during active engagement in problem-solving activities is precipitated by their own thinking and feelings ... responsiveness implies a degree of understanding as well as involvement and interest in the activity. (Owens, 1996, p. 101)

With this notion in mind, I present a personal review of the paper *The Role of Visualisation in Young Students Learning* (Owens, 1999). In doing so, I am also aware that each comes to the task of considering the paper with different personal repertoires of knowledge. Inevitably, we see the paper in our own personal way.

Within her paper, Owens considers two features designed to inform teachers about young children's early spatio-mathematical development. The first is a 'framework' that provides a basis for teachers to assess children's thinking and build a teaching programme. The second is a mechanism for assessing the children against the framework. It is claimed that an important aspect of the two is the relationship between spatial understanding and visualisation. Indeed, some of the tasks are 'specifically designed to encourage visualisation' and the framework itself is associated with a 'hierarchical' list of imagery strategies.

My personal reading of Owens has been influenced by two questions:

- first, how should we interpret the fact that some pupils seem to find the study of mathematics relatively easy whilst others find it virtually impossible?
- second, what can it add to our efforts to establish some kind of underlying theoretical structure that may help us further our understanding of mathematical thinking?

Perception, action and reflection

Geometry builds from the fundamental perception of figures and their shape, supported by action and reflection to move from practical measurement to theoretical deduction and Euclidean proof. This was a theme which Tall (1995) alluded to in his plenary address to PME in Brazil. He spoke of the way in which elementary mathematics begins with '*perceptions of*' and '*actions on*' objects in the external world.

> The perceived objects are first seen as visio-spatial gestalts, but then, as they are analysed and their properties are teased out, they are described verbally, leading in turn to classification (first into collections and then into hierarchy's...Tall, 1995, p 61.

To establish the distinction between the perceptive and manipulative aspects of early spatial development and the verbal/symbolic development of arithmetic and algebra Tall suggested that a different kind of development stemmed from *actions on* objects. Here the process of counting is developed using number words that become conceptualised as number concepts.

Early mathematical concepts are strongly associated with preliminary activities involving perception and action within the physical world and reflection on both perception and action (Gray, Pitta, Tall & Pinto, in press). Such a development requires the ability to concentrate the mind and give careful thought to an act or idea and then to filter out irrelevancies and separate notions from their context. It involves the construction of relationships between and amongst objects and of the inter-relationships of the actions on them. It may be that such a process works to the advantage of the more successful. An emphasis on one or more of the activities of perception, action or reflection leads not only to different kinds of mathematics, but also to a spectrum of success and failure depending on the nature of the focus in the individual activity.

In any context involving an action with objects, the individual has the possibility of attending to different aspects of the situation. Indeed, this is an issue that Cobb, Yackel and Wood (1992) see as one of the great problems in learning mathematics, particularly if learning and teaching are approached in a representational context. In their search for substance and meaning, some children may be distinctly disadvantaged right at the start of their mathematical development, but it is a disadvantage that may not make itself apparent in the earlier stages of cognitive development.

Any considered attempt to establish the way children think as opposed to simply measuring their level of achievement has to be welcomed. I see the Owens paper in this context. But there is more — it hints at a divergence in spatial thinking that may match the one identified in arithmetic/algebraic thinking. This is not to say that I applaud the paper in all of its aspects. As a research paper it has many technical weaknesses, one of the major ones being the extensive inclusion of the mechanisms of assessment (Table 1) at the expense of empirical evidence from which the reader may make judgements. What we see is the researcher's

interpretation of the evidence. In a sense, we have a description of the researcher's image of the child's image.

The framework and possible links with van Hiele

The earlier work of Owens (see for example 1992, 1996, 1998) led to the development of a framework to inform teachers of young students' early spatial mathematical development. The 1992 test was developed at the recognition level of spatial development (Owens, 1992,) and was therefore associated with Van Hiele Level 1 (van Hiele 1986).

Dominated by perception, van Hiele Level 1 suggests that appearance becomes the mechanism through which learners operate on shape and other geometric configurations. However, though perception is the foundation of geometry, it takes the power of language to make hierarchical classifications. Figures are initially perceived as gestalts but then may be described and classified through verbalising their properties, to give the notions of points, lines, planes, triangles, squares, rectangles, circles, spheres, etc. Initially these words may operate at a single generic level, so that a square (with four *equal* sides and every angle a right angle) is not considered as a rectangle (with only *opposite* sides equal). Again, through verbal discussion, instruction and construction, the child may begin to see hierarchies with one idea classified within another, so that "a square is a rectangle is a quadrilateral", or "a square is a rhombus is a parallelogram is a quadrilateral".

Owens' contribution to this development has been to tease out the coarser framework and provide a finer grained analysis that may be beneficial to teachers. Focussing on orientation and motion, part whole recognition and the use of language and classification, she presents what may be a useable set of criteria to establish children's thinking. However, I wonder how these criteria differ from the van Hiele level 1, that of establishing a visual gestalt, and van Hiele level 2, that of being able to characterize shapes by their properties. It seems self evident though that these two need embedding in an associated language context in recognition that:

> The criterion for having a concepts is not that of being able to say its name, but that of behaving in a way indicative of classifying new data according to the similarities which go to form this concept. (Skemp, 1986. P. 26)

Evidence of divergent thinking

Of course, it is important to place these notions into a context which has meaning for the teachers of young children. However, it is equally important not to over-generalise from the outcomes — a factor that does seem to dominate this part of the paper, particularly since we are considering a "theoretical framework". We may accept that students 'need to recognise shapes in different orientations' but it is far less easy to accept (in the absence of any empirical data from which to make a personal analysis) that:

- movement is imagined by students as they make associations between shapes

- that the need to complete shapes using imagery are necessary skills for students.

Equally, it is difficult to accept that *all* students will "realise" and/or "develop relationships" or "associate particular words" or use "words to represent their imagery". These expressions project the hopes of the pedagogue not the realism of the learning experience.

In the cognitive context, we see the framework presented as a model which informs us about children's thinking. In the pedagogic context, we see the model as a framework from which teaching could be developed. Such a suggestion reminds me of efforts to turn Piagetian theories into a mathematics curriculum. Indeed, we see similarities with the Piagetian notion of a stage theory and Owens claims that the 'imagery strategies' through which the different aspects of spatial knowledge become evident 'are more or less likely to emerge and be used by children in an order'. Any divergence from this hierarchy of development is simply explained in terms of 'intuition or incidental learning'. No evidence in the paper supports either of these arguments. Most appears to be based upon teaching experiments (for example Owens, 1992, 1996) and/or through the analysis of children's spatial problem solving abilities (see for example Owens & Clements, 1998). Any claims about a hierarchical process of growing strategy sophistication would seem to be best addressed by a longer-term developmental study with individual students.

The notion that there are different strategies associated with children's spatial thinking is important and perhaps we are seeing the first stages in an attempt to mirror for spatial development the research in elementary arithmetic which has proven to be so beneficial. The evidence presented within typical examples suggests that there are differences in the way that children think. Though the study refers to a sample of 50 children, 'typical responses' presented for the reader to make judgements are only drawn from 6. For four of these children it is possible to consider their responses over the 6 items which stimulated responses. An analysis of the responses of these four suggests distinct behaviours not an ordered development. The data within Table 3 may be re-interpreted; not to simply provide 'typical responses' but to indicate qualitatively different thinking representing a spectrum of varying between perceptual and figurative extremes. We see, for example, that "*" always uses "emergent" strategies, "perceptual" strategies dominate the thinking of "◊", pictorial imagery that of "⇒" and the more sophisticated strategies are used by "●" and "■". Responses associated with the emergent strategy, suggest that the child identified as "*" is at a stage of "pre-recognition" (Clements and Battista, 1992) based upon a deficiency in perceptual activity whilst child "◊" appears to be firmly embedded in perceptual strategy use. My conclusion from the evidence would be that some operate on a perceptual level, whilst others operate at a figurative level which itself may reflect differing degrees of sophistication.

A focus on imagery and visualisation

Piaget and Inhelder drew our attention to the relationship between imagery and perception:

> Perception is the knowledge of objects resulting from direct contact with them. As against this, representation or imagination involves the evocation of objects in their absence or, when it runs parallel to perception, in their presence. It completes perceptual knowledge by reference to objects not actually perceived... (Piaget

As more progress is made on the research front the concept of image has become less clear (Cooper, 1995). In a sense, Owens adds to this lack of clarity. Through her implicit recognition that human cognition requires different representational constructs, she adds another dimension to our perceptions of image and visualisation. Images are significant components of cognition and their interpretation has particular relevance to the study of mathematics. However, our interpretation of the notions, and the evidence we use to describe and classify them, is often somewhat speculative and open to interpretation.

It may be correct to make the assumption that there is a functional equivalence between images and processes formed on images, and the corresponding external objects and the perceptual operations that the images and the imagined operations were thought to stimulate. To do so, however, suggests that images, like visual perceptions, have depictive or picture-like qualities. Here we are faced with an elementary problem — whether or not the notion of imagery can be synonymous with the notion of visualisation.

Guttierez (1996), in his excellent discussion of the various ways visualisation, image and mental image have been used in mathematics, suggests that a

> "mental image is a mental representation of a mathematical concept or property containing information based upon pictorial, graphical or diagrammatic elements [whilst] visualisation or visual thinking is a kind of reasoning based on the use of mental images".
>
> (Gutierrez, 1996, p. 6)

He considered that mental images were a basic element in visualization. Using the notions of concept image (the student's mental picture of a geometrical figure) and concept definition (the student's verbal definition to define a geometrical figure) Matsuo (1993) suggested that the more these converge. the more likely it is that the student moves from level 1 to level 2. Such a hypothesis would seem to be consistent with Tall's (1995) view and Skemp's (1986) criteria for the possession of a concept. Equally, the evidence suggested by Owens' responses from "●" and "■" would seem to support this view. Interestingly, Matsuo then suggested that there might be a difference between a state of understanding that is specified by the visual mode and a state of understanding which is clarified by the visual mode. I take this to mean a difference between the visual mode being necessary for understanding and the visual mode being a generator of understanding. In an entirely different study that looks at imagery in the context of elementary

arithmetic, Gray & Pitta (1997) draw a distinction between the use of imagery that is essential to thought and the use of imagery that generates thought.

It is possible that such a distinction may be interpreted from the evidence presented by Owens, where we see notions of perception and imagery being jointly classified to interpret imagery strategies. The fact that we see distinctions between children who rely extensively on perception and others who evoke imagery of a visual form may not be the whole of the story.

Though it would seem that the ability to visualise provides strength in the context of developing spatial awareness, the labels 'visualiser' and 'non-visualiser' may not be indicative of level of mathematical achievement. Pitta (1998) has shown that children at extremes of achievement may be strong visualisers. Equally, children at the extremes could be identified as non-visualisers. To focus solely on the incidence of visual imagery may not provide an insight into the qualitative differences between children, whereas a focus on imagery in both visual and non-visual form may.

The framework devised by Owens may lead us some way towards our understanding of children's understanding. It may also be suggesting that there is a diverging approach to elementary geometry which matches diverging approaches to elementary arithmetic (see Gray and Tall, 1994). Such a divergence, based upon qualitatively different interpretations that children place on spatial activity, may be manifested in the formation of qualitatively different forms of imagery and/or qualitatively different kinds of imagery. Visual imagery may be one of these forms but a broader view of the notion of image would not disregard the product of imaging in any modality.

I started this paper by asking two questions, one associated with the way in which children deal with the study of mathematics; the other associated with the formation of an underlying theoretical structure. The evidence from the framework developed by Owens would suggest that more sophisticated thinking reflects the ability to disregard details and focus on the generalizations that support choice. This was not to say that the detail was unavailable to them — it was and could be incorporated and used if needed.

The ability to create mental imagery is inherent in us all and it would seem that a visual stimulus would evoke visual imagery to a greater extent that verbal stimulus. Pitta (1998) has suggested that it is quite possible for children to posses the same visual image but to then attach different meanings to it. Therefore, whereas the visual image of the more successful child may be used to refresh memory or as a skeleton that ideas, equivalencies and relationships may be attached to, that same visual image may be used in an active mental episode for the less successful.

It is implicit from the Piagetian and the constructivist perspective that the knowledge and the beliefs that learners bring to a situation can influence the meanings they construct from that situation. Kay Owens uses the word

responsiveness to mean a similar thing. The responsiveness of the sample in the survey illustrates that the differences in strategy use may not only be apparent when children's responses to the problems are considered but, also a manifestation of the use of memory. A tendency to focus on surface characteristics of the stimuli may be more strongly related to the use of short-term memory. On the other hand, emphasis on long term memory use may mean retrieval of mental imagery which could be both meaning related information or carry surface characteristics. The truth of the matter is we really do not know. The study of imagery in any context is fraught with difficulty. We make an assumption that report, description and external representation in the form of words, drawings and actions provide an indication of the nature of the mental image. Any efforts to explain or provide a description that relates to reality can be very different from the truth. However, I would suggest that the strength of this paper lies in the possible insights it provides to another divergence in mathematical thinking.

PROJECT GROUPS

Project Group PG1:
Algebra: Epistemology, Cognition and New Technologies

Epistemological and Cognitive Issues about *Equations* and *Inequalities* keeping into account the aspects related to the use of Computers

Coordinators: Jean-Philippe Drouhard, IREM & IUFM de Nice, France

Alan Bell, Shell Centre for Mathematical Education, University of Nottingham, UK

Sonia Ursini, Departamento de Matemática Educativa, Instituto Politénico Nacional, México

Aims of the group:

The members of the 1998 PME Working Group on "Algebra: Epistemology, Cognition and New Technologies" wished to continue their work as a Project Group. They will be involved, until April 1999, in the elaboration (through e-mail exchanges) of a "Discussion Document" which will be circulated before the Haifa Conference, with the aim of involving all people willing to attend the PME-XXIII Project Group.

This Discussion Document will concern "Epistemological and Cognitive Issues about Equations and Inequalities, keeping into account the aspects related to the use of Computers" as a "case study". This document will be available to the participants in the Project Group website:

http://math.unice.fr/~iremnice/pme_wg_aecnt/index.html

The PME-XXIII Project Group will be devoted to discuss prepared reactions to the Discussion Document, and to elaborate the guidelines for the chapters of an electronic (or paper) volume which might be written during the following year and discussed at the PME-XXIV Conference.

Project Group PG2:
Classroom Research Project Group

Coordinators: Simon Goodchild, College of St Mark and St John, Plymouth, UK
Ruth Shane, Kaye College of Education, Beer Sheva, Israel

This Project Group has evolved from the Classroom Research Working Group that has met at PME conferences for a number of years. The focus of the group is the methodology of classroom research. In the past the group has discussed a range of issues crucial to all who are engaged in classroom research, from the consideration of the types of questions that are explored, through the methods and technologies that can be applied, to the approaches taken in the analysis of data that arises from classroom research.

When the group met in Stellenbosch last year it was decided to collaborate in the production of a book that collected together accounts of a variety of methodologies used by members of the group in their own classroom research activity. This project is progressing and one intention, as planned in 1998, is to share a draft version of the resulting book with the Project Group in Haifa.

The other intention of the Group is to move on to consider in more detail approaches taken in the analysis of qualitative data arising from classroom research. This issue was raised in discussion in 1998 and it became clear then that a useful outcome from the Project Group would be the publication of a resource that could be used to both illustrate and provide experience of different approaches to qualitative data analysis. The Group will consider the most suitable media for publishing this work; this could be a CD ROM, the development of a web site or a collection of printed papers.

The goal is to produce a useful companion to the book about methods for gathering data. The sessions will incorporate opportunities for members to share their own approaches to data analysis.

Project Group PG3:
Cultural Aspects in the Learning of Mathematics

Coordinators: Norma Presmeg, Florida State University, USA
Marta Civil, University of Arizona, USA
Phil Clarkson, Australian Catholic University, Australia

The four subgroups of this Project Group are working towards functioning websites that will enable continued collaboration between the members of each subgroup between meetings. Suggestions for a published product will be considered at the meetings in Haifa. The specific topics of the subgroups are as follows:

1. Theoretical perspectives on cultural aspects of learning mathematics.

2. Classroom culture and social practices.

3. Power relations (political, socioeconomic, etc.).

4. Language and culture.

As in Lahti and Stellenbosch, the twin aims of the meetings will be to welcome newcomers to the group as well as to continue the exploration of issues introduced in the interactions of the specific topic groups. This exploration will have the purpose of consolidating the website constructed by Phil Clarkson after the meeting in Stellenbosch. A presentation on a separate page of the website for each specific topic will highlight the results of the Project Group's work in each of these areas, and enable further collaboration.

Project Group PG4:
Research on Mathematics Teacher Development

Coordinators: Andrea Peter-Koop, University of Münster, Germany
Regina D. Möller, University of Landau, Germany
Vania M. Santos-Wagner, Federal University of Rio de Janeiro, Brazil

This Project Group has emerged from a Discussion Group (1986-1989) which was continued as a Working Group between 1990 and 1998. One major asset of this group has been its cohesiveness and its wide representation across many countries.

Goal of the Project Group

During recent years the group has been concerned with developing, communicating and examining paradigms and frameworks for research in mathematics teacher development. From previous group discussions and individual presentations emerged the need to explore the implications of collaboration and collaborative research in mathematics teacher education in a variety of different settings across the world. Therefore, in 1998 the group decided to collaboratively prepare a book on this issue. The working title of the book in progress is „Collaboration and Co-operation in Mathematics Teacher Education: Chances and Implications".

Since the meetings in Stellenbosch last year, altogether 18 abstracts were submitted, of which 13 have been accepted as potential chapters. At this stage additional chapters are still possible and most welcome. The authors of the accepted proposals agreed to submit draft versions of their manuscripts to the co-ordinators by May 99 in order for them to be distributed prior to and during the 1999 sessions.

Plans for the Project Group Activities at PME 23

During the two sessions in 1999 we will need to (1) clarify the theoretical foundations and concepts of the book, (2) develop its structure and (3) begin the peer review process with respect to the manuscripts submitted so far.

Central to the first session will be the discussion and clarification of the concepts of collaboration and co-operation as guiding elements of the joint product. In order to facilitate intense discussions, we will work in small groups each focussing on different aspects with the aim to jointly develop a 'concept map'.

At the end of the session, copies of all submitted manuscripts will be distributed in order to allow the participants to be prepared for the discussion of the papers.

The main focus of the second session will be to reflect on the levels, modes and purposes of collaboration and co-operation addressed in the individual chapters in order to prepare the structure of the book. At this stage it will become clear which additional chapter(s) would complement the publication. Our final task will be to develop a working plan for the time period until PME 24 in Japan.

Project Group PG5:
Social Aspects of Mathematics Education

Coordinators: Jo Boaler, Stanford University, USA
Paola Valero, Royal Danish School of Educational Studies, Denmark

The recent evolution of mathematics education as a field of research has brought growing interest in the social dimension of mathematics education practices. The existence and permanence over the years of the PME working group "Social Aspects of Mathematics Education" is one of the multiple evidences of such an interest. Recognition of the importance of social perspectives on learning poses questions and challenges for researchers working within mathematics education. What does it mean to adopt a research approach that considers the social aspects of mathematics education? Which theories and conceptual frameworks are useful and appropriate for such an approach? Which questions may be addressed by such a perspective? Which research methodologies are suitable for this endeavor? Which criteria for research quality are relevant? What are the social and economic implications of this approach?

Mathematics education is facing the new challenge of taking and understanding a social perspective on the teaching and learning of mathematics, aperspective that has been shown to illuminate significant research questions, processes and results. Such a perspective requires deliberation about the range of research methods and methodologies that are consonant with social dimensions of mathematics education. Such deliberations should broaden our understanding about the practices of mathematics education and possibilities for action.

Therefore, this project group intends collecting a series of papers and publish them in the form of a book whose working tittle is "The Social Dimension of MathematicsEducation: Theoretical, Methodological and Practical Issues". The book addresses the issue of research on the social dimension of mathematics education, and it will include one or more of the following topics:

1. The meaning of the "social" for research in mathematics education
2. Theoretical approaches encompassed within such a dimension
3. Appropriate methodologies and methods
4. The quality of research and research findings
5. The connection between research and practice

Given that the process of the call for papers and submission of proposals has already advanced, the sessions of the project group will be devoted to presenting some of the papers that will make part of the book and receiving critical comments from the group members.

Project Group PG6:
The Teaching and Learning of Stochastics

Coordinators: John Truran, University of Adelaide, South Australia
Kathleen Truran, University of South Australia
Dani Ben-Zvi, Weizmann Institute of Science, Israel
Carmen Batanero, University of Granada, Spain

This project group exists as a focus for members interested in the psychology of the teaching and learning of probability, statistics and combinatorics. It maintains an informal network between conferences by means of an electronically distributed newsletter. It particularly seeks to bring together interested people from all language groups, and does its best to provide translation facilities as appropriate.

Part of our Project Group meetings in the PME 23 Conference will also be devoted to ensuring that all of us have an opportunity to talk about our work. People who wish to be involved in this Project Group are invited to make a 10 minute presentation on their interests. This might be supported by two or three overhead transparencies and perhaps some handouts of work, which they think will be of interest for others. We shall also discuss Projects being done jointly with the International Study Group for the Teaching and Learning of Probability and Statistics.

Work is continuing on the preparation of a book on *Teaching Statistics - Teaching and Learning Statistics: Implications for Research* – which has its basis in psychological and educational research. The basic outlines of this work were decided at our meeting in 1998. Some material is also being prepared for a book on Advanced Mathematical Thinking. Some material will be available for group comment at this PME meeting.

DISCUSSION GROUPS

Discussion Group DG1:

Exploring Different Ways of Working with Video in Research and Inservice Work

Coordinators: Judy Mousley, Deakin University, Australia
Chris Breen, University of Cape Town, South Africa
Harold Frederick, Arizona State University, USA

This discussion group is concerned with the use of video as a means for obtaining data for research purposes and in teacher education.

During the 1998 PME Conference, the group centered its work around the ways in which video data could be re-presented when endeavouring to communicate research to others and to enrich our research stories. Issues around the 'truth' of classroom data obtained from a videotape was explored against a background of conflicting realities. Discussions around these themes elicited energetic debate.

We would like to invite people who are interested in this area to contact Judy Mousley directly and to submit questions or issues that may stimulate discussion and practical activities. Similarly, anyone who would like to offer a short activity that will maximise the participation of those attending the sessions should send a brief proposal for it to Judy (who can also give details about data projection and VCR facilities that will be available, as well as about videotape format).

Questions that will be used to shape the 1999 sessions include:

- How does the viewer's experience influence what they get from a video lesson?
- What impact do extras (commentary, dialogue, transcription) have on interpretation?
- Are there clinical versus descriptive/analytical orientations to viewing lessons?
- Does video data enable researchers to come closer to classroom reality?
- Can experts identify and isolate examples of their theoretical perspectives in videos of mathematics classrooms?
- What are various "points of dialogue" in videos of mathematics classrooms?

The coordinators wish to signal their interest in this becoming a Project Group in 2000, so part of one session will be used for planning future work.

Discussion Group DG2:
Learning and Teaching Elementary Number Theory

Coordinators: Rina Zazkis, Simon Fraser University, Canada
Stephen Campbell, University of California, Irvine, USA

The discussion group on learning and teaching elementary number theory convened for the first time at PME 21 in Lahti, Finland and continued its work at PME 22 in Stellenbosch, South Africa. Referring to "elementary number theory" we think of concepts associated with multiplicative structure of natural numbers, such as factors, divisors, multiples, prime and composite numbers, GCD and LCM, divisibility and divisibility "rules", prime factorization and the Fundamental Theorem of Arithmetic, among others.

A central mandate and guiding motivation for this group is to explore the extent to which elementary number theory can serve as a gateway leading from concrete arithmetic understanding to more abstract levels of algebraic understanding. During the last two years the discussion group covered a broad spectrum of issues, including

- the nature of number theory, its influence on the historical development of mathematics, and its philosophical implications regarding the nature of mathematics more generally
- the role of number theory in the K-16 curriculum
- difficulties teachers and students alike may encounter in understanding introductory concepts of number theory
- the utility of number theory as a vehicle for teaching and learning mathematical concepts such as uniqueness, variables, and proof
- theories and methods for conducting research into these areas

Participants enthusiastically recognized the need to encourage, conduct, and disseminate research into the learning and teaching of elementary number theory. This year, we propose to discuss in more detail some of the issues, especially with respect to the utility of number theory in learning and appreciating mathematical structure and patterns. We also wish to share several insights from research in this area that have influenced or may influence our teaching practice.

Some of the participants from last year's discussion group have offered to give short 5-15 minute presentations of work that they have been conducting. These presentations will serve as a focus for discussion and as an opportunity for feedback from other participants. Another objective is to identify and pursue specific items for potential collaboration in the areas of learning and teaching introductory number theory, further research and its dissemination.

Discussion Group DG3:
Mathematics in Working Practice

Coordinators: Richard Noss, University of London, UK
Celia Hoyles, University of London, UK
Rudolf Straesser, University of Klagenfurt, Austria

The Discussion Group on "Mathematics in Working Practice" starts from the well-known dilemma:

- Apart from basic arithmetic, Mathematics is not used at the workplace (a statement always offered by workers when asked to describe the Mathematics they use at work).

- The use of Mathematics is growing in production, reproduction and other societal domains and is penetrating more and more domains of practice.

Starting from these contradictory statements, the Discussion Group will look into:

- the current use of Mathematics at the workplace,

- research methodologies to explore the uses of Mathematics in the workplace,

- current and future ways to teach/learn Mathematics so that it connects more strongly with the workplace,

- the role of "new technologies" and other artifacts in using, teaching and learning work-related Mathematics,

- the foundation of a research network on Mathematics in vocational contexts.

Discussion Group DG4:
Teachers' and Pupils' Mathematics-Related Beliefs

Coordinators: Erkki Pehkonen, University of Helsinki, Finland
Fulvia Furinghetti, University of Genoa, Italy

The importance of beliefs/conceptions in the study of cognitive and metacognitive phenomena, as well as teachers' behavior and attitudes in the classroom are widely recognized. The following passage[1] expresses very significantly this importance with respect to the study of students' performances:

> "purely cognitive" behavior is extremely rare, and that what is often taken for pure cognition is actually shaped - if not distorted - by a variety of factors. [...] The thesis advanced here is that the cognitive behaviors we customarily study in experimental fashion take place within, and are shaped by, a broad social-cognitive and metacognitive matrix. That is, the tangible cognitive actions produced by our experimental subjects are often the result of consciously or unconsciously held beliefs about (a) the task at hand, (b) the social environment within which the task takes place, and (c) the individual problem solver's perception of self and his or her relation to the task and the environment.

As for teachers, many studies have shown that beliefs are behind teachers' behavior in their classroom and act as a filter to indications of curriculum developers[2].

The discussion group will focus on the following three main issues, in addition to issues which will emerge from participants' contributions:

- Terminology: Some points need a careful discussion in order to agree on terminology and description of terms. Even the words 'belief' and 'conception' have different meanings for different researchers.
- Methodology: How do we detect and analyze beliefs, which in their nature are entities hidden and elusive?
- Effect: How may studies on beliefs/conceptions affect the classroom practice and strategies for teacher education?

Discussion Group DG5:
Understanding of Multiplicative Concepts

Coordinators: Tad Watanabe, Towson University, USA
Julia Anghileri, Homerton College, University of Cambridge, UK
Angela Pesci, University of Pavia, Italy

Mathematical concepts within the 'multiplicative conceptual fields" include multiplication and division operations, fractions, ratio and proportion, and linear functions (Vergnaud, 1988). Understanding of these concepts mark significant points in students' development as mathematics learners. Moreover, although these concepts are taught at different grade levels, their developments are closely connected (Harel & Confrey, 1994).

This dicussion group is a continuation of the Working Group on the same topic which had been in existence for 3 years. There will be opportunities for participants to informally share insights they have gained in their previous studies, discuss ideas they are planning to pursue and develop potential collaborative research opportunities. Although we will not limit our discussion to any specific topic, we have agreed to spend some time discussing two ideas: (1) proportional reasoning, and (2) development of algorithms for multiplicative operations.

SHORT ORAL COMMUNICATIONS

BECOMING A MATHEMATICS TEACHER EDUCATOR: REFLECTIONS AND ANALYSIS

Bridget Arvold

University of Illinois

If findings from research on becoming a mathematics teacher extend to becoming a mathematics teacher educator, then investigation into becoming a mathematics teacher educator is crucial. Based on the assumption that mathematics teacher educators impact not only their students but ultimately their students' students, studies of becoming a mathematics teacher educator may illuminate not only our understanding of a scaffolding of impact but also the complex process of becoming. Unfortunately, research related to teacher educators is minimal and focuses primarily on problems of identity (See Reynolds, 1995).

To initiate research in mathematics teacher educator's becoming, I scoured recent PME-NA conference proceedings for author interest in teacher education. A diverse group of seventeen of the 72 mathematics educators contacted, responding electronically to an open-ended request to share their thoughts on the meaning of becoming a mathematics teacher educator and on significant experiences that had influenced or were influencing them in becoming mathematics teacher educators. Attribution of sense making to the constructions of individuals and the introduction of only "sensitizing concepts" to research participants supported a research framework of interactionist theory as promoted by Blumer (1969).

Although interpretations of becoming a mathematics teacher educator were diverse and exposed distinct perspectives such as personal growth, upward movement in a hierarchy of authority, moral development, and service, a common focus on communication permeated the data. Expressions of personal "naivete" as a teacher as well as struggles to understand the "complexity of teaching" and of one's "impact on teachers" contrasted with expressions of exploring "mirrors to our souls" and "compromising an intellectual side." This small collective study suggests that a wide variety of interpretations of becoming a mathematics teacher educator and related attributions are prevalent. Follow-up research into how various interpretations of one's own becoming interacts with one's practice and impacts students and students' students warrants continued research in this area.

TWO ASPECTS OF THE MATHEMATICAL RATIONALITY. FUNCTIONS OF THE COUNTEREXAMPLE

Gustavo Barallobres, Mabel Panizza
Universidad de Buenos Aires, Argentina

This work deals with two identically constituent aspects of mathematical rationality, involved when dealing with conjecture, and which depend whether the aim is to determine the conjecture's truth or its validity domain.

According to this context, two different marks are particularly worth reading a counterexample when dealing with a refutation: either to inform us whether the conjecture is true or false (logical status) or to inform us the of conditions under which it would be true (mathematical status).

Both sides, neither opposed to nor subordinated to each other, have to do with the didactic responsibility domain.

After a cognitive and epistemological analysis, we have identified a number of variables that could be considered to be relevant for a parallel and complementary development of both aspects of mathematical rationality as they could command different focusing.

In doing so, we have mainly considered Balacheff´ contributions (1991) in relation with the student's treatment of a counterexample and Duval's contributions(1995) in reference to the components of the sense of a proposition outside a theoretic context of enunciation.

The **variables** which have been identified are:

As regards the conjecture:

- Validity domain (finite, infinite)
- Author of the conjecture(student, partner, teacher)
- Knowledge nature (intuitive, learned)
- Interaction between the "epistemic" value and the logical true value

As regards the counterexamples:

- Quantity (one, few, a lot, infinite)
- Characterizable ensemble (yes, no)

During the oral communication, we will ground our choices of these categories and present a few problems belonging to the algebra domain which have been chosen on account of them. We will also report some results of an empirical study which aims to observe the cognitive functioning of the students (ages 15-18) when facing such problems.

FROM NATURAL LANGUAGE TO SYMBOLIC EXPRESSION: STUDENTS' DIFFICULTIES IN THE PROCESS OF NAMING.

Luciana Bazzini, Department of Mathematics, University of Padova, Italy.

The use of symbolic expressions seems to be a relevant cause of difficulties in students at different school levels. Most difficulties emerge because of the incapability to relate the algebraic code to the semantics of natural language. The student able to express the relationships among the elements of a given problem correctly, by means of the natural language, can be unable to express the same relationships through the algebraic code.

The passage from natural to symbolic language is a key point in the development of algebraic thinking and asks for special attention in teaching.

Starting from the analysis of students' difficulties when they have to coach their stream of thinking in order to condense the most relevant aspects of a given problem into a formula, we have deserved special attention to the initial approach in the construction of algebraic expressions. Our focus is on the *process of naming*, i.e. the process of assigning names to the elements of a problem in order to construct a symbolic expression functional to the problem's solution.

In this process the role of letters is crucial. Letters can be used to give a name to the elements involved in the problem and to emphasize the relationships among the elements within an algebraic expression. The choice of names to designate objects is strictly linked to the control of the variables introduced: since algebraic formulas are usually not a linear stenography of what is expressed by means of natural language, difficulties emerge, especially for novices (Arzarello, Bazzini and Chiappini, 1994)

An additional contribution is given by a study carried out with a sample of 244 students (aged 15-16 years) attending the first two grades of upper secondary school in Italy. The study was set when the students have attended at least two years of algebra. A questionnaire was submitted to the pupils: all items required a translation of statements expressed in natural language into symbolic expressions involving the use of letters. In particular we are concerned in studying the students' responses in the case that the mathematical elements are already named by a letter, compared with the case when they are not.

Two main features emerge from the data analysis: a difficulty in the items not simply requiring a step by step translation from natural to symbolic language and a drop down of correct answers in the items requiring the process of naming for the elements of the problem. There is evidence that the semantic control of letters should be systematically carried out by means of adequate coordination of different semiotic registers (according to Duval, 1995).

A RELATIONAL ANALYSIS OF A MATHEMATICAL LEARNING EPISODE

Margot Berger

University of the Witwatersrand

Most members of the mathematics education community would agree that learning is a complex and interrelated phenomenon. In this paper I demonstrate how the framework of Activity Theory (Leont'ev) offers a tool for the analysis of mathematical learning episodes which is commensurate with that perspective.

Certain mathematics educational researchers (such as Crawford, Meira) use Activity Theory or aspects of it in their interpretations, but detailed and multi–leveled analyses in terms of this theory are not common in the literature of mathematics education research.

In line with Activity Theory, which proposes purposeful human activity as the unit of analysis, I explicate mathematical learning in the classroom in terms of the **relationships** between the pupil's activities and the different elements of the learning system: the pupil with his/her own history and motives, the goal of the mathematical task as subjectively perceived by the pupil, the activities of the pupil (purposeful or automated), the actual mathematical task, the social interactions (which include the teacher's mediations), the tools and the setting.

Furthermore I argue that although it is necessary to regard these components as analytically distinct, they are, in fact, interrelated and mutually constitute the learning episode.

The episode which I analyse and interpret, derives from a case study of a lesson in which two Grade 8 girls, working as a pair, are videod as they embark on a mathematical task. The task involves moving from a graphical representation of the changing water levels in a bath tub to a real–world description of a sequence of events which could generate such a graph. The task is given in a lesson published on the internet and as such, is presented to the girls on a computer screen.

In this particular episode, the relationship between goals and activities is foregrounded. The analysis shows how the pupils struggle to articulate the goal of this task; how teacher mediation is required to explicate the goal; how the motives and cultural background of each girl serve to re–orientate the goals of the other and how the maths activities change as the goal does.

This small example illustrates the usefulness of Activity Theory as a multi–focal lens through which to view the mathematical learning that may take place in the classroom.

THE EFFECT OF DRAGGING IN A DYNAMIC GEOMETRY ENVIRONMENT ON STUDENTS' STRATEGIES SOLVING LOCUS PROBLEMS

Irina Bershadsky and Orit Zaslavsky

Technion, Haifa

The concept of locus of points can serve as a unifying idea in geometry, reflecting a basic and general approach in modern mathematics. In school, traditionally, the approach to the notion of locus puts more emphasis on deductive inference and computational methods for finding the algebraic equations of a limited class of geometric loci, rather than pays attention to intuitive, geometric, visual aspects, which are at the heart of this notion (Hershkowitz, Friedlander, Dreyfus, 1991).

The special visual features of Dynamic Geometry Environments open new perspectives and powerful opportunities for mathematics education. However, these opportunities can raise new difficulties. To make optimal use of computerized environment, one must understand how students interact with the environment and how students' mathematical thinking is reflected and affected by their use of the environment (Hazzan & Goldenberg, 1997).

The goals of this study are to explore the way in which dynamic features are used by students while solving locus problems and the effect that this use might have on the understanding of the concept of locus.

We report the main results of one case-study investigating the knowledge constructed by a Grade 11 student while solving locus problems in a Dynamic Geometry Environment during 12 sessions of about 2 hours each. A qualitative data analysis was based on everything that the student said, constructed on the computer screen and wrote on paper during these sessions.

Data analysis points to several stages through which the student went: At first, the student was inclined to implement a *segment-based approach* to construct loci defined by their properties. Then, by dragging points and marking their trace, the student was able to find and reflect on the geometrical relations and properties that remained unchanged under the dragging transformation. This process led to the student's insight of "seeing" in his mind the locus as a global entity. The dragged points on the computer screen played a significant role in the student's strategies. Finally, the student developed an awareness of the limitations of his own *segment-based* strategy and moved to a more global perception of locus and its construction.

USING THE UNDERGRADUATE MATHEMATICS CLASSROOM TO CHALLENGE PROSPECTIVE SECONDARY TEACHERS' NOTIONS OF MATHEMATICAL DISCOURSE

Maria L. Blanton

University of Massachusetts Dartmouth

The way that teacher and students interact with mathematical ideas in the social context of the classroom structures students' thinking about mathematics (Wertsch & Toma, 1995) and so ultimately, prospective teachers' [PTs] thinking about teaching mathematics (Lortie, 1975).The purpose of this proposal is to discuss results of using a one-semester, undergraduate geometry course to challenge PTs' notions of mathematical discourse [MD]. The course was structured to engage PTs (9 total) as student participants in MD, as students in the pedagogy of MD, and as architects of MD. As geometry students, PTs were expected to establish mathematical ideas through conjecture, justification, and peer argumentation. The resulting MD, which PTs reported as differing from their previous experiences in undergraduate mathematics, became a springboard for in-class analyses on the nature of our dialoguing. The characterization of discourse as univocal or dialogic (Wertsch & Toma, 1995; see also Lotman, 1988) was used to frame discussions about MD. To engage PTs as architects of MD, each PT taught a one-hour lesson as part of the class. The lesson was videotaped, transcribed, and analyzed with respect to the nature of MD by the PT. Data for this study consisted of video recordings of the geometry class, PTs' discourse analyses of their teaching, clinical interviews with each PT about his or her discourse analysis, PTs' pre/post reflections about their notions of MD, and PTs' reflections about the pedagogical and mathematical structure of the geometry course. Results indicate that PTs matured throughout the semester in their ability to engage in and reflect on MD. Moreover, by examining MD in the mathematics classroom, PTs were able to dissect a mathematically authentic discursive event *as they created it*, allowing them to apprentice more powerful techniques of MD than might be possible in other contexts. Additionally, PTs' teaching episodes and subsequent discourse analyses revealed to PTs the complexity of MD and deepened class discussions about MD. In conclusion, the model used in this class seemed to give PTs a concrete, experiential approach to understanding the MD needed to support students' mathematical thinking.

MATHEMATICS AND LITERATURE: LEARNING MATHEMATICS IN A FOLK-TALE CONTEXT

Malka Brender, Nomy Dickman, Rachel Heller, Larisa Marku, Alla Shmukler,
Clara Ziskin, and Orit Zaslavsky
Technion, Haifa

In the past decade there have been many calls for connecting mathematics and other domains (e.g., NCTM, 1989). The reasons for such calls are cognitive as well as affective. The current study is based on the assumption that connecting literature and mathematics can help decrease students' math anxiety, motivate them to learn mathematics, and consequently, improve their attitudes towards mathematics

For the purpose of the study, a special booklet was developed called "On the Fairy Tale Wings". This booklet continues a long lasting tradition of combining mathematics and literature, which began in the 19th century. It includes the original text in addition to a Hebrew translation of a Russian folk-tale called *Princess the Frog*, new episodes interlacing the main plot and its characters, and mathematical and logical problems associated with these episodes. The booklet and its activities are intended for middle and high school students. For example, one type of problem deals with plotting pictures of the various folk-tale characters by computer generated graphs of functions.

In order to study possible effects of learning mathematics in such a context, an experiment was conducted in which students had to read the folk-tale and engage in the accompanying assignments. At the end of the experiment the students were asked to pose new problems based on this folk-tale as well as other tales that they know.

Three 8th grade classes of students participated in the study. An attitude questionnaire was administered prior to the experiment and after its completion. In addition, classroom observations and student and teacher journals were documented and analyzed. The findings point to students' increase in positive attitudes towards mathematics and their inclinations and desires to combine mathematics and literature in school. Interestingly, students' motivation to pose worthwhile mathematical problems was also enhanced.

ACQUISITION OF THE MODEL OF PROPORTIONALITY SUPPORTED BY A HYPERMEDIA DOCUMENT

Isabel Cabrita and Armando Alves de Oliveira
Universidade de Aveiro – Portugal

Our study was based on three fundamental pillars — problem-solving, the model of direct proportionality and the 'new' information and communication technologies. The main objective of the study, which was carried out with 7th Grade students, was to develop and validate a hypermedia document which, designed according to a problem-solving methodology and a constructivist view of learning, might intervene in the acquisition of the model of Direct Proportionality (Alves de Oliveira & Cabrita, 1997 e Cabrita 1999).

We opted for an extra-curricular experimentation of our hypermedia programme for two main reasons: firstly, the use of computers in the classroom situation is not (yet) a systematic reality in Portuguese schools; and secondly, for several reasons which have to do essentially with the democratization of schooling, the classroom space is not the most suitable to cope with the individual rhythm of each student, or, cause and consequence of the above, to respect different browsing behaviours. Although we believe that this strategy could bring added advantages, we were conscious of the fact that it would certainly bring with it new responsibilities for teachers who will increasingly have to know how to negotiate the knowledge acquire in spaces other than the microcosm of the classroom, leading to a broadening of the horizons of their professional development

In this context, and following the conclusion of the research (Cabrita, 1998), which we propose to divulgue in this paper, it was possible to offer indications in three directions: about how interactive teaching programmes should be designed and put into effect; about how, where and in what conditions they should be exploited and about the implications of this study for teacher education.

PROSPECTIVE SECONDARY MATHEMATICS TEACHERS' CONCEPTIONS OF FUNCTION: MATHEMATICAL AND PEDAGOGICAL UNDERSTANDINGS

Insook Cha, University of Michigan, Ann Arbor, USA
Melvin (Skip) Wilson, Virginia Polytechnic Institute and State University, USA

This study investigates the three research questions: (1) What are the common definitions of function given by preservice teachers?, (2) What are the common preferred definitions of function for teaching given by preservice teachers?, (3) What conceptions tend to impede or allow the selection of certain definitions of function for teaching? Twenty-one preservice teachers enrolled in a required mathematics methods course in the Fall Semester 1997 at a large mid-western university in the US were subjects of the study. Preservice teachers' conceptions were investigated both before and after they completed an instructional unit about the teaching of functions. Open-ended questionnaires, observations, and written documents of 21 subjects were collected and three subjects were each interviewed twice.

Most subjects could not give more than one definitional description nor discuss features of definitions. Analogical (machine/equations) definitions were the most popular. Logical (set-theoretical) and genetical (dependence) definitions were not common. Before the instructional unit, when selecting definitions to use in teaching, most subjects were concerned with pedagogical reasons (whether they thought students could easily understand/memorize the definition) rather than mathematical reasons (whether the definition allows students to learn the nature of the function concept). In contrast, after the unit most subjects were concerned with mathematical reasons. This study also illustrates the importance of integrating different domains of knowledge for a good pedagogical content preparation. An understanding of functional relationships and their relation to the genetical definitions as well as an appreciation for the usefulness of functional relationships and the importance of multiple representations within and outside mathematics were all significant factors allowing the selection of genetical definitions. Preservice teachers' conceptions of students' understandings and potential misunderstandings of the function concept were important factors impeding logical definitions (particularly, correspondence and set definitions). Some preservice teachers were reluctant to select a correspondence definition for students because they believed that students might not readily grasp the ideas of correspondence or sets.

MATHEMATICS TEACHERS' USE OF THE NEW TECHNOLOGY

Cosette Crisan
South Bank University

Interest in teachers' subject matter knowledge and pedagogical content knowledge has risen in recent years (Cochran *et al*, 1993, Meredith, 1993, Ruhama *et al*, 1996). With the increased availability of the new technology (graphics calculators and/or computers together with different items of educational software) in our schools, it is important to examine how these components of teachers' professional knowledge base affect and are affected by its use in teachers' instruction (Zehavi, 1997, Simmt, 1997).

The focus of this session is to report on a pilot study that involved a number of secondary mathematics teachers who regard themselves as confident and competent users of IT in their mathematics lessons. Three main factors affecting teachers' use of the new technology emerged from the analysis of the interviews: types of hardware available in schools and their accessibility, software & resources on the use of IT and departmental policy. The presentation will also give an account of teachers' reasons for starting to use IT, reasons for using IT in their mathematics lessons as well as reporting on teachers' views regarding the value of using IT with respect to todays' school mathematics, teaching of mathematics and their knowledge of mathematics.

In the analysis of the data there is evidence to suggest that the use of the new technology enriches and challenges teachers' knowledge of mathematics as well as their instruction. The findings point out to the importance of teachers' own learning experiences when doing mathematics with the new technology.

The longer term intention is to develop a theoretical model which accounts for teachers' learning about IT and teachers' incorporation of IT into their planning for teaching mathematics. It is hoped that this will have useful implications for pre-service and in-service teacher education area.

An Activity Approach to Dynamic Assessment

Chris Day

South Bank University

Ferrara (1987) investigated static tests which provide an index of a child's developmental level. She discovered that the rate of adaptation to similar, but more complex problems can provide a far more comprehensive index. This is indicated inversely by the number of hints needed in the second training phase of a test-train-retest procedure. In applying her assessment procedure, Ferrara (1987 p 106) found that children who scored highly on the post-test were not simply the ones who did well on the pre-test. Multiple regression indicated that background knowledge accounted for 22% of the variance in residual gain scores and neither IQ nor 'Learning Efficiency' (total hints to reach mastery in simple addition problems) produced any increase in this. However 'transfer efficiency' (total hints to reach mastery in 'transfer and far transfer' problems) explained an additional 32% of the variance in residual gain scores.

I have adapted Ferrara's basic method for use in the evaluation of a mathematics teaching program that I have conducted in English middle schools. This mathematics teaching program was based on principles of Activity Theory described by N Talyzina (1981). Although my intentions were rather different, my own assessment results were consistent with Ferrara's. I have, however, taken the view that Dynamic Assessment is essentially an assessment of social interaction and cannot provide an index of individual potential. I will suggest some theoretical considerations concerning the genesis of the generalisation and fluency of mental actions that I consider to be of central importance for the development of Dynamic Assessment procedures. I will also briefly present some of my results and I will outline some modifications to Ferrara's method which I have used to develop the Dynamic Assessment procedure within the theoretical framework of Activity Theory.

THE " CESAME " PROJECT: MATHEMATICAL DISCUSSIONS AND ASPECTS OF KNOWLEDGE

Jean-Philippe DROUHARD
DIERF (IUFM de Nice)
drouhard@unice.fr

Catherine SACKUR
GECO (IREM de Nice)
sackur@unice.fr

Within the research field of Social Constructivism (Ernest, 1995), we are working on a project called CESAME: in Nice (France): J-Ph. Drouhard, M. Maurel &. C. Sackur; in Paris (France): T. Assude & N. Douek; in Madrid (Spain): Y. Paquelier; in Buenos Aires (Argentina): G. Barallobres & M. Panizza. The word, "CESAME", is an acronym of the following French words: "Construction Expériencielle du Savoir" et "Autrui" dans les Mathématiques Enseignées ", which could be more or less well translated as: " the Subject's Experience of Dialogues with Interlocutors ("Others") in the Social Construction of Taught Mathematical Knowledge ".

Our starting point was the following. What is the teacher supposed to do, at the end of a *Scientific Debate* (Legrand, 1988) or more generally of a *Mathematical Discussion* (Bartolini-Bussi, 1991), in order to turn the many statements yielded by the discussion into "official" mathematical statements, which is "Institutionalisation" in the terms of the Theory of Didactic Situations (Brousseau, 1997, Margolinas 1992, 1993)? And what is s/he actually doing? On the one hand, in a strict Social Constructivist point of view, the group is supposed to " construct " the whole mathematical knowledge by itself, the teacher's role being just to lead the discussion. On the other hand, the teacher actually says something about the new common knowledge. Well, what does s/he says?

Obviously, the teacher institutionalises something more than the strict 'content' of the mathematical text. In order to give a framework to this idea, we propose to consider that knowledge present three aspects. The *first aspect* is made of the mathematical *content* of the knowledge, the *semantics* of the related statements (definitions, theorems...). The *second aspect* contains the rules of the mathematical game ('game' in the sense of Wittgenstein), the principles that make the definitions define as they are supposed to do, the theorems prove as they are supposed to do etc. The *third aspect* contains the most general believes about mathematics, as for instance "mathematics is a matter of understanding" or in the contrary (as many students say), "algebra is just a matter of formal rules".

Within this framework, to learn mathematics is to learn mathematical contents (aspect I), is also to learn *how to do* mathematics the way mathematics are supposed to be done (aspect II) and is also to learn *what* are mathematics (III). On the other hand, to teach that a statement is mathematical, is also to teach that mathematics are made (III) of statements like the one which is taught (I)!

After a first theoretical study we are at present collecting more empirical data.

WHAT DO STUDENTS DO WITH CONJECTURES? PRE-SERVICE TEACHERS' RESPONSES TO A GENERALIZATION TASK

Laurie D. Edwards
St. Mary's College
Rina Zazkis
Simon Fraser University

Problem-solving and generalization are central activities in mathematics, with the solution to difficult problems often requiring generalization across specific cases. In order to support students' learning of generalization , teachers of mathematics require experience with this process themselves. This study examines the work of undergraduate students enrolled in a mathematics course for prospective elementary school teachers, as they grappled with a challenging problem in number theory (determining the number of squares crossed by a diagonal in a rectangular grid). The central research question examined how students responded to evidence that did not confirm their conjectures. Although in such a case, it is mathematically normative to reject or revise the conjecture, not all students had internalized this norm. An analysis of 27 written problem solving journals revealed that although few students were successful at finding a complete and correct general solution to the problem, most responded appropriately to disconfirming evidence. Variants from the normative response are described and implications for instruction discussed.

Literacy-in-mathematics perception of mathematics educators: From Literacy-in-mathematics to mathematics literacy

Hanna Ezer, Levinsky College
Dorit Patkin, Hakkibutzim College of Education
Shosh Millet, Achva Academic College

In this paper we present the relations between literacy and mathematics as perceived by mathematics educators such as pre-service teachers, in-service teachers and teacher trainers. The relations between mathematics and literacy develop on the backdrop of the perception of using literate activities in the disciplines in order to develop learning and thinking (Fulwiler and Young, 1990; Ackerman, 1993).

The purpose of this study is to investigate through questionnaires and interviews the participants' perceptions of the notion of literacy in general, the relations between literacy and mathematics in particular and the contribution of literacy to the teaching and learning of mathematics. All participants had been exposed to the notion of literacy in mathematics during a one year in-service and pre-service courses.

Findings indicate that students and teachers of mathematics hold medium to low perception of literacy in general and literacy in mathematics in particular, though teacher trainers hold high perception of both. Yet, pre-service teachers reveal higher perception of literacy in general, probably due to exposure to literacy learning in other courses in a teacher training college.

Following the study results we recommend the use of literacy activities such as oral discussion, reflective journal, writing process (Waywood, 1992; Scheibelhut, 1994) etc. in mathematics in-service and pre-service courses. The training period should be longer, using reflective tools and coaching to strengthen the perception of **literacy-in-mathematics** in order to develop **mathematics literacy** in teachers and student teachers as well as in school students.

TEACHER DEVELOPMENT: A SELF-INQUIRY APPROACH

Razia Fakir Mohammad, University of Oxford, Department of Educational Studies, Oxford, UK

In this presentation I offer and analyse accounts of how teachers and a mentor learned about their practice through a process of self-inquiry in a research study in Pakistan. Action research was the method for analysing and learning from the significant accounts of the teachers' practice. The purpose of the study was not to examine the meaning of being a teacher, nor to provide teaching strategies and underlying teaching practice, but to explore the ways in which action research contributed to the teachers' process of development by helping them to create their own theories of teaching and learning. The investigation was carried out in a Karachi school as a partnership between a mentor and two mathematics secondary school teachers in 1996. The agenda for study had two parallel strands: in one, teachers learned to search their own classroom practice on their own as insider and perceived themselves as an agent of change of their own practice rather than received knowers; in the second the mentor was involved in researching the teachers' learning as a result of teachers' research. It was a two-level inquiry with a co-operative learning agreement. As a participant observer the mentor-researcher performed the role of an observer, who observed the lessons and took notes; a listener, who listened to the teachers very carefully; a stimulus, who encouraged them to reflect on the significant aspects of teaching and learning; a task-keeper, who focused their thinking; and a guide, who helped them to improve their practice and develop their own theories of learning. On the other hand the teachers were involved in planning, implementing and reflecting through the period of study. They had three roles: teachers - planning and implementing their teaching; researchers - researching their practice by examining and reflecting; learners - developing new understanding of children's learning mathematics. The data was collected in one academic year. The mentor-researcher's data included field notes, transcription of audio recording of dialogue and notes from reflective journals. Teacher-researchers maintained reflective journals as a record of significant accounts of teaching and meeting with mentors. All the details of data were shared among the participants(teacher-researchers and mentor-researcher) on an on-going basis. There was on-going data analysis, which helped the participants to plan and decide further actions. The findings show action research as an evolving experience, because of the nature and significance of development of self-reflection and a sense of ownership of the participants concerning their actions and development of theories in collaboration. This presentation will share some insights, which show how reflection and dialogue on the classroom events helped the teachers to learn and understand the different aspects of mathematics and teaching mathematics and an understanding of action research as a result of practical experience of conducting the research.

MEANING PRODUCTION FOR FUNCTION: PARALLEL AXES

Authors: Janete B. Frant and Monica Rabello de Castro

Affiliation Universidade Santa Úrsula - Instituto de Educação Matemática

The purpose of this study is to investigate how high school students produce meaning for linear function while working in an unusual environment. This environment, called P.A.R—Parallel Axes Representation, was proposed by Arcavi and Bruckheimer (1996). In this presentation we will discuss the process followed by two students while developing a formula to relate the cartesian representation to PAR representation.

The theoretical framework is based on the notion of meaning production proposed by Lins (1997). We agree with Lins that meaning production is related to enunciation, actually he defined meaning production as everything that is effectively said about an object. In this way, we are analyzing the dialogues that arise during students' argumentation. In order to analyze data we develop a argumentation strategy model based on Perelman's Argumentation Treatment (1996).

The study took place in a public high school in 1997. Two 10th grade students were videotaped during 6 one-hour-and-forty-minute meetings.

Three points will be discussed: 1) How to find the image of a point in PAR, 2) the Crucial Point and 3) the Formula to enable relating cartesian and PAR representation.

Fragments of Crucial Point Dialogue

1. P- I told you to not connect
2. F- So it's all wrong
3. P- No. Why is it all wrong?
4. F- Because if it doesn't work for one [point], it can't work for the others.
5. P- Cool
6. F- Uaaauuu, it always connect in the same point. I discovered it the Crucial Point.
7. F- Is everything already invented or we can invent things too?
8. P- I don't know
9. F- Because I'll call it crucial point because I think it's cool, but I do think they already invented it.

Partial Findings: We found that working in this unusual environment students were able to be flexible in using algebraic and graphic representation, to elaborate a formula to pass from cartesian to PAR representation and vice-versa. Moreover, they believed they were able to invent mathematics.

Computers and the teachers' role in mathematics learning environment. Some episodes from the classroom.

Anne Berit Fuglestad

Agder College, Kristiansand, Norway

In a teaching experiment, with students of age 10 - 14, computers were used in the teaching of decimal numbers with some spreadsheet tasks (Fuglestad, 1996b; Fuglestad, 1996a). Based on a constructivist view of learning (Davis, Maher, & Noddings, 1990), the aim was to implement a diagnostic teaching approach (Bell, 1993) to stimulate the students' construction of knowledge.

In order to help the class teachers combine the use of computers with a diagnostic teaching approach, some spreadsheet tasks were provided on student worksheets. The teachers were given an introduction to computers in the classroom including spreadsheets, diagnostic teaching and the worksheets over three days.

The teachers' role appeared to be crucial in utilising the potential of the computer and spreadsheet tasks. Clearly, this can be seen from episodes where the students' misconceptions were provoked and discussed, and from other episodes which revealed less. The teacher's or observer's intervention, asking questions or giving suggestions for further trial, was of major importance. The teacher should not give the answers too quickly, but give the students time to reflect on their experience and discuss in small groups and in class. There was also a need to give clear introductions, to follow up, to summarise findings and to provide further discussion in the class.

The teachers' awareness of diagnostic teaching was vaguer than expected at the end of the research. However, some elements were implemented and in particular some spreadsheet tasks helped them to achieve this. The computer apparently has the potential to be a useful tool in diagnostic teaching, but there is a need to strengthen the teachers awareness of their role in implementing this.

What do Mathematics Senior Phase Teachers Understand about the new Outcomes Based Curriculum 2005?

Ms. Mellony Graven
RADMASTE Centre, University of the Witwatersrand, South Africa

The Programme for Leader Educators in Secondary Mathematics Education (PLESME) began workshops with teachers from schools in Soweto and Eldorado Park (both urban townships outside Johannesburg) in January 1999. The primary goal of this programme is to:

* create leader teachers in mathematics with the capacity to interpret, critique and implement current curriculum innovations in mathematics education in South Africa and to support other teachers to do the same.

South Africa is currently embarking on radical curriculum change which aims to implement an outcomes approach to education. This curriculum places a significant emphasis on the contextualisation of mathematics, socially, politically, economically and historically. It also places a significant emphasis on mathematising particular mathematical processes such as mathematics communication, interpretation and justification.

Previous research work, conducted by myself, indicated that very little information about curriculum development was being disseminated in these areas. The interim curriculum, which was to be implemented at the Senior Phase Level in 1995, had never reached the schools and little or no information had reached them about the new outcomes based education curriculum which was initially scheduled to be implemented at the Senior Phase level in 1997.

The research work presented here is part of a broader two year research plan which aims to investigate mathematics teachers' learning especially as it relates to implementing 'new' aspects of mathematics emphasised within the current South African context of curriculum change.

The PLESME Programme and its related research began in October 1998. This research paper will look at some preliminary findings of baseline questionnaires and interviews conducted with ten teachers from Soweto and Eldorado Park. The interviews and questionnaires covered a range of topics such as teachers' views on how mathematics should be taught, their understanding of the new curriculum and its related mathematics specific outcomes, who teachers talk to about their mathematics teaching etc.

In this presentation I will discuss teachers' understanding of the new curriculum and the related mathematics outcomes as revealed by analysis of the transcriptions of recorded interviews with teachers and their written responses to the questionnaires.

Some preliminary findings indicate that:

- teachers have not received any documentation relating to the new curriculum. Most of their opinions have been informed by what they have read in newspapers and what they have heard from teachers who have implemented it in grade 1.
- there is a mixture of positive and negative attitudes towards the value of the new curriculum and variation in their understanding
- teachers have difficulty understanding the meaning of the maths specific outcomes

WHEN OBSTACLES SEEM TOO BIG

Michael D. Hardy

University of Southern Mississippi Gulf Coast

This paper is based on a case study of Sharon, a middle school mathematics teacher who endorsed a constructivist epistemology and strove to use a variety of instructional strategies to teach for understanding as well as computational skill. The goal of the study was to gain insight into how Sharon made sense of her teaching experiences by investigating both her constructions of such experiences and her beliefs about teaching and learning.

Over the course of the study, it became apparent that a discrepancy existed between Sharon's teaching and her ideal for teaching. Sharon was aware of this discrepancy but was able to justify it. Hence, it did not perturb her. Sharon's efforts to use a variety of instructional strategies were further impeded by student resistance, her conception of her role as an educator, and limited engagement in critical reflection. However, participation in communicative discourse (Habermas, 1987) could have perturbed Sharon with respect to her beliefs and practice, helped her envision alternatives for her practice, and provided support for her efforts to alter her pedagogy. This is significant because all of these potential outcomes are components of the process of teacher change (Shaw & Jakubowski, 1991). Thus, participating in communicative discourse could help teachers alter their practice and overcome pedagogical constraints.

ATTITUDES OF PROSPECTIVE HIGHSCHOOL MATHEMATICS TEACHERS TOWARDS INTEGRATING INFORMATION TECHNOLOGIES IN THEIR FUTURE TEACHING

Orit Hazzan

Technion – Israel Institute of Technology, Haifa

& Oranim – College for Education, Tivon

ISRAEL

Hundreds of papers are published nowadays arguing that computers become an integral part of our lives and, as such, should be integrated into educational systems as well (Cf. Edelson, Pea and Gomez, 1996; Flake, 1996). Since such integration requires a change in teaching methods, teachers play a central role in such a transition. Of course, this is also true in regard to teaching of mathematics.

The talk presents attitudes of prospective mathematics teachers towards integrating computers in their classes in the future. A course took place, which focused on didactical and cognitive aspects of learning mathematics with computers. At the end of a course, ninety-four prospective teachers (from 4 classes) were asked to present reasons, pro and con, that would influence their use of computers in their future mathematics teaching. Based on written questionnaires and class discussions, the reasons given by the prospective teachers were grouped into the following two-dimensional theoretical framework:

	learner	teacher	mathematical content	learning environment	class atmosphere
cognitive factors					
affective factors					
social factors					

In the presentation I explain what each category means, present reasons given by the prospective mathematics teachers, and suggest some plausible implications of these attitudes on mathematics education.

STUDENT'S OWN MATHEMATICS AS AN EXPLANATION FOR ERRORS IN DRUG CALCULATIONS

Sinikka Huhtala

Department of Teacher Education, University of Helsinki, Finland

Accurate mathematical calculations are a critical skill that nurses must demonstrate in order to safely administer medications. However a review of published research shows that many nursing students are unable to accurately calculate medication dosages because they are deficient in basic mathematical skills: they have deficiencies in decimals, fractions and metric conversion. They also fail to recognize incorrect answers, they have negative attitudes toward mathematics and little confidence in their ability to solve problems. (e.g. Cartwright 1996, Huhtala 1996, Pozehl 1996)

This study explains the errors in drug calculations with student's own mathematics. Data for this study has been collected by tape recording small group instruction of practical nurse students in a mathematics clinic (Case studies).

The student's own mathematics consists of experiences as a learner in mathematics, emotions towards mathematics and strategies and mini-theories which students use while studying mathematics. When a student has very negative experiences and math anxiety, she/he tries to avoid mathematics and chooses superficial strategies while working with mathematical problems instead of trying to understand. These strategies may change to permanent mini-theories like "in division you must always divide the bigger number by the smaller" or that "multiplication always makes bigger and division always makes smaller" or " when you convert grams to milligrams the answer always has four numbers". As a result this own mathematics leads to errors like this:

> Mrs. Malmi (aged 64) is to take 40 IU of Insulin. The strength of Insulin is 100 IU/ml; how much should the patient be taking?
>
> 100 IU/ml : 40 IU = 2,5 ml

The short oral presentation will further describe the student's own mathematics and how this should be taken into consideration in the instruction.

INSTITUTIONAL RELATION TO A MATHEMATICAL CONCEPT: THE CASE OF LIMITS OF FUNCTIONS IN MOZAMBIQUE

Danielle Huillet and Balbina Mutemba
(Eduardo Mondlane University, Maputo, Mozambique)

Changes of settings introduced by the teacher could help the students to understand different aspects of a concept and make their conceptions evolve (Douady, 1986). The concept of limit may be defined and limits determined in a purely analytical setting, but concept may also be illustrated and studied in numerical and graphical settings. Students may learn to work in various settings, but experience indicates that they often see no link between them.

This paper presents the first results of an on-going research which aims to construct a didactical engineering (Artigue, 1992), using changes of settings, in order to improve the teaching and learning of limits of functions in the Mozambican Secondary School.

In the very first place, and using the anthropological approach of Chevallard (1992), the institutional relation of the secondary school to this concept has been analyzed through the contents of curricula, textbooks and final exams. This study suggested that limits of functions are shown as algebraic transformations and procedures that the students have to learn in order to calculate limits. Usually the results of the calculation are not interpreted.
The only book produced in Mozambique on this topic at this level has a very formal approach (formal definitions and demonstrations). However it only requires the students to apply procedures. In the final secondary school exams, there are always two exercises to calculate complicated limits and very few exercises linking limits with graphs. It seems that the secondary school institution has an "algebraic conception" of limits of function as an opportunity of creating algebraic transformations for the learners to apply.

In that moment the relationship of some secondary school's teachers to this concept is being studied through a questionnaire and interviews.

THE PROCESS OF ACCEPTANCE OF THE REALISTIC MATHEMATICS CURRICULUM BY TEACHERS IN HARARE

GODWIN HUNGWE

UNIVERSITY OF ZIMBABWE

The study will investigate the process of acceptance of the realistic mathematics curriculum by secondary school mathematics teachers in Harare, Zimbabwe.

According to the realistic mathematics curriculum students should be guided to re-discover mathematical concepts and skills from contextual situations and from class discussions. Teachers should stimulate pupils to find their own solutions instead of teaching by demonstration (Freudenthal, 1973; Gravemeijer, 1994; van Galen & Feijs, 1991). Research in The Netherlands showed that initially teachers followed the realistic mathematics curriculum mechanically but after familiarisation, they implemented it more flexibly (Gravemeijer, 1994).

The current mathematics curricula in Zimbabwe were investigated for evidence of the presence of the realistic mathematics curriculum. A sample of mathematics teachers in Harare, will complete questionnaires, be interviewed and observed while teaching. Only the teachers who are unaware of the realistic mathematics curriculum will be in-serviced in the processes of this curriculum and be observed while teaching. They then will complete questionnaires and be interviewed again.

Documentary evidence revealed that the current mathematics curricula in Zimbabwe do not promote the realistic mathematics curriculum. The pre-treatment questionnaires and interviews will hopefully reveal the teachers' current beliefs and practice in mathematics instruction, while on the other hand the post-treatment ones may reveal acceptance or non-acceptance of the curriculum by the teachers.

The Effects of the Exposure to the "Math is Next" Database on Teachers' Methods in Teaching Mathematics to Young Children

Bat-Sheva Ilany, Ilana Binyamin Paul, Miriam Ben Yehuda, Rina Gafny, Nehama Horin
Beit Berl College, Israel

"Math Is Next" is a computerized database intended to help the teacher to construct a work program for developing mathematical thinking in young children. The database assists the teacher in planning the work and in constructing a rich, experiential and authentic mathematical learning environment, that combines creativity and use of language and is appropriate for the individual needs of every learner. At the foundation of the database is a matrix that lists the academic skills, on one axis (mathematical concepts and development of thinking skills), and the cognitive processes through which we transmit information (processing of visual, audio and sensomotor information and memory), on the other axis. These information processing options play an important role in everyday life and in acquiring the foundations of academic skills, reading and arithmetic. Junctions of coordinates form "cells" and we inserted the appropriate activities in each cell. Attached to the activity card there are, frequently, related cards with additional suggestions and games for similar materials that can be prepared for the children.

The program was tested in 21 kindergartens and lower elementary school grades. The study findings indicate improvement in the teachers' self-confidence and sense of competence to teach mathematics, as well as changes in their methods of working in the kindergarten and classroom. The study method was qualitative, employing the following tools: Semi - structured interviews, Observations, Supervision and reporting. The study findings indicate that following the use of the database, changes took place in two principal areas: A. Changes in the teacher's sense of competence and degree of confidence and readiness to deal with the subject of the development of mathematical thinking in young children. B. Changes in the teacher's teaching methods came along with the developing sense of competence and acquired self-confidence:

The findings show that the "Math Is Next" database is user friendly and easy to operate. The teachers did not view the database as "just another tool", but as a pivotal tool that can assist and can be "relied" upon in constructing the curriculum for young children. Other teachers pointed out the substantial contribution of the database to the teaching of mathematics to young children and the changes that took place in their teaching. According to them, the principal contribution of the database is its structured organization (search table) that enables the teachers to teach mathematics by employing a variety of teaching methods, with which they were unfamiliar prior to encountering the computerized database.

The conclusions of this study are that when teachers are offered a tool that presents content in a well organized and well defined form that fulfills their teachers' needs, they feel greater confidence and competence in dealing with teaching mathematics. As a result, these teachers engage the children in mathematical activities more frequently and are more inclined to attempt a variety of new teaching methods.

DEVELOPING SKILLS OF ADVANCED MATHEMATICAL THINKING

Kahn, P. E., Department of Mathematics, Liverpool Hope University College

It is becoming apparent that many students studying mathematics in higher education do not possess the necessary skills of advanced mathematical thinking, especially in the UK [1]. This paper describes an action research project that sought to help 40 first year undergraduates at the author's institution develop a variety these skills, going beyond a focus on one skill.

The project initially identified several skills as critical to the study of advanced mathematics. These were the ability to write mathematical text, think logically, solve problems, improve own learning of mathematics, and make connections between concepts [2]. A metacognitive approach to skill acquisition was followed, in which the aim was to direct students towards active and deep, rather than surface, approaches to learning. The students were alternatively introduced to content from abstract algebra and to the skills themselves, with learning in each of these areas reinforcing learning in the other area.

A variety of methods were employed to consider the effectiveness of the innovation. Student evaluation schedules and examination results indicated that the innovation was positively received and led to good outcomes. Coursework and the teaching experience indicated that the skills were unfamiliar. They further indicated that too many elements of the first skill, writing mathematical text, had been covered in the time available. Work on developing the remaining skills was thus scaled down, with outcomes on coursework improving. The need for an appropriate balance of familiar and unfamiliar material was also apparent. A standard instrument [3] indicated increases in students' confidence for their study and that motivation had remained good. Qualitative questionnaires further linked increases in confidence to good outcomes and suggested this had been aided by the integrated nature of the work on skills and content. Responses also indicated a shift towards more cohesive views of mathematics, which is of importance to deep learning. Promoting skills as relevant to every area of mathematics may have helped lead to this shift. Responses finally indicated that some students had begun to take greater account of the nature of mathematics in their learning.

The project indicates that a need exists to help students develop the skills of advanced mathematical thinking and provides a variety of lessons for programmes that make dedicated teaching and learning available to meet this need. Finally, it is interesting to note that such programmes may wish to consider ways in which these skills can be applied in a wider context than just the study of mathematics.

COMMUNICATIVE INTERACTIVE PROCESSES IN PRIMARY VERSUS SECONDARY MATHEMATICS CLASSROOM

M. Kaldrimidou[1], H. Sakonidis[2], M. Tzekaki[3]
[1]University of Ioannina, [2]Democritus University of Thrace, [3]Aristotle University of Thessaloniki, Greece

A number of studies have put emphasis on the importance of the interactive patterns of teaching and learning in the acquisition and the development of mathematical knowledge. An essential aspect of this view is that the way the teacher defines the frame of mathematical knowledge, poses questions, refuses and reinforces students' answers and propositions provides decisive orientation for the children with regard to what the legitimate conceptions of mathematical knowledge are.

However, as many researchers argue, there should not be a total shift of analytical attention from subject matter-structure to social-interactional structure because there is then «a risk of destroying theoretical mathematical meaning by a reduction and an hypostasis of mathematical relations instead of inducing an enrichment of meaning by the interactive construction of new and more general relations» (Steinbring, 1998).

An analysis of the interaction in the mathematics classroom that takes into serious consideration the epistemological as well as the social-interactional conditions helps to provide a better understanding of how the communicative patterns and routines emerge and «makes it possible to re-establish a sound interactive mathematical reasoning that has been destroyed by these communicative patterns and routines» (Steinbring, 1997).

The results of an earlier study (Ikonomou, Kaldrimidou, Sakonidis and Tzekaki, 1998) showed that the teaching approach adopted by Greek primary teachers, possibly because of their poor mathematical pre-service training, does not often allow pupils to conceive the epistemological features of mathematics. In the present study, a comparison between primary and secondary mathematics lessons is carried out with respect to the following questions: What kind of ideas and meanings regarding mathematical knowledge are constituted during the course of the mathematics teaching? How do the communicative patterns and the epistemological constraints of the mathematical knowledge influence each other? What hinders or favours the development of mathematical meaning during the course of classroom interaction?

Diagnose and Treat –Pupils with mathematics difficulties in middle schools

YOUSEF KHOURY & NASIF FRANCIS - Wiezmann Insititute

Arab pupils in middle schools in Israel learn mathematics according to the Rehovot program. The textbooks and the supplementary material of the program have been created and implemented by the mathematics group at the science teaching department of Weizmann Institute of Rehovot. Among this group there is a special team whose members are Arab educators, their work is devoted to the translation of the textbooks and the supplementary material in the Arab junior high school. The present project is one of the special and important activities of the Arab team of the mathematics group. The clear objective of the project is to identify the specific difficulties that face the low capacity student in regular classes as well as in classes of lowest level where from the beginning the material was written for these pupils, and trying to create remedial materials.

This project is distinguished by:

- The approach that adopt from the beginning is the implementation of the research to create the materials.
- The involvement of the teachers in diagnostic stage of the process and his commitment to implement the remedial material.
- The originality and the accordance for needs of the Arab pupils and teachers.
- The development of the tools and the suggestions for treatment in the project are done on the basic of academic research. Those tools contain a lot of attractive worksheets, games and computer activities.

The project process:

First stage: numbers and number problems: (From the elementary school curriculum)

Second stage: algebraic expressions (early algebra learning)

Third stage: algebraic expressions (in process)

Diagnose and treat algebraic expressions

The importance of the subject for studying mathematics in later grades of the high school, and Algebra "is a source of considerable confusion and negative attitude among pupils"[1], motivated us to diagnose the difficulties faced by Arab pupils concerning this topic and to find how to treat them

The diagnosis

We choose to check three topics:

1) Substitution in different algebraic expressions;

2) Operations on algebraic expressions in order to get similar expressions;

3) Translation of problems in mathematical language;

Findings:

We find most difficulties in distributive law and its applications to get similar expressions, and translation of word problems with two variables.

The following topics were found difficult for part of the pupils

* Substitution of big numbers in expressions,
* Number substitution in expressions with multiplication or subtraction.
* Negative number substitution in expression with subtraction and multiplication.
* Similar expression especially applying the distributive law
* Associatively and distributive laws and the application in expressions with multiplication with the variables out of the parentheses.
* Translation of problems in mathematical language.

The project has been implemented in some of the Arab middle schools in Israel and the results were satisfied. This was obtained from the assessment that was carried out at the end in classes and replies of the pupils, teachers, directors and parents.

RELATIONSHIP BETWEEN PCK AND LESSON PLANS: DOES IMPROVEMENT IN TEACHERS' PCK EFFECT THEIR LESSON PLANS?

Ronith Klein and Dina Tirosh

Kibbutzim College of Education, Tel Aviv

School of Education, Tel Aviv University, Tel Aviv

Recent journals and PME papers discussed the importance of teachers' familiarity with students' ways of thinking (e.g. Even & Tirosh, 1995; Jaworski, 1998). Studies have shown that participation in programs focusing on children's thinking could increase teachers' awareness of students' incorrect responses and their possible sources (e.g., klein, Barkai, Tirosh and Tsamir, 1998). Several programs (CGI, for example) explore the impact of teachers' knowledge of students' thinking on actual teaching practices. The main aim of this study was to explore the effect of a workshop specifically designed for enhancing inservice teachers' knowledge of students' ways of thinking about rational numbers on lesson plans on Multiplication and Division word problems with Rational Numbers (MDRN).

Fourteen experienced elementary teachers participated in the course. Participants were asked to plan a teaching unit on MDRN, at the beginning and again at the end of the workshop. Our main aim was to explore the extent to which the participants took account of students' ways of thinking in this planning.

We hypothesized that teachers would adjust their lesson plans, taking account of common, systematic students' conceptions and misconceptions when planning instruction. Our data did not fully confirm this assumption. Still, in the lesson plans submitted at the beginning of the course, only few written references were made to possible, common incorrect students' responses whereas at the end of the course some building on students' common incorrect responses occurred .

During our presentation we shall describe the course and raise some alternative explanations as to why more substantial improvements in teachers' lesson plans were not found.

Mistaken conjectures as a trigger to develop basic probabilistic reasoning

Lilya Kot, Sara Kiro, Abraham Arcavi
Department of Science Teaching
Weizmann Institute of Science - Israel

In a comprehensive review of the research on understanding and learning probability and statistics, Shaughnessy (1992, p. 465) claims that most people's intuitive and immediate responses to probability problems make no use of elementary concepts to estimate the likelihood of events and thus produce wrong answers. Moreover, he points out that "non-mathematical ways of estimating likelihoods" can be deep rooted and good teaching may not always change them. Nevertheless, we propose that an appropriate learning trajectory with the characteristics described below may be successful with non-academically oriented high school students.

The learning trajectory proposed: a) presents engaging situations close to students' experiences, b) relies on students' common sense, c) respects all conjectures, d) supports and encourages the use of visual representations to make sense of situations, and e) promotes the discussion of opposing conjectures which can be empirically tested and analyzed.

The following is an example of a series of problems used in our curriculum project (Arcavi, Hadas and Dreyfus, 1994). "Efrat and Donna play the 'fingers' game: each of them shows simultaneously a number of fingers on their right hand. If the sum of what both show is even, Efrat wins, if it is odd, Donna wins. If you think the game is fair, explain, if not, who has greater chances to win, and why?"

This is a common game, well known to the students. A great majority of them do not hesitate, and without further analysis, claim that the game is fair, possibly because of its popularity. Students are encouraged to build a table representation to display all possible situations, in the light of which they realize that the game is slightly unfair. After a series of such problems, students learn to develop the habit of checking their initial conjectures against a visual representation of the space of all possibilities.

In the short oral presentation, we will show data from pairs of students solving a series of problems (similar to the above) in which they face opposing conjectures to check. Some pairs had previous instruction in probability and others had not, but all of them raised initial conjectures which were wrong. We will show how they slowly changed their conjectures by using table representations to make sense of the problem, and how they started to develop a different approach towards similar problems.

RESEARCH ON THE VALIDITY OF "TWO-AXES PROCESS MODEL" OF UNDERSTANDING MATHEMATICS

Masataka Koyama
Hiroshima University, Japan

The problem of understanding mathematics has been a main issue buckled down by some researchers in PME. Koyama (1992) discussed basic components that are substantially common to the process models and presented the so-called "two-axes process model" of understanding mathematics as a useful and effective framework for mathematics teachers. The model consists of two axes, i.e. the vertical axis implying levels of understanding such as mathematical entities, relations of them, and general relations, and the horizontal axis implying three learning stages of intuitive, reflective, and analytic at each level. There are two prominent characteristics in the "two-axes process model". First, it might be noted that the model reflects upon the complementarity of intuition and logical thinking, and that the role of reflective thinking in understanding mathematics is explicitly set up in the model. Second, the model could be a useful and effective one because it has both descriptive and prescriptive characteristics.

It is a significant task for us to examine both validity and effectiveness of the model in terms of practices of the teaching and learning of mathematics. Focussing on the validity of "two-axes process model" of understanding mathematics, Koyama (1996) demonstrated the validity of three stages at a certain level of understanding mathematics by analyzing a fifth grade elementary school mathematics class in Japan. The purpose of this research is to closely examine the validity by analyzing data collected in three different mathematics teachers' classrooms at the national elementary school attached to Hiroshima University.

As a result of this research, we find out the followings. First, the "two-axes process model" of understanding mathematics is valid in such a sense that it could describe children's development of understanding mathematics in their classroom. Second, we could characterize such a teaching and learning of mathematics as the dialectic process of children's individual and social constructions that enables them to understand mathematics deeply and in their meaningful way. In order to realize such mathematics classroom, it is suggested that a teacher should make a teaching and learning plan in the light of "two-axes process model" of understanding mathematics and that she/he should play a role as a facilitator for the dialectic process. There are two important features of teacher's role: The one, related to children's individual construction, is to set a problematic situation in which they are able to be conscious of their own learning tasks and encourage them to have various mathematical ideas and ways. The other, related to children's social construction, is to encourage and allow them to make, explain, and discuss their various representations.

INTERACTION BETWEEN KNOWLEDGE AND CONTEXTS ON ABILITY TO SOLVE PROBLEMS: THE ROLE OF DIFFERENT LEARNING CONDITIONS

Bracha Kramarski

The Institute for the Advancement of Social Integration
School of Education, Bar-Ilan University

How do children solve mathematical problems, which are the same in mathematical content, but different in the contexts presented in them? Are mathematical problems, which embedded in concrete contexts easier to solve than those, which appear in abstract contexts? To what extent do contexts exert different effects on children's understanding of abstract mathematical concepts? How do different learning conditions influence the development of the ability to solve problems presented in different contexts?

The current research relates to these issues and focuses on problems which deal with the linear function graph. 384 students participated in the study. Boys and girls from the eighth grade who were studying the subject: "the linear function graph" under different learning conditions: cooperative learning with metacognitive training, the whole class with metacognitive training, cooperative learning and the whole class without metacognitive training. The metacognitive training is based on a model of self-addressed questions: comprehension questions, strategic questions, and connection questions. (Mevarech & Kramarski, 1997; Schoenfeld, 1985). All the students were tested both at the beginning of the experiment and afterwards with problems presented in concrete and abstract contexts, which tested skills of graph reading and graph drawing (transfer). It was found that students who were exposed to metacognitive training whether in cooperative learning or in whole class improved by the end of the experiment the ability to read and draw graphs (transfer) as opposed to the students who were not exposed to this training. The greatest improvement was found among the students who were exposed to this training in cooperative learning. Similarly, the students exposed to metacognitive training revealed an equal ability in solving problems presented in different contexts: concrete/abstract, as against students who were not exposed to metacognitive training, who showed a greater ability to solve problems presented in concrete contexts. The findings are discussed from a theoretical and practical aspect.

CONSTRUCTIONS OF NEW MATHEMATICAL KNOWLEDGE IN DIFFERENT LEARNING ENVIRONMENTS

Christian Kratzin

Institut für Entwicklung & Erforschung des Mathematikunterrichts, Universität Dortmund, Germany

In this paper I would like to report some findings and results of our ongoing research-project "Epistemological and social-interactive constraints for the construction of new mathematical knowledge (in primary mathematics teaching)"[1].

During autumn 1997 we observed and video taped about 30 mathematics lessons in grades 3-4 of primary school. In this lessons the teachers used two different kinds of learning environments, which beforehand were developed by our research-team. One typ of learning environment can be characterized as arithmetic-structural and the other one as geometric-visual.

The epistemological and interpretative analysis of the interactions in some selected transcribed teaching episodes from the two kinds of learning environments shows, that the constraints and the chances for the children to develop generalized arguments (which are necessary and undispensable for the construction of new mathematical knowledge) are depending on some special features of the respective learning environment.

When preparing the learning environments we assumed that it would be easier for the children to develop the view for the generalities within the scope of a geometric-visual reference context, because there one can construct relations and connections not only on an arithmetical level but also on a geometrical one. Our observations and analyses have set us right: In a geometric-visual learning environment the children mainly produce concret interpretations and construction that are merely related to individual cases; whereas in an arithmetic-structural context the children more often reach the point where they are able to see the general in the particular.

In a geometric-visual context it is much more difficult for the children to get a certain distance from the concrete (geometrical) objects, that sometimes even can be touched by the children (for instance in forms of the counters used to build up movable dott patterns) and which perhaps chain the view too strongly to the particularities.

MATHEMATICS ASSESSMENT IN A NEW CURRICULUM MODEL IN SOUTH AFRICA

Daniel Krupanandan, Springfield College Of Education South Africa.

South Africa has seen the introduction of " Curriculum 2005 " or commonly known as " Outcomes Based Education(OBE) " , a new vision of curriculum transformation in our country since 1998. This renaissance in the teaching and learning of mathematics has been initiated through readings of many policy documents and attendance of many curriculum workshops.

Despite the stirling efforts of the education departments, the speed and urgency with which the training and informing process has taken place has left many committed mathematics teachers lagging on the road to the successful introduction of " Curriculum 2005 ".

This paper will provide the results of a research conducted amongst 400 primary mathematics teachers, who completed a questionnaire based on their understandings of the new curriculum model, with particular reference to their views on mathematics assessment in the OBE model. 40 primary mathematics teachers were also interviewed.

Since assessment in mathematics is a central component to any curriculum model, it was not encouraging to find that almost 97% of the teachers involved in the research had conflicting views about assessment in mathematics or they were implementing assessment strategies that were not entirely consistent with an OBE curriculum model. Mogens Niss(1998) comments that this is an international phenomenon," During the last couple of decades, the field of mathematics education has developed considerably in the area of ideals and goals, and the theory and practice, whereas assessment concepts and practices have not developed so much ".

The results of the research has challenged teacher educators to undertake intense in-servive programs to assist primary mathematics teachers make the paradigm shifts in implementing assessment strategies that measure not only knowledge, but attitudes and values as well.

THE LANGUAGE OF MATHEMATICS AS THE OBJECT FOR SPECIAL STUDY

Raissa Lozinskaia, Tomsk Polytechnical University, Russia

Mathematics is a definite world outlook. "Mathematics is of great interest in itself, first of all as the totality of objective truths. Besides, mathematics gives convenient and fruitful ways of describing various phenomena of real world and in this sense really performs the function of a language (Kudrjavtsev, 1980).

One of the aims of "MPI-project" (the leader — Prof. E. Gelfman) is working out the system of methods and ways of successful acquisition of mathematics language. Our basic task was to compare psychological - pedagogic fundamentals of mathematics education as well as of a foreign language.

L.S. Vigotsky (Vigotsky, 1982) pointed out that the main role in concept formation is played by "a functional usage of a word" as a means of advancement of characteristics of an object, their synthesis and generalization. That's why our system of exercises includes such tasks as to teach students work with different values of one and the same sign, to be able to single out essential, general and particular for the solution of a concrete problem. It was pointed out that students fail in mathematics very often due to mistakes in translating mathematical expressions into natural language (Bell & Malone, 1992; Ferrari, 1996). We have worked out special tasks, which form the skills of performing verbal-figurative translation, teach students to draw schemes, to pass over from real situations to mathematical models.

Mathematics language, like natural language is metaphorical (Sfard, 1996). We look for metaphors of mathematics language. Perfect acquisition of any foreign as well as of mathematics language is a long process and presupposes operating units of both the languages without translation. That's why we specially initiate situations where students work within the frames of some conventional agreement of mathematics language, when students themselves have to construct the system of this language. Teaching mathematics language should include study of semantics (values of signs, symbols, concepts) as well as of syntax (rules according to which signs are united in sentences or formulas); that's why a student should understand how a new notion or a symbol is connected with a system of concepts, i.e. it is necessary to establish the system of different links between notions, including genetic one.

AVERAGE, TEACHERS AND STUDENTS

Zvia Markovits
Oranim School of Education, Israel

Mathematics-Classroom–Situation (MCS) Cases are real or hypothetical classroom situations involving mathematics, in which the teacher has to respond to a student's question or idea. Previous research studies (e.g. Even and Markovits, 1997) indicate the potential of MCS-Cases in raising mathematical as well as pedagogical issues.

The Average Situation deals with the dilemma of accepting an answer which seems to be unreasonable in everyday life situations as an answer to a mathematical problem.

The Average Situation:

> "A student was given the following problem:
> *At Narkisim School there are 3 fifth grade classes. In the first class there are 31 students, in the second 24 students and in the third 28 students. Find the average number of students in the fifth grade classes. The student answered: There is no average here. You* [teacher] *told us that there is not such an answer 27 2/3 students."*
> How would you respond?

The situation was given to about 60 teachers who teach mathematics in the upper grades of elementary school. Most of the teachers agreed that there is an average in this situation, but many of them suggested that the average should be 27 or 28, since the answer is people. Many of fifth and sixth graders, given this problem, were able to correctly use the averaging algorithm, but unable to accept 27 2/3 as the answer to the given problem. It seems that students and teachers developed an uncompleted understanding of the average concept.

It is interesting to point out that while many research studies suggest that students do not use "out of school" experience when dealing with mathematics problems in school, in this case they did apply everyday life considerations.

PROBLEMS OF CONCEPTUAL CHANGE ON THE ENLARGEMENTS OF THE NUMBER CONCEPT

Kaarina Merenluoto, Department of Education, University of Turku, Finland

Erno Lehtinen, Department of Teacher Education, University of Turku, Finland

The cognitive processes of concept acquisition do not follow the logical hierarchy of mathematics (Tall 1991) of a typical curriculum. The structure of mathematics may appear fragmentary and discontinuous for the student The crucial idea in conceptual change is the radical reconstruction of prior knowledge. This complicated process leads however often systematically to misconceptions because the prior knowledge may not be transformable into the new subject matter (Vosniadou 1994).

The dual nature of mathematical concepts (Sfard 1991), the long development period between the operational use and structural definition of the concept (Boyer 1959), the high level of abstraction of advanced mathematics and the low nature of abstraction in the every day mathematics all seem to refer to the problems of conceptual change in the learning of mathematics.

We collected an extensive data from students (n=640) in high school calculus courses. The results showed that the vast majority continued to use the logic of natural numbers in tasks on the domain of rational and real numbers and their concept of more advanced numbers was confused. These findings suggest important considerations for planning conceptual change supporting learning environments.

TUTORIAL INTERACTIONS AND DIDACTICS OF MATHEMATICS : RECOGNITION OF FRACTIONS IN PRIMARY SCHOOL AND VOCATIONAL EDUCATION

Maryvonne MERRI, Assistant Professor of learning psychology
Ecole Nationale de Formation Agronomique, Toulouse (France)
Research Team "Cognition and didactics", University of Paris VIII
Marie-Paule Vannier
Institut Universitaire de Formation des Maîtres de Melun (France)
(Dissertation director : Gérard Vergnaud)

When working as a mathematics teacher trainer, every cognitive psychologist has to face a recurring epistemological problem : initially, the most important psychology concepts did not refer to didactical situations. This short oral communication intends to discuss the pertinence of Piaget's and Vergnaud's concepts of *schème* in describing tutorial interactions in student problem-solving activity.

The same fraction recognition task was proposed to primary school teachers (for 10 year-olds) and to vocational school mathematics teachers (for 15 year-olds). Every teacher could adjust this task to his own particular teaching methods. Tutoring sessions are defined as interaction periods for problem-solving achievement. They are analysed and then related to the larger didactical process.

A few videotaped examples will illustrate one of the most important characteristics of action on problem-solving *schèmes* in didactical contexts : tutorial interactions must therefore achieve much more than simple completion of the task.

When interacting, teachers and students do not just consider problem-solving as a "private" cognitive activity. They can (explicitly or implicitly) refer individual knowledge to mathematical norms inside and outside the classroom. How can tutorial interactions improve students *schème* and prepare them to share this skill with the community ? The authors will analyse the theoretical consequences of these two dialectics (private vs public and individual vs collective knowledge) on Gérard Vergnaud's concept of *schème*.

ON DEVELOPING TRIDIMENSIONAL SPACE AT SCHOOL*

A.L. Mesquita (U. de Lille/IUFMNPdC)

Geometry appears nowadays as "one of the most universal and useful tools in all parts of mathematics" (J. Dieudonné, 1981, quoted by C. Mammana & V. Villani, ICMI Discussion Document, 1998). However, there is "a gap between the increasing importance of geometry [...], as well in research and in society, and the decline of its role in school curricula" (*op. cit.*, p.338). It is the case in France, where school programs give a reduced place to geometry. The aim of the project we are developing at present has as a central aim the valorization of geometry and space at school. It is a longitudinal case-study, in course of implementation in a primary school of the northern of France, since 1997/98, and it concerns the two groups of pupils (i.e., about fifty pupils) during their school attendance. The main assumptioms of the project are:

1) The first step to introduction of geometry at school concerns the space: for us, the beginning of geometry at school is centered on tridimensional space, and this in articulation with geography, the other subject-matter concerning the study of space at school.

2) A didactical progression is clearly assumed and developed along all the school-attendance: from space to plane; from plane to line; from line to point. Interactions between these entities are strongly stimulated; in particular, transitions between them are considered decisive steps in the learning of geometry .

3) A special attention is given to the different registers of representation (in the sense of R. Duval, 1995, i.e., the semiotic systems of presentation of knowledge) used in geometry, and to their articulation.

In the beginning of school-attendance (ages 6 to 8), our attention is centered on tridimensional space and on the transition from space to the plane. Activities of problematization appears to be decisive to this transition, in general neglected by teaching (A.L.Mesquita *et al.*, 1998). These activities are associated with the construction of objects and other activities of material manipulation, which are privileged, at this phase. The presentation will enable a discussion about the main assumptions of this study, as well as some initial results concerning its implementation.

COOPERATIVE GROUPWORK A VEHICLE FOR DEMOCRACY IN BLACK SOUTH AFRICAN MATHEMATICS CLASSROOMS?

Duduzile Mkhize, RADMASTE, Witwatersrand University, SA.

The behaviour and attitudes of learners in mathematics classrooms is by and large determined by the way the teacher interacts with them. On the other hand teachers are driven by the curriculum to act the way they do. The new curriculum , Curriculum 2005 (C005) that was launched in 1997 in South Africa has to change mathematics classroom practices, especially in black schools. The EduSource Survey (1996) revealed that authoritarian approaches were prevalent in the teaching of mathematics in South African black schools. Hindle(1997) contends teachers in the past were turned into factory workers, thus uncritical compliance was expected from them. This was all in line with the non-democratic curriculum of the day! C005 is viewed as a curriculum that should promote democracy in mathematics classrooms and cooperative groupwork could be an ideal vehicle for this.

C005's view of mathematics, "It is a human activity that deals with patterns, problem-solving, logical thinking, etc. in an attempt to understand the world and make use of that understanding. This understanding is expressed, developed and contested through language, symbols and social interaction", implies the need to create social interaction to express and debate the understanding in the classroom.

This study aimed to improve cooperative groupwork practices in mathematics classrooms. Learners were encouraged to develop rules for working in groups. Linear programming lessons in a cooperative groupwork mode were prepared and conducted with grade 11 learners. Each session took two hours. After five sessions learners were asked to complete the self assessment forms. The rules and self assessment comments are summarised below.
Rules: "No parasites, give others a chance to talk, respect other members' opinion, we help each other, listen and pay attention to one another, patience."
What went well: "Everyone came with an idea, everyone was thinking, we understood very well most of the things we did, at last we gained something from a maths lesson and I enjoyed the lessons."

The rules indicate what learners value in cooperative groupwork. Clearly, the inculcation of the democratic principles such as listening to one another, a chance for all to give their opinions is inculcated through cooperative groupwork.

TEACHING MATH WITH TECHNOLOGIES: A NATIONAL PROJECT IN MEXICO

Simon Mochon and Teresa Rojano

Center for Research and Advanced Studies, IPN, Mexico

Since 1997, the Ministry of Education of Mexico has being sponsoring a national program to teach mathematics with technologies at the secondary level. The tools used in the classroom are a combination of calculators (TI-92) and computer 'open' software: "Spreadsheets" (all purposes), "Stella" (Modeling package), "MathWorlds" (Mathematics of Change package) and "Cabri" (Dynamical Geometry package). Parallel to this program, there is an ongoing research project that has as its main purpose to investigate the impact of this technological implementation in students' learning, teaching practices and curricular transformation.

The Mexican Math Curriculum calls for a close connection with real life situations. The actual practice however is far from this. In addition, topics are introduced from general principles down to particular examples. This new educational program stresses the opposite, bottom to top approach. Another important element is collaborative learning. The interaction student-computer and student-student are being studied within the framework of Vygotsky's perspective on mediational means and the zone of proximal development. Cultural influences are also being considered.

Within the classroom, we have used very effectively a teaching strategy that in part consists of coupling a math modeling approach with worksheet guidance. A recent antecedent of this method is a collaborative Mexico/UK research project (Sutherland et al, 1996) aimed at investigating the role of modeling with spreadsheets across a range of subject areas (physics, chemistry, and biology). In this research, the spreadsheet was introduced into the students' science classrooms to construct models, "artificial worlds" (Mellar et al, 1994), that were explored and analyzed and which enhanced students' understanding of the scientific ideas related to the model.

This presentation will concentrate on two aspects of the project: the phase of teachers' training and the design, implementation and evaluation of activities for the classroom. The teachers received seminars on 1) the use of the software (each teacher learned and used only one software package), 2) the methodology related to teaching with computers and 3) how to structure the activities. We found that teachers still followed a traditional model to design the activities but have a substantial advance on their role in the classroom. We will also describe briefly some preliminary results on the students' cognitive and affective development. This data was obtained from classroom observations and tests throughout the school year (the tests contain questions about the most relevant concepts introduced by the software packages).

MODELS OF MATHEMATICS UNDERSTANDING

Judith A. Mousley

Deakin University

The problem

Meanings that teachers, teacher educators and curriculum documents hold for the term *mathematical understanding* shape curriculum planning, teaching, and assessment in schools and in teacher education. However, these are rarely articulated.

Some models from the literature

_structural progression (e.g. Piaget; Sinclair; von Glasersfeld)
_zones of achieved and potential (e.g. Vygotsky)
_different forms of knowledge (e.g. Maslow; Skemp; Gray & Tall)
_levels of understanding (Herscovics & Bergeron)
_lattice: acts interwoven with situations (Sierpinski)
_recursive process of organising knowledge structures (Pirie & Kieren)
_socio-linguistic activity (Wittgenstein)

Results from a (pilot) survey of mathematics educators

Ideas that best matched the respondents':

_a shift from "unable to explain" to "able to explain"
_grasping meaning
_a mental organisation or structuring of experience
_moving from one zone of knowledge to another
_appreciation of what lies beneath a statement (or solution, etc.)

Physical models that best suited their ideas:

_a three-dimensional web	_a lattice or woven fabric
_a tree	_a spiral

Different types of mathematical understanding most commonly mentioned:

_instrumental relational (4 people)	_iconic symbolic relational factual conceptual analytical	_visual/spatial logical numerical inter-relation al	_rote concrete conceptual abstract	_instrumental relational logical symbolic

As well as outlining the key characteristics of the results of this pilot study and their relationships to the literature, the presentation will identify some of the methodological problems experienced when analysing responses to forced-choice items on the questionnaire.

MULTI-WORLD PARADIGM IN MATHEMATICAL LEARNING

Tadao NAKAHARA
Hiroshima University JAPAN

Lately, the mathematical education is under significant influence of three perspectives including radical constructivism, social interactionism, and social culturism, and a lot of studies are being conducted on the mathematical education based on each of such paradigms or combinations thereof. Table 1 shows comparisons among such thoughts from different view points.

View point	Radical const.	Social interactionism	Social culturism
Nature of cognition	Construction by individuals	Construction by community	Enculturation
View of language	Means of thought expression	Containing a process of interpretation	Medium of cultural transmission
View of learning	Cognitive self-organization	Social interactions	Participation to cultural practices

The above comparisons reveal a common aspect among three perspectives: all of three perspectives view that children's activities play very important roles in mathematical learning, and they position social interaction as an important means in learning. However, on the other hand, they have distinct differences in any of the views of cognition, language, and learning. In particular, difference in the view of the nature of cognition is a matter of principle that is mutually incompatible, and the integration of those perspectives is considered theoretically impossible.

However, in the observations and analyses of children's practical activities in mathematical learning, the three perspectives are frequently seen at the same class. While those three perspectives are mutually conflicting theoretically, it is considered unavoidable to integrate and coordinate the three perspectives in order to explain the realities of learning in fair manner. The studies of mathematics learning by Cobb and Bauersfeld should be considered as have been suggested based on such standpoint.

The author calls the above-shown view the multi-world paradigm in mathematical learning. It contains the three worlds of the radical constructivism, social interactionism, and social culturism. He shows theoretical as well as practical study of mathematical learning based on the multi-world paradigm.

HELPING TO DEVELOP THE ABILITY OF ARGUMENTATION IN MATHEMATICS[1]

L. Nasser and L. Tinoco
IM – UFRJ- Brazil

This research was motivated by the project carried out by C. Hoyles (1997) in the U K , in which students are led to evaluate and write proofs to basic mathematics statements, in Algebra and Geometry, under the light of the British National Curriculum. The functions of proof and its role in the teaching of mathematics have been the focus of several papers (Hanna, 1990; de Villiers, 1991; Hanna & Jahnke, 1996). Concerning the functions of poof, we agree that:

> *In the educational domain it is natural to view proof first and foremost as explanation, and in consequence to value those proofs which best help to explain.(Hanna & Jahnke, 1996, p.903)*

The kinds of argumentation and the analysis of the difficulties considered in this work are based on Balacheff (1987), Rezende & Nasser (1994) and van Hiele (1986). The main aims are to.
- identify some kinds of argumentation used by secondary mathematics students in Rio de Janeiro;
- develop and test activities to promote the progress in their levels of argumentation;
- suggest trends to the enhancement of the levels of argumentation of students, as well as of prospective and in-service mathematics teachers.

After the first trials with 14-16 year old students, it became clear that the majority of the Brazilian mathematics teachers do not require their students to justify their answers, mainly because this was not stressed in the curriculum (it appears in the new curriculum proposed). As a consequence, students show difficulties in justifying a statement or in explaining how they reason when solving a problem. Several strategies to improve these abilities have been tried by the teachers and undergraduate students involved in our project, such as:
- after answering a task individually and listening to the teacher's explanation, students work in groups, discussing a joint solution to the same task;
- students have to evaluate justifications given by other students;
- items requiring logical reasoning are often proposed, despite the topic being studied;
- the same task is proposed both to students that have learned or not the correspondent mathematical content, in order to investigate the differences in the kinds of argumentation used;
- students use dynamic geometry softwares to verify the veracity (or not) of a statement and after convinced of its truth (or not), are led to justify or prove it (or to seek for a counter-example);
- activities requiring the recognition of a theorem and its reciprocal have been used with pre-service and in-service teachers.

This research is still in development, but we can already conclude that the lack of experience in self-assessment stresses the difficulties to evaluate someone else's justifications and that the symbolism of the mathematics teaching may be an obstacle for students to write in mathematics. One strategy to improve the students' level of argumentation is requiring justifications to all their answers, and proposing challenging problems requiring logical reasoning. This must be done all the time, all over the year.

A STUDY ON THE FUNCTION OF TRANSACTIONAL WRITING: A FUNCTION MODEL OF SOCIO-MATHEMATICAL SKILL IN MATHEMATICS EDUCATION

Hiroyuki Ninomiya

Hiroshima University Graduate School, Japan

Writing activities in mathematics education has been focused on, and many writing activities have reported, e.g. practices in NCTM's Standards based curricula in America, whereas there are some reports about Mathematical Writing in Japan. Most of the writing activities can be classified into the following three types; Journal writing, Expository writing, and Creative writing. Journal writing is about mathematics classes; Expository writing is about the topics of mathematics with problem solving activities; and Creative writing is literatures with mathematical terms.

Britton et al.(1975) classified the functions of journal writing into the following two types, expressive function and transactional function, and Ninomiya(1998) defined two types of Journal Writing: Expressive writing, and Transactional writing. Expressive writing expresses students' emotional affairs, and Transactional writing refers to the students' understanding or the development of mathematics abilities.

Examining the precede studies, we can find two aspects in Transactional writings; as a method of mathematics learning, and as an aim of mathematics learning. These two aspects are two faces of a coin, and any Transactional writing activities have both of them. Moreover, Transactional writing has two functions. When the aspect as a method is highlighted, writing works in students' interaction as Social Skill. On the other hand, the aspect as an aim is highlighted, writing works as Mathematical Skill when students think and do mathematics. Because of the duality of the aspects in Transactional writing, two functions are related, and a Function Model of Socio-Mathematical Skill in Mathematics Education can be established as Figure 1.

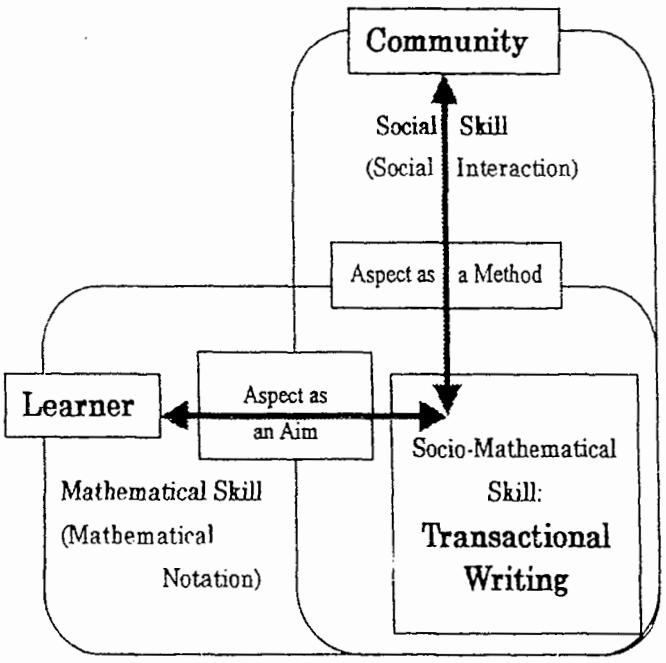

Fig. 1 A Function Model of Socio-Mathematical Skill

Difficulties in calculating the volume of three-dimensional arrays of cubes

Guri A. Nortvedt, Department of Teacher Education and School Development, Faculty of Education, University of Oslo, Norway.

On a national survey of students understanding of measurements and units for grades 6 and 9 in Norwegian schools students were asked to write texts explaining how they solve specific volume problems. These texts have been investigated qualitatively in order to identify patterns in the children's approaches and to seek information about their conceptual understanding of volume. As a result of this investigation several categories for different text stereotypes have been developed in an emergent manner, making it possible to investigate the texts quantitatively as well.

When calculating the number of cubes needed to build a three-dimensional array, the two most common approaches for successful children was to calculate the volume by a formulae alike approach or building the volume in terms of layers (Nortvedt, 1998). Another group of children gave answers like 30, 40, 80, or 96 when asked how many cubes are needed to build the box in fig. 1. (19,2 % of grade 6 students, 16,4 % of grade 9 students).

These students wrote short texts and did not always explain in a sufficient manner their approach to the problem. From the analysis of the texts it seems likely that some of these students did not read the illustration as three-dimensional. From other explanations an emerging possibility is that some students viewed the side of the cube as a representative for the volume of the cube, concluding that when they could count 40 "sides", the number of cubes needed is also 40. Battista and Clement (1996) suggest that many students are unable to numerate the cubes due to lack of ability to co-ordinate separate views of the array and thereby fail in constructing a mental model of the array.

The presentation at the PME-conference will focus on presenting stereotype texts written by students calculating the number of cubes on the surface of the array, and possible consequences for the teaching of this topic will be outlined.

'EVERYDAY' CONTEXTS IN SCHOOL MATHEMATICS

Thabiso Nyabanyaba
University of the Witwatersrand, South Africa

It is now widely accepted among educationists that school mathematics is not an abstract, immutable and monolithic body of knowledge that applies across contexts. To that end, the use of contexts, especially 'real' life contexts, in order to generate school mathematics knowledge has become widely recommended. My study of how teachers understand 'relevance' as it refers to relating school mathematics to the everyday experiences of students adds to the growing debate on the use of contexts in school mathematics (Boaler, 1993). In my study, teachers were asked to discuss, in focus group interviews, how they would make school mathematics more 'relevant' to the students' everyday experiences and what difficulties they anticipated in this practice. Practical scenarios were used in order to provoke discussion. Among the many interesting issues that emerged from this study was the ease with which teachers were distracted by the very contexts or scenarios that were supposed to generate their mathematical discussions.

The new *Curriculum 2005* for South Africa, advocates 'relevant', 'integrated' learning, rather than the memorisation of discrete facts (DoE, 1997). The discussions of the teachers in this study highlight the challenges that teachers are likely to face in the implementation of a 'relevant' curriculum. The study also suggests the prospect of such contexts to produce highly complex understanding.

In this presentation I will use two critical incidents to illustrate the nature of the discussion and what issues emerged around the use of contexts in school mathematics practice. In one of the incidents, teachers were to discuss how they would make the teaching of 'parallel lines' more relevant to the students' everyday experiences. Several very interesting suggestions were made, including the use of electricity power lines to illustrate parallel lines. The discussion centred on precise mathematical terminology and what was proper to do pedagogically. In another scenario teachers were to discuss the usefulness and limitation of using a football log table to assess students' mathematics ability. The discussion centred explicitly on the scenario. The usefulness and limitations were only referred to implicitly.

These scenarios illustrate what can happen in school as students are immersed in contexts, especially contexts that they know about. Therefore, potent as 'real' life contexts are in the teaching of school mathematics, many teachers are going to find it a difficult exercise to draw the students' discussions towards the mathematical experiences and away from the novelty of the 'everyday' experiences.

MATHEMATICAL ACTIVITY IN THE CLASSROOM: GEOMETRIC DYNAMIC ENVIRONMENT AS A WINDOW FOR LEARNING

Gisélia Correia Piteira

Centro Competência Nónio

Faculdade de Ciências da Universidade de Lisboa

The following principles are assumed as a basis for the ongoing research: (1) the mathematics classroom is a system of activity, including all activity in and among its elements' interactions; (2) students don't interact only with the environment but all their action is mediated by artefacts; (3) knowledge is located in the community, being shared by the persons involved through social interaction and mediated by artefacts; (4) mathematical objects make sense within the social interactions, (5) technology is relevant as a window for mediation of knowledge (Kuutti, 1996). It is also accepted that the environment that supports our exploration of geometry influences in different ways the appropriation of concepts and skills. Learning geometry with paper, pencil, ruler and compass is quite different from having access to dynamic software such as *Geometer's Sketchpad* or *Cabri-Géomètre*. Putting away mechanic tasks of construction, measure and calculation, time is used to a dynamic and active work in geometry (Laborde, 1993).

With the support of this assumptions, this communication presents a research project which aim is to study mathematical activity in the classroom, occurring among its elements and mediated by geometric dynamic environments identifying how mathematical meanings emerge from that activity (Voigt, 1994; Wertsch, 1991). Drawing on a qualitative approach my analysis focus on the mathematical activity of an ordinary 9th grade class, working in geometry with Sketchpad. Eight lessons were observed and video-recorded. Students work was saved and copied to be observed and analysed. An overview of the outcomes and results of the preliminary analysis are described and analysed in this paper.

A SOCIAL REPRESENTATION APPROACH TO INVESTIGATE LEARNING

Authors: Monica Rabello de Castro and Janete B. Frant

Affiliation Universidade Santa Úrsula - Instituto de Educação Matemática

Abstract

The purpose of this study is to better understand how students learn mathematics. Specifically, our aim is to investigate and analyze how high school students deal with the idea of function and, how can a teacher tell that a student acquire the function concept. In order to talk about learning, we reviewed the notions of concept and representation in mathematics education. A glimpse on the works of Winner, Herschkowitz, Fischbeim and others lead us to raise the hypothesis that concept acquisition is extremely related to the notion of representation. We argue that an approach from the field of social representation can help us to build a theoretical model to analyze mathematical learning.

This study has been developed in a federal high school in Brazil, students from 9th grade and 11th grade are being observed while working in activities about the concept of function. Some of these activities involve using computer software.

The relationship between concept and representation is found mainly in research findings about different representation for functions using multirepresentational software. The work of Hershcowitz and Schwartz was very relevant. (Herschkowitz and Schwartz 1997, Villareal and Borba 1998). To build a framework for this study we review the literature about concepts, definitions, and representation. (Fainguelernt 1999, Fischbein 1994, Vinner 1994, Varela 1991, Nuñez et all 1997). It is accepted that a concept is different from its definition, being the concept broader. The notion of representation is regarded as a medium between the external world and the internal one. The concept is situated at the thinking level, the representation is regarded as an expression of this concept and it is distinct from the concept. However the nature of concept was not touched. A different perspective come from the works of Vinner, Hershcowitz and Schwartz, they add a component to the concept-relation paradigma that is the concept image. Varela and Nuñez bring different perspectives to this discussion establishing that it is not a pregiven outer world and an internal one. A new model to look for the concept acquisition based on the theory of social representations (Moscovici) and the argumentation strategy theory (Frant and Rabello in press) gave us a strong theoretical support for analyzing data and will be shown.

Partial Findings: Students used linear and quadratic functions as prototypes, confirming Hershcowitz.

The concept of function seems to be part only of the school environment, the students did not give any example about everyday life problems.

Students use strategies of daily life while learning mathematics concepts.

DEFINITIONS FOR THE CONCEPT OF MAXIMUM / MINIMUM OF A FUNCTION

Shakre Rasslan, Oranim School of Education. Israel

Definitions of a relative (local) maximum / minimum of a function in a certain domain were examined in 204 Israeli Arab high school students. A questionnaire was designed to explore some aspects of the concept. One of the research questions aimed to check whether the students knew how to define the concept of a local maximum / minimum of a function. Another question was whether the students knew how to apply the techniques of calculating extremum points for specific functions. A third question examined the misconception that a maximum minimum of a function is the largest / smallest value of the function. The results show that 56% of our sample knew the definition, but the entire picture was not encouraging.

This study examines several aspects of the definitions that junior high school students have regarding maximum / minimum of a function. Concept images and concept definitions have been discussed in detail in several papers (Vinner and Hershkowits, 1980). We will therefore introduce them here very briefly. All mathematical concepts except the primitive ones have formal definitions. Many of these definitions have been introduced to high school or college students at one time or another. The student, on the other hand, does not necessarily use the definition when deciding whether a given mathematical object is an example or a non-example of the concept. In most cases, he or she decides on the basis of a concept image, that is, the set of all the mental pictures associated in his / her mind with the *name* of the concept, together with all the properties characterizing them.

The concepts of the maximum as well as the minimum of a function are central in the chapter about derivative of functions. In many countries, including Israel, the chapter on derivative of functions is taught in the tenth grade. The topic is mentioned time and again in high school courses and elementary college courses (pre-calculus and calculus). In most mathematical textbooks one can find definitions such as the following: *We say that f has a* ***relative*** *(or* ***local) maximum*** *at x_o iff there exists a neighborhood V of x_o such that $f(x) \leq f(x_o)$ for all $x \in V$.* (Kitchen, 1968). The definition of a relative minimum can be obtained simply by reversing the inequality in the above definition.

Sometimes, in order to present a new concept, authors of mathematics textbooks limit themselves first to a "special case" which is supposed to illustrate the rigorous definition. The "special case" in our instance was the *continuous and polynomial functions*. The "special case" approach frequently causes serious difficulties in the formulation and the application of concept definitions (Rasslan and Vinner, 1998).

Taking into account the difficulties mentioned in this study, at least some doubts should be raised whether the "special case" approach to the maximum / minimum concept is the most effective way of teaching such a concept. The pool of examples introduced to the students should include many different examples. Only this may increase the chance that one or two examples will not become a prototype and, as such, also a concept substitute.

Spatial ability and declarative knowledge in a geometry problem solving context

Kristina Reiss

Department of Mathematics, Carl von Ossietzky University Oldenburg, Germany

Research question

Is there a correlation between declarative knowledge about geometrical concepts and spatial ability as it is assessed by standardized tests?

Method

The sample comprised 60 students of grade 7. They took part in individual interviews. In the first part of the interview the students were asked to solve spatial geometry problems (compare Pospeschill & Reiss, 1999, for a description of the tasks presented). In the second part of the interview the students constructed a concept map using concepts related to the problem solving context. Furthermore aspects of spatial ability and general intelligence were assessed using appropriate subtests of the German non-verbal intelligence test PSB (Horn, 1969). The subjects were incidentally assigned to one of two groups. The problems were presented to these groups either in an environment making use of real solids or in a computer environment

Results

The quality of a concept map does not depend on the environment in which the students worked whether it was the computer or the real cube environment ($r_t = .140$; $p = .1149$). The interpretation for this can be twofold. On one hand it may mean that the two groups do not differ essentially in their verbal abilities. On the other hand it may mean that neither the computer environment nor the cube environment induces a certain cognitive style. Analyzing the correlation between the concepts maps and the PSB scores one has to distinguish between the two groups of. Items which present aspects of spatial ability are not indicators for the students' achievement in concept mapping ($r_t = -.009$; $p = .9923$ rsp. $r_t = .094$; $p = .2896$ for the subtests). In contrast, the correlations between concept mapping and general interlligence ($r_t = .217$; $p = .0142$ rsp. $r_t = .212$; $p = .0165$ for these subtests) are siginificant. Thus, general intelligence is a better predictor for good results in concept mapping on geometry concepts than spatial ability.

ON APPLICATION OF ELEMENTS OF COMMUNICATION THEORY IN CLASSROOM PRACTICE

Kaarin Riives, University of Tartu

The process of teaching and learning is one of many communication processes [2,3]. This note refers to a test undertaken to check the effects of certain theoretical considerations and possibilities in practical work with first-year university students..

The **aim** of a teacher is creation of a positive attitude, motivation to study and interest in the material to be handled. The aim of a student is, in general, to gain a pass in the compulsory subject of the chosen university course. The active party in the **alignment** of these **aims,** at last during the initial stage, is the teacher, whose knowledge and experience as well as **emotional intelligence** will determine the success of the joint undertaking. In **classroom**, at the first meeting, I explained my vision of the forthcoming work to all groups, emphasizing the need for sustained independent effort and feedback, from the student's as well as the teacher's poits of view. Aims and the means for their achievement were formulated. It was interesting to observe the process of alignment of aims within the separate groups. The specialized groups showed a greater initial interest in what was presented than the groups who took mathematics as a general subject. The level of previous knowledge was also essentially different. During the course of the study both categories displayed a noticeable increase in appreciation, but for different reasons. The former began to see their subject material in the light of greater generality than previously comprehended while the latter perceived a new ability in a subject that had formerly seemed difficult and uninteresting. Ongoing work as a **contact preserving** phase requires a variety of means to disseminate information. Parallel use was made of analytic-axiomatic treatment and visualization. Essential results were drawn together and tabulated for systematization and revision of the subject. Reception turned out positive beyond expectations in all groups as the material was made intelligible to all students willing to cooperate regardless of **their cognitive and learning style** [4] as well as differences in initial interest and level of knowledge. This became evident through **feedback** already quite early after commencement of work when the first assignments were lodged and discussions took place on the topics dealt with. Informal discussions gave a picture of the student's attitudes towards the subject studied [1]. The **effectiveness** of the joint work can be assessed by how much the results justified the aims. The formal assessment turned out to be positive for all students who were prepared to cooperate. The moral assessment ought not to be overlooked. Our resultative strenuous work gave joy and satisfaction to all participants.

"WRITTEN CONVERSATION FORM" AS PROMOTER OF TEACHERS' CHANGE

Naomi Robinson
Department of Science Teaching
Weizmann Institute of Science

Na'ama Adin
Department of Science Teaching
Weizmann Institute of Science

There is a growing recognition of the importance of the social context in which teaching and learning occurs. It becomes clear that any attempt to dissociate the cognitive from the metacognitive, and social aspects of learning, denies the reality of the learning situation (Clarke, 1987). Journal writing, on a regular basis, in the mathematics classroom, has become a tool for promoting reflection. Researchers indicate that teacher reflection on their teaching has two important results: (1) if reflection on instruction becomes a habit, it improves teaching and (2) reflective teachers will also encourage their students to reflect on learning (Cobb et al, 1997). The present study is part of a project aimed at teaching mathematics classes with a heterogeneous student population. The purpose of the project is to promote the learning of mathematics within groups of students of various mathematical abilities, by basing the learning processes on complex, and open-ended mathematical tasks. In order to work according to this philosophy, teachers must change their views and practice in many aspects. During in-service courses, the "Written Conversation Form" (WCF) was chosen as the tool for teacher reflection. The idea of the WCF was based on Clarke's (1987) report about IMPACT – a program aimed to promote student reflection. The WCF was intended to be a means of communication between each participant teacher and the course's teaching staff. The WCF contains questions about both cognitive and affective issues and also allows for other remarks. At the end of each session, the participants were asked to fill in a WCF and received written feedback during the next meeting. Participants' responses to WCF were collected and were photocopied before returning to the participants. The use of WCF during the course had several results. It strengthened and deepened the teachers' understanding of the course's main ideas. It enhanced teachers' reflection on teaching, on students' learning, and on learning materials. It also raised teachers' awareness to the WCF's potential to provide information about their students, and their own instruction.

IS A COUNTER EXAMPLE ALWAYS ENOUGH TO REFUTE A MATHEMATICAL STATEMENT?

Gila Ron and Orit Zaslavsky

Technion, Haifa

The present study examines students' understanding of the role of counter examples in mathematics. This is another part of a larger study, which was reported in Zaslavsky and Ron (1998). The focus of this presentation was on the validity students attribute to the use of a counter-example in establishing the truth of a mathematical statement.

Two hundred and four students participated in the study. The students were top level 9^{th} and 10^{th} grade students from four different schools.

Two parallel questionnaires were constructed. Both questionnaires describe an imaginary debate between 3 students who try to establish the truth of a false mathematical statement and to justify their conclusion. The first imaginary student claims that the statement is true and justifies his decision by an example. The second imaginary student claims the statement is false and justifies this claim by using a counter example. The third student claims, like the second, that the statement is false, but he criticizes the use of an example for refutation and suggests another way to refute it. The two questionnaires differ in the context. The first deals with a geometric statement, while the second deals with a question taken from a pre-calculus context. The students were requested to provide written responses expressing their opinion about the standpoint of each of the imaginary students.

The analysis of the written responses led to the following findings:

Most of the students did not accept the verification of a statement based on an example as sufficient evidence that a statement is true.

Many students did not accept a counter example as sufficient evidence that a statement is false. The extent to which students were willing to accept a refutation based on a counter-example varied according to the different tasks: About 80% of the students accepted the use of a counter-example to refute a geometric statement, while only 23% of the students accepted it for the pre-calculus context

There were also students whose responses reflected confusion and inconsistency. These students agreed both with the imaginary student who used a counter-example to refute the false statement, and with the student who criticized him for the use of a counter-example.

TEACHERS' VIEWS ON MATHEMATICS, MATHEMATICS TEACHING AND THEIR PRACTICES

Lynn Rossouw & Eddie Smith
University of the Western Cape, South Africa

This research project describes teachers current views on school mathematics and classroom teaching in relation to the new curriculum requirements.

Purposes: We address three main questions: (a) *What views on mathematics and mathematical activity appear to be prevalent among teachers?* (b) *What views of teaching mathematics that would facilitate learning are used in classrooms?* and (c) *What teaching strategies are employed by these teachers in their classroom?* To address and synthesise these questions we constructed a theoretical framework around teacher's views on mathematics and that of teaching, in relation to an Outcomes-Based curriculum, using data from the eight grade 3 teachers'.

Methodology: An ethnographic research design is used (Hammersley & Atkinson, 1995), as its qualitative methods enabled the researchers' sufficient flexibility for describing, interpreting, exploring and explaining the views teachers have of mathematics and their teaching. The research data was gathered through (a) direct observation and (b) indepth interviews. The research analysis draws on the twenty-four classroom observations and sixteen pre- and post-interviews.

Summary Findings: The views on mathematics and teaching held by the teachers can be categorized into three groups: (a) transmission, (b) empirical and (c) connected. They are by no means water tight categories, as there is some overlap in teachers' views however, it helps us to identify the dominant views held by a specific teacher.

The views of the teachers involved in this study about mathematics and mathematical activities are in direct conflict with a pedagogical practice articulated in an Outcomes-based approach, which offers learners opportunities to engage in problem-solving, logical thinking, recognising patterns, and implementing a pedagogy that focuses on conjecture, conceptual exploration and reflective, critical discussion. The predominant views of mathematics and mathematics teaching among the subjects of this study is that, of a system of algorithm transmitted by teachers to be committed to memory by their students.

Through a process of systematic observation of classroom interactions and interview it was possible to identify teaching styles that do not accord with the expectation of the Outcomes-based approach.

TRIANGULAR RELATIONSHIP INSTITUTION-TEACHERS- SECONDARY SCHOOL PUPILS: THE CASE OF INEQUALITIES

(Reseach in Progress)

By Luis Weng San and Ribas Gwambe

Brijlall (1996) contends that the forever burdening task of solving inequalities by senior secondary higher grade pupils is consistently an issue debated by mathematics educators. This contention is also a concern in Mozambique. A significant number of new comers at the Eduardo Mondlane University pursuing Physics majors, Chemistry majors and Engineering seem unable to relate certain mathematical concepts to each other. Particularly, in solving inequalities students seem not to see and explore the connection between algebraic and graphical approaches. Besides, it seems that a lot of students epistemologically consider equations and inequalities the same mathematical entities.

Although, there has been a great deal of research on issues regarding inequalities, little was done in this area in Mozambique (e.g. San, 1996) and almost nothing was investigated related to the research question of this study.

The purpose of this study is to improve mathematics teaching at secondary school level, especially the syllabi and teaching methods. In order to approach this objective, we intend to study how the current way of teaching affects the pupils' skills and understanding of mathematical concepts, particularly in the teaching of inequalities.

Therefore, out of several activities it will be studied the contents of curricula, textbooks and final exams of secondary school in order to find out if and how the link between algebraic and graphical approaches is presented. For this short paper it is just aimed to present some preliminary findings of the study of curricula and final exams of secondary school focusing on link between algebraic and graphical approaches.

TASKS FOR ASSESSING RELATIONAL UNDERSTANDING OF FUNCTIONS BASED ON THE OPERATIONAL/STRUCTURAL DISTINCTION

Thomas L. Schroeder, John E. Donovan II, Corinne M. Schaeffer, &
Christopher P. Reisch
State University of New York at Buffalo, USA

We are interested in gaining insight into the teaching and learning of mathematics by developing and administering assessment tasks that probe students' understanding. In particular, we are interested in students' relational understanding (Skemp, 1978) of functions in precalculus and calculus classes. Our work in this area has been influenced by Sfard's (1991) views on the duality of operational conceptions and structural conceptions in mathematics, and by the algebra tasks discussed by Sfard and Linchevski (1994) in terms of the distinction between operational and structural conceptions.

We have developed a number of non-routine problems which we think demand structural conceptions of functions. Unlike routine tasks which may appear to require structural thinking but which students can handle successfully with an instrumentally learned and understood procedure, we believe that these tasks, when used in interviews, can provide evidence concerning the versatility and adaptability of students' knowledge and the nature of their conceptions -- operational, structural, or pseudostructrual.

In this short oral communication we will describe some of the tasks we have developed, and we will discuss the results of the interviews in terms of the qualities of the students' understanding of functions.

RE-THINKING THE NOTION OF SLOPE UNDER CHANGE OF SCALE

Hagit Sela, Orit Zaslavsky, and Uri Leron

Technion, Haifa

The current study addresses the mathematical, cognitive and pedagogical implications of changing the scale in a coordinate system. It was stimulated by the increasing use of graphical technologies for learning mathematics in the past decade, in which students are often told that they can zoom in or out as they like, since the "behavior" of the graphs of the functions under investigation does not change. They observe very different pictures, and are expected to "see through" these pictures a common behavior. A number of studies indicate the illusions and pitfalls with which such technologies present students (e.g., Goldenberg, 1988; Hillel et. al., 1992). Some of these illusions and pitfalls have to do with the connection between geometry and algebra, and particularly, with a number of basic mathematical concepts that may be interpreted differently from a geometric perspective than from an algebraic one. Our study focuses on the notion of slope of a straight line, and the interplay between its geometric and algebraic meanings.

For the purpose of the study we constructed a set of tasks, in which the change of scale played a role in eliciting how people interpret the connection between slope as a geometric entity related to angle, and slope as an analytic/algebraic property of a function related to the difference-quotient. The tasks were given to a diverse population of people: High school students, secondary mathematics teachers, mathematics educators and mathematicians. In addition, interviews and classroom observations were conducted and documented.

Two main results will be discussed:

- Generally, three approaches were identified: A dominating geometric approach to slope, a dominating analytic approach to slope, and a combined approach that takes into account the conditions under which the geometric system is isomorphic to the algebraic system.
- Similar approaches and conflicts were found across mathematicians, mathematics teachers, and high school students.

In our attempt to offer explanations to these findings, we revisit the notion of slope of a linear function, the assumptions for which it is invariant under different representations, and the connections between the "worlds" of algebra and geometry.

MATHEMATICAL MODELING BY PRE-SERVICE TEACHERS IN A PHYSICS COURSE[1]

Gilli Shama[2] and John Layman, University of Maryland

In the last two decades there is a growing call for making connections between mathematics and science. Scientific situations include stories and experiments. Experiments are sensorial, they include detailed raw information, and they are bounded by physical constraints. Stories are verbal and abstract, they serve as a summary and they are not necessarily bounded. Shama and Layman (1997) found that modeling processes carried by students are affected by the type of the situation.

This paper describes a study of the effect of a physics course on pre-service teachers' (N=22) ability to model a scientific situation (as a story and as an experiment). In the physics course small groups of students designed experiments, carried them out, and presented their results with supporting evidence. Graphs of linear relationships from experiments involving a microcomputer based laboratory were mainly examined.

The course affect was examined by a pen and paper pre and post tests. Each test is composed of two parts, asking to obtain an equation for scientific situation. In Part I, given a story and observing only an experimental setting, individual students are asked to design an experiment, to predict data and to give a representing equation. In Part II the same situation was given to pairs of students to be designed and carried out with the actual experiment.

The students' responses to both tests revealed that in the experimental part they used more graphs and tables, constructed algebraic representations with a better format, used better methods to obtain the slope, and described better the connection between the equation and the data, than were the situation was described only verbally.

From the beginning of the course to its end, the students' responses improved in both parts of the tests. The responses to the part II improved more than the responses to part I. No improvement was found only in checking of the equation back with the data, as Hodgson and Harpster (1997) found "students often proceed from problem to solution without looking back at their efforts or revising their models" (p. 260).

MODELS FOR TEACHER ENHANCEMENT IN MATHEMATICS EDUCATION: A TWO-YEAR PROGRAM IN THE BEDUIN SCHOOLS

Ruth Shane
Kaye College of Education Beersheva, Israel

Both standardized tests and informal evaluation showed a low level of mathematics achievement in the Beduin elementary schools of the Southern District in Israel. Recent articles have confirmed the conclusion that children's achievement is affected by teacher expertise which can be improved by teacher education. In particular, curriculum-centered professional development can improve the teaching of mathematics (Cohen & Hill,1997). Therefore, math educators at Kaye College proposed an intervention focusing on teacher education, merging two interrelated components: on-site school supervision and a weekly workshop for the teachers. This research examines the results of the program for the years, 1997-1999.

Traditionally, there have been two separate components to teacher education: subject matter and "methods." Shulman's (1986) definition of pedagogic content knowledge is, however, a reorganization of this knowledge base for teacher development, such that the mathematics be transparently relevant for the elementary teacher and the didactics be integrally faithful to the mathematics. This perspective is particularly relevant in designing a teacher enhancement program.

While cultural issues have been raised in how children learn mathematics, little has been studied about culture and teacher development programs. The awareness that everyone – senior staff, teachers, and pupils - is bringing to the project their own knowledge base for teaching and learning mathematics and that this base must be acknowledged, respected, shared, and developed, is a another key feature of the program.

In the fall of 1997, forty teachers from thirteen Beduin elementary schools were chosen for the program by their principals, 3 from each school, at least one from grades 1-3 and one from grades 4-6. In 1998-99, the program moved into a second phase with the same participants. Two of the Beduin teachers became part of the on-site supervision team.

The findings of this study are based on an analysis of the audiotapes of staff meetings and interviews with participants. Issues of cultural reference are considered - the borders of mathematics, language, politics, and cooperation. The focus is on identifying and categorizing evidence of the professional development of the teachers, of their developing knowledge for teaching mathematics (Shane, 1998).

THE TEACHER – THE DECISIVE AGENT IN THE QUALITY OF TEACHING

Nadja Stehlíková and Milan Hejný [1]
Faculty of Education, Charles University, Prague

The contribution is based on the research and experiences of the authors related to the teaching of mathematics in the Czech and Slovak Republics. From the idea expressed in the title, which is the authors' strong belief, it follows that the improvement of teaching mathematics is only possible via *teachers' pedagogical work*. About twenty years ago we hoped that this could be done by giving the teacher new effective teaching methods, and that he/she would implement them and thus improve his/her teaching. However, this way yielded little improvement, and failed completely to change the instructive way of teaching. The similar experience has been confirmed by many authors[2].

Our understanding of the problem of *influencing teachers* was substantially changed by the following experience.

Dana was a secondary school teacher, who had taught in an instructive way for twenty years. She was satisfied with her work. She enthusiastically took part in our research. Then came conflict. Dana's opposition to our opinions was very strong. She was not willing to accept that the results showed that her students knew algorithms but their knowledge suffered from formalism (= parrot-like knowledge). She prepared her own experiment to persuade us that her students understood mathematics well.

The results of her experiment were not as she expected. This influenced her considerably. When she told us about her experience, she was crying. She was sorry: "for the years when I taught in an ineffective instructive way". In the next years, she systematically and creatively changed the way of teaching different topics and looked for new ways of working with students. She was excited by this work.

The most important result of Dana's case is that the change in her pedagogical beliefs was not brought about by our advice or instruction, but by her independent work. The didactic knowledge cannot be transmitted from researchers to teachers but rather it must be *reconstructed and made meaningful by teachers themselves*.

We believe that a teacher who does independent experimental and research work changes his/her pedagogical consciousness and attitude in a positive direction. This belief has brought about a profound change in our approach to research collaboration both with practising teachers and students - future teachers. In this collaboration, we create a similar climate for them as we, the researchers, have when solving different research problems. Rather than tell the teachers the basic results and principles of the research methods we encouraged them to do their own experiments and to analyse the students' outcomes.

[1] The contribution was aided by the grants GAČR No. 406/97/P132 and GAČR No. 406/99/1696.

TEACHERS IN A PROCESS OF CHANGE: REFORMING MATHEMATICS BY BUILDING ON CHILDREN'S THINKING

Steinberg Ruti

Hakibbutzim State Teacher College and
Ministry of Education, Elementary School Dept.,Israel

This research describes case studies of six teachers (grades 1 to 3) who implemented an innovative approach to teaching mathematics, Cognitively Guided Instruction. The teachers learned about children's thinking in solving mathematics problems from current research and from listening to the children. This knowledge served as the basis for instruction in a constructivist approach. Reflectiveness and teacher-research were encouraged. This paper describes the teachers' changes and provides insight into the process of change.

Research methods included about 100 in-class observations conducted in a full school year, interviews with the teachers at the beginning and the end of the year, conversations with them and short reflective writing by the teachers.

Results and discussion. Five of the teachers changed their beliefs markedly during the year. They came to believe that children can learn mathematics concepts without direct instruction and actively construct mathematical knowledge. The teachers also moved toward a new view of their role in the classroom, typified by coaching, listening, creating dialog, directing discussion and giving children opportunities to solve problems, reflect on their solutions and present them orally and in writing. The teachers made substantial changes in their teaching: they gave many more challenging problems, they altered classroom organization, created a rich mathematics environment and learned to listen to and learn from the children. Teachers worked with heterogeneous small groups and encouraged the acceptance of a variety of solution strategies.

The five-level model of Fennema, Carpenter, Franke, et al. (1996) was used to assess the teachers' changes in beliefs and instruction. All 6 teachers started at level 1. One new teacher stayed in level 1. One teacher changed to level 3, two teachers moved to level 4 and two teachers moved to level 5 in only one year Teachers who moved towards the higher levels also developed more in their ability to conduct discussions. I present here quotations of the teachers' perceptions of their changing roles in the classroom:

- *In the past I used to stand in front of the class, teach, repeat, drill. Today I let the students experiment. I am more of a coach, standing next to them, looking from the side, observing, giving advice, helping if someone gets stuck.*
- *To give challenges that encourage children to think, act, search, and generalize. To present conflicts, dilemmas, to let the children find varied ways to solve problems. To monitor, to be present. When a child needs help, to be supportive I see my role a lot less as transmitting knowledge.*

EMPHASIZING MULTIPLE REPRESENTATIONS IN ALGEBRAIC ACTIVITIES

TABACH MICHAL

Department of Science Teaching, Weizmann Institute of Science

Computers facilitate, and can thus be used to promote the use of multiple representations. Conventional algebra teaching focused mainly on the symbolic (algebraic) representation. This can pose serious obstacles in the process of effective and meaningful learning (Kieran 1992). Hence, the use of various representations is recommended from the very beginning of learning algebra (NCTM Standards 1989).

Each representation (*algebraic, verbal, numerical* and *graphical*) has advantages and disadvantages. The need to encourage students' individual styles of thinking make the importance of working with various representations obvious. In the case of algebra, spreadsheets and graph plotters allow for quick and well-organized sequences and tables of numbers and a wide variety of graphs.

Flexibility in work with a variety of representations cannot be expected to occur spontaneously. Appropriate tasks are needed, designed to raise student awareness and ability to use several representations simultaneously, whether learning algebra is technologically based or in a more conventional environment.

Savings is an activity designed for beginning algebra learning in the 7^{th} grade, and was developed as part of a comprehensive curricula project – *Compu-math*. In the presentation, I will use the *Savings* activity to demonstrate both guidelines for the design of such activities and episodes from students' activity.

GENERALIZING WITH EXCEL AT THE BEGINNING OF LEARNING ALGEBRA.

Naomi Taizi

Weizmann Institute of Science, Israel

Generalizations in early algebra

At the beginning of learning algebra, generalizations are made and applied in a variety of ways. The use of variables is an advanced stage in generalizing or applying a pattern. The use of large numbers, or the "reversed" use of a pattern are two possible ways to require students to generalize without variables (Friedlander et al., 1989).

We observed that students tend to avoid generalizations by performing a step-by-step development of a sequence. Therefore, the requirement to apply a pattern for large numbers does not allow students to follow this path.

Generalizing with Excel

Over the last few years, we experimented with Excel as a tool for generalizing patterns, at the beginning algebra stage. The students were exposed to three main methods of developing number sequences: (a) "dragging" two adjacent cells to produce a linear sequence with the corresponding rate of variation, (b) "dragging" a formula that uses the previous cell to construct the next one (i.e., regression) and (c) "dragging" a formula that uses the place indicator (situated in another column) to construct the sequence.

Several difficulties arise in students' attempts to generalize patterns, using Excel in this way:

* Students prefer to follow their natural tendencies and use regression, rather than employ a formula with the place indicator as a variable.
* Students may get confused by the need to cope with the Excel syntax of writing formulas, in addition to the traditional algebraic form.
* The power of Excel allows students to perform a direct search of numbers in very long sequences, rather than encourage them to use more sophisticated ways which rely on the general rule of the sequence.
* Excel's ability to produce large quantities of numbers de-emphasizes students' need to justify an observed pattern.

Examples of these difficulties and of attempts to overcome them will be reported in our presentation.

MODELING FIBONACCI: TWO UNIFIX CUBE PROBLEMS

Lynn Tarlow and Emily Dann
Rutgers University

Theoretical Framework Research at Rutgers University carried out over the last decade has centered on the use of unifix cube towers to build models for constructing various mathematical ideas. Chief among these have been those related to combinatorics and proof (Maher & Martino, 1996; Maher & Speiser, 1997). Papert (1980) encourages the use of models for mathematics that provide learners rich concrete environments through which they can explore mathematical ideas and relationships. This gives them references for future problem modeling. This paper presents an analysis of two problems, illustrating the power of immersion in model understanding for extension into other areas of mathematics.

Motivating Question When presented with the challenge of finding a non-recursive formula for the nth term of the Fibonacci sequence, one of the authors created a tower model representation. This representation answered her question: "How could I make this task understandable to my students?" Problem situations were developed that resulted in two different ways of building towers that provide a concrete representation of the Fibonacci structure. These models lead to a non-recursive formula based on combinatorics.

The Models The original tower problem requires one to find all possible towers of height n when allowed to select from two colors. This results in a concrete model of the task of finding how many combinations exist. The first model created to produce the Fibonacci structure uses individual white unifix cubes and blue unifix cubes paired in twos. The second uses individual unifix cubes of white and blue and requires that no two blue cubes will be adjacent.

Presentation The oral presentation will invite the audience to participate in forming each inductive step as images of the towers are created on an overhead projector. Participants will be able to see the Fibonacci sequence develop in a unique setting.

Children's number concepts: Implications for teacher education.

Noel Thomas
Charles Sturt University

Results of research involving the clinical interviewing of 132 children (Grades K to 6) are used to draw implications for the training of primary school teachers in understanding the needs of young children when learning mathematics. In the study, it was found that children have difficulties with using numeration as a number system and this could be a result of limited instructional experiences. Common teaching practice focusses on the numbers 1 to 1000 (the limits of the usual representations with Dienes blocks) and algorithm-related techniques using place values separately. Also, multiplication and division need to be more closely linked, and more experiences bringing out the recursive nature of repeated groupings need to be provided.

In particular, the research highlights that the teaching of numeration as compartmentalised knowledge restricts the construction of relationships. It is argued that the teaching of numeration requires a more holistic perspective of what children need to develop in their learning of number. Curriculum and teaching need to reflect the goal of achieving understanding of the structure of the number system through key processes of: counting, grouping, partitioning and regrouping and the formation of multiunit values. Moreover, children must be helped to build their own mental connections between their intuitive knowledge, various models that might be used and the formal rules of numeration. Finally, children need to build their own models as a means of constructing meaning for the number system.

In this report, the implications of a reliance on the modelling of number with Dienes base ten blocks is explored through the use of explanations given by teacher education students to a question requiring an extension to common use of the blocks. It is demonstrated that some student teachers do not understand the multiplicative structure of the number system. The students use numbers efficiently but do not see a relationship between the model they are using and number as a base ten system.

UNIVERSAL THEOREMS: A PARADIGMATIC MODEL OF MATHEMATICAL THEOREMS

Chaim Tirosh

Kibbutzim College of Education, Tel Aviv

A paradigmatic model is a particular instance or a subclass of objects, accepted as a representative of the whole class (Fischbein, 1987). This particular representation of the concept has a strong impact on students' cognitive decisions, and may exert a coercive effect on their ways of reasoning. Examples of paradigmatic models of various mathematical concepts are described in the mathematics education research literature (e.g., Hershkowitz & Vinner, 1982).

Mathematics teaching and learning attends to different types of mathematical theorems, including universal (quantifier) theorems, equivalence theorems, existence theorems and uniqueness theorems. This study aims at determining whether one of these types of theorems acts as a paradigmatic model for prospective elementary teachers.

Three classes of mathematics majors, prospective elementary teachers, women in their second or third out of four years' teacher education program in two Israeli State Teachers' Colleges, participated in this study. At the beginning of the academic year, these prospective teachers answered two questionnaires. The first included nine mathematical propositions. Participants were asked to consider each proposition, to decide whether it was true or false and to prove their assertions. The second questionnaire consisted of six propositions, each accompanied by four to seven prepared arguments in favor of or against the proposition. The prospective teachers were asked to judge the truth of each statement as well as to determine if each presented argument was a valid mathematical truth. Analysis of prospective teachers' responses to both questionnaires suggests that universal theorems serve as paradigmatic models of mathematical theorems, for this population. In the presentation I shall provide various examples of items from both questionnaires, typical prospective teachers' responses and some, educational implications.

WHAT COUNTS AS EVIDENCE: UNCOVERING THE FOUNDATIONS OF FAILURE IN MATHEMATICS LEARNING

Dianne Tomazos and Carrol Hall
Education Department of Western Australia

The Education Department of Western Australia is implementing a major reform of the curriculum using an outcomes based approach. Rather than prescribing what must be taught, the department has made explicit the learning outcomes which all students should achieve, and assigned to each school the responsibility and flexibility to develop "their own teaching and learning programs according to their circumstance, ethos and the needs their students" (Curriculum Council 1998 p.6). The role of the classroom teacher in making ongoing professional judgements about student learning has become central to this process. Determining what counts as evidence of having achieved outcomes, along with the early identification of students 'at risk' of failing to achieve outcomes, are therefore essential research foci.

In this presentation the authors will report on a collaborative action research project in progress* which is designed to assist teachers develop strategies for identifying, accelerating and monitoring students who, by the end of primary school (approx 12 years old), have not achieved a sufficient level of mathematics learning to enable them to make adequate progress in secondary school. A feature of the project has been the opportunity for year seven primary generalist teachers and year eight secondary mathematics teachers to work together to investigate and analyse the features of children's developing mathematical ideas which are likely to put them 'at risk' of future failure to achieve. Although the project is still in the early stages of development, some important issues are emerging.

There are distinctive differences in the way primary and secondary schools in this state operate and this has implications for the ways in which the respective teachers are able to interact with students, and consequently the types of evidence they use to make judgements about students' learning. Developing a common unbiased means by which evidence of achievement in mathematics is determined by teachers in their day to day classroom practise is a major challenge, as Watson (1997) has also noted.

What children cannot do in mathematics is usually the initial focus when teachers are asked to identify students 'at risk', and this is relatively easy to ascertain. Why they cannot do it then becomes the central question as teachers explore strategies for accelerating students' learning. However, questions about why children CAN do mathematics are also emerging as important issues in the project - there are children who can do the expected mathematics by the end of their primary schooling, but for the wrong reasons, thereby laying the foundations for later failure.

"NO ANSWER" AS A PROBLEMATIC RESPONSE: THE CASE OF INEQUALITIES

Pessia Tsamir* Nava Almog**

Kibutzim College of Education* Tel Aviv University* Beit Berl College**

There is a growing interest in the last couple of years, in learning and teaching algebraic inequalities. Traditionally, the related mathematics education literature consisted mainly on papers suggesting preferable teaching methods, and only few papers either describe students' ways of thinking about inequalities or examine the impacts of given teaching methods on students' conceptions (e.g. Linchevski & Sfard, 1991, Piez & Voxman, 1997, Tsamir, Almog & Tirosh, 1998).

Our study investigated 355 high school, mathematics majoring students' solutions to various types of inequalities, including linear, quadratic, absolute value, rational and irrational ones. A 30 items questionnaire was administered to the participants, and they were given two hours to solve these inequalities and explain their solutions. Those who presented unusual (correct or incorrect) solutions were orally interviewed; in order to get a better insight into their ideas.

The first phase of the analysis of data related to each type of an inequality, focusing on preferred solving methods, common mistakes, and possible reasons for these mistakes. In the second phase, a more general perspective was taken. Incorrect solutions, common to several types of inequalities were detached and possible sources were suggested. This analysis revealed that in all inequalities, cases in which the solution was either "there is no value to satisfy the inequality", or "no numbers satisfy this inequality" were found to be extremely problematic for a substantial number of the participants. Most outstanding were students difficulties with '$\geq$' inequalities, where students tended to claim, even in purely numeric cases such as $3 \geq 3$ or $7 \geq 3$, that no numbers can both be smaller than and equal to another number, and thus there is 'no answer'. In the oral presentation examples will be presented, and possible implications to instruction will be described and discussed.

MATHEMATICAL BECOMING: THE PLACE OF MATHEMATICS IN THE UNFOLDING STORIES OF LEARNERS' IDENTITIES.

Peter Winbourne
South Bank University

The research to be reported in this session is framed by theories of situated cognition. The tools for analysing apprenticeship models of learning provided by this perspective (Lave 1988,1996, Lave and Wenger, 1991) are used to describe mathematics classrooms in terms of multiple intersections of practices and trajectories. (Winbourne and Watson, 1998.)

A central focus of this session will be the exposition and justification of a methodology which enables the learner's developing identity (or, more appropriately, identities) to be characterised. This methodology, essentially biographical, draws upon the work of writers such as Ricoeur (1984, 1985, 1988), and Brown (1997). It is used to claim the legitimacy and validity of adding a narrative dimension to the researcher's description of learning. In this research, the processes of mathematics learning observed in the classroom are placed in the wider contexts of the lives of the people who happen to come together in that classroom (in that school.)

Data drawn from observations of a small group of learners - 'inside' and 'outside' of the classroom - will be presented. These data, woven into narratives, will allow particular classroom events, associated with learning of specific pieces of mathematics, to be presented as strands in possible stories of the learners' lives. The discussion will focus on aspects of those stories which describe the learners' developing identity within the practice of school mathematics seen as but one of the many practices in which learners participate. These stories provide a powerful account not just of what, but of how and why people learn.

The research suggests that learning happens as much as a result of the complex identities in practice that teachers and learners bring with them when they step into the classroom as anything that happens to them once they are there.

VISUALIZATION OF SOLUTIONS OF A QUADRATIC EQUATION

Kiyosi Yamaguti
Kyushu Sangyo University, Fukuoka 813-8503, Japan

To solve a quadratic equation is one of important topics of high school mathematics. If the numbers considering are restricted to the real numbers, then the equation has no solution when the discriminant of the equation is negative. By introducing the complex number, any equation has (complex) solution. A real solution can see as an intersection of the graph of quadratic function and the x-axis. How visualize elementary an imaginary solution on the complex plane would be important for teaching of high school mathematics.

We first recall three visualizations of the products of complex numbers in the complex plane in the sense of Hamilton. Secondary, we consider the geometric constructions of solutions of quadratic equations. To construct imaginary solutions is essentially equivalent to construct two real solutions. In fact, given a quadratic equation (1): $ax^2+ bx+ c=0$, then consider a quadratic equation (2): $ax^2+bx+c^*=0$, where $c^*:=(b^2/2a)-c$, associated with (1), then (1) has two imaginary solutions if and only if (2) has two real solutions. We shall give some geometric constructions by using parallelism and drawing of circle in the orthogonal coordinate plane. Example: Assume the discriminant D of the equation (1) is negative. Then, the solution of (1) is a solution of the system of equations (3) $x=-b/2a$, (4) $x^2+y^2=c/a$. Hence, the imaginary solution is obtained as intersection of the axis (3) of parabola and the circle (4). Assume $a>0$, $D>0$ in (1). Then, (2) has imaginary solution points P^*, Q^*, that are obtained by above. The real solutions of (1) are the intersection of the x-axis and a circle with center $(-b/2a, 0)$ and P^*Q^* as a diameter.

The above geometric constructions are elementary. However, these constructions need that student understands the theoretical reasoning on solutions of quadratic equations and the properties of the graphs of quadratic functions.

A graphing calculator can also use for these constructions. Therefore, such a construction of the solution could assist students for visual and theoretical understanding for a solution of quadratic equation.

UNDERSTANDING THE CONNECTIONS BETWEEN THE GRAPH OF A FUNCTION AND THE GRAPH OF ITS DERIVATIVE

Smadar Zamir and Orit Zaslavsky

Technion, Haifa

The notion of derivative is fundamental in pre-calculus and calculus courses. There are many calls recommending that emphasis be drawn to connections between properties of the graph of a function and the graph of its derivative (Hallet, 1991; Tall, 1991; NCTM, 1989). Yet, in spite of the qualitative and visual aspects the notion of derivative, students often treat it technically without understanding its meaning. One way to create opportunities for the recommended kind of learning experiences dealing with derivatives can be done with a *Gradient Measurer* (Tall, 1991). This tool provides ways to pointwise construct the graph of the slopes of a given graph. Thus, it enables the student to construct the graph of a derivative function without having to know its analytic expression.

The purpose of the present study was: (1) to explore ways in which students understand and solve problems associated with the connections between the graph of a function and the graph of its derivative; and (2) to examine the influence of learning experiences based on the use of a *Gradient Measurer* on students' interpretation and application of these connections.

Nineteen 11-grade students participated in the study. The students encountered a series of learning activities based on the use of a *Gradient Measurer* to construct graphs of derivatives. They were given a written questionnaire prior to this intervention and again after its completion. Both questionnaires were similar in structure and content, and included 13 problems dealing with visual connections between the graph of a function and the graph of its derivative. All the problems could be solved without the use of any analytic expression of the function or its derivative.

Analysis of students written responses to both questionnaires pointed to five main approaches students used: 1. Expressing the need for an explicit analytic expression of a function or of its derivative; 2. Attributing similarity between the graph of a function and the graph of its derivative; 3. Turning to familiar families of functions; 4. Applying familiar theorems; 5. Examining or constructing the slopes of the graph at various points. Some approaches were more helpful than others for solving the above kind of problems. The findings indicate an increase in use of the more helpful approaches.

CONFRONTING AND MODIFYING STUDENTS' INTUITIVE RULES IN NUMBER THEORY

Rina Zazkis

Simon Fraser University.

This study adds another example to a rich collection of mathematical and scientific situations presented by Stavy and Tirosh in which the intuitive rule "the more of A, the more of B" has been applied. It is students' intuitive belief that a larger number has more factors.

This study is situated within the research on learning mathematics at the undergraduate level in general and learning introductory Number Theory by preservice elementary school teachers in particular. I will introduce "the rule" by demonstrating excerpts from interviews with preservice elementary school teachers. I will discuss the robustness of this rule by considering how students assigned truth value to the following two statements:

(1) "If a natural number a is bigger than a natural number b, then the number of factors of a is bigger than the number of factors of b."

(2) "If a natural composite number a is bigger than a natural composite number b, then the number of factors of a is bigger than the number of factors of b."

I will analyze the differences in students responses to the two statements, pointing out to a pattern emerging in students' struggle to reconcile their intuition with conflicting evidence. Further, I will show students' tendency to consider "conflicting evidence" as exceptions, their willingness to amend the rule, but not to give it up. In conclusion, I will argue the importance of instructor's awareness of students' potential misconceptions. Pedagogical approaches that confront students' popular beliefs (without giving explicit reference to those), and attempt to deepen students' understanding of the relationship between natural numbers and their factors will be suggested.

IMPROVING STUDENTS' MATHEMATICAL THINKING: THE ROLE OF DIFFERENT INTERACTIONS IN A COMPUTER ENVIRONMENT

ORIT ZEICHNER, BRACHA KRAMARSKI, ZEMIRA MEVARECH
SCHOOL OF EDUCATION
BAR-ILAN UNIVERSITY, ISRAEL

The goals of mathematics teaching published by the National Council of Teachers of Mathematics (NCTM, 1989) placed special emphasis on doing mathematics in a manner that encouraged students to develop their ability to solve problems, think and give reasons for the solution process. The present study examined the effect of learning in a computerized environment with interactions based on different types of feedback, on achievements in mathematics and on developing mathematical communication. The study is based on the Self-Regulation Learning model and two types of feedback provided by the computer when the student made a mistake. metacognitive feedback (SRL) (Mevarech, & Kramarski 1997) and knowledge of results (KR) feedback. To test mathematical thinking and communication, subjects (186) were given an achievement test in arithmetic series that examined general term formula, rule of recursion, verbal problems, and overall score. To test mathematical communication, students' explanations were analyzed, first as right/wrong explanations, and then in terms of type of rationale according to the categories. algebraic rationales, verbal rationales, and algebraic and verbal rationales. The main conclusion of this study is that students working in a computerized environment with metacognitive feedback attained higher achievements and demonstrated better ability to explain their solutions than students who worked with knowledge of results feedback. The authors also bring theoretical and practical applications of the research findings.

POSTER PRESENTATIONS

MOTIVATING TEACHERS TO USE ALTERNATIVE ASSESSMENT

Jeanne Albert
Weizmann Institute of Science - Israel

This poster describes a national project which uses mathematical investigative tasks for assessment in elementary schools. During the first three years of the project, the researcher found that elementary school teachers believe that understanding and thinking are their most important goals in teaching mathematics. Nevertheless they are still creating mostly traditional tests.

In 1994 the Israeli Ministry of Education funded a project to create test item banks for use in school-based assessment. The mathematics investigative tasks which we created were guided by the following principles:

- to present mathematics as a subject which requires dealing with authentic, worthwhile problems.
- to emphasize the process of solving instead of final solutions.
- to emphasize processes of higher level thinking - e.g., generalization, justification, estimation.
- to downplay the use of calculation techniques and encourage the use of calculators.
- to introduce the students to unknown problems without algorithmic solutions.
- to introduce the students to problems with many solutions.
- to integrate various branches of mathematics.
- to enable each student to reach his highest possible mathematical ability.
- to enable even students with lower mathematical abilities to experience mathematical investigations.

In order to encourage teachers to use investigative mathematics tasks as assessment tools workshops were given. The general plan of a workshop was adapted from a model Clarke (1995) developed for familiarizing students with newly introduced criteria of assessment. There is evidence that teachers' participation in these workshops has an impact on their instruction and assessment.

In the poster will be displayed:

- Teachers' beliefs.
- Examples of typical elementary school mathematics tests.
- Mathematical investigative tasks from the test bank with students' work.
- Examples of tests which have been influenced by workshop participation.

Clarke, D. (1995). Quality Mathematics: How Can We Tell? *Mathematics Teacher*, 88(4), 326-328.

Mathematical sense-making strategies of non-academically oriented students

Yoni Amir and Orly Gottlib
Department of Science Teaching
Weizmann Institute of Science - Israel

"Shay" is a curriculum development project for non academically oriented students (ages 15-18) in Israel, who undertake a national matriculation examination at the end of high school. The curriculum includes the basics of analytic geometry, calculus, statistics, probability, linear programming, trigonometry and stereometry. The approach of the learning materials stresses graphical and visual aspects, uses of and connections among multiple representations, informal intuitive reasoning, and estimation. In the records collected, we found instances of flexibility, control mechanisms and resourcefulness in student thinking which may exceed those usually found in more mathematically able students.

In the poster, we will display:

- Background information of the "Shay" program, and its pedagogical rationale.
- Examples of student work in which:
a) a problem clearly identified with one mathematical subdomain is solved using tools from another subdomain
b) problems which require formal tools, are solved informally,
c) the search for alternative perspectives on a solution approach reveals a mistake in the original approach.

The examples will be presented in its original written form, translated into English, and analyzed. The analysis will suggest the ways in which the learning materials support students' sense making attempts and strengthen their confidence and self-esteem.

TEACHERS' BELIEFS AND USE OF NON-ROUTINE PROBLEMS IN MATHEMATICS TEACHING

Dalia Asman Gordon College, Haifa , Israel **Zvia Markovits** Oranim School of Education, Israel

This study focuses on teachers' beliefs regarding mathematics non-routine problems and ways in which teachers cope with this kind of problem.

Interviews were conducted with thirty elementary school teachers from three different groups.

a. Ten in-service mathematics teachers. (T)

b. Ten in-service teachers who participated for at least two years in teachers' development programs. (TT)

d. Ten pre-service teachers specializing in math, in their last year of study (PST)

Teachers were first asked about their general beliefs concerning mathematics problem solving. Then, each teacher solved eleven non-routine problems. Each problem was followed by a series of questions exploring their beliefs about the problem. Questions included: Would you pose this problem to your students, to the whole class or part of it? Would you give this problem in an examination?

One of the problems was the Bell Problem.

At the top of a high tower, there are three bells. One Rings every 10 minutes, the second every 8 minutes, and the third every 5 minutes. They all rang together at 12:00. When is the next time they would ring altogether?

The following table indicates the number of teachers who solved this problem and distribution of their answers concerning some of the follow up questions.

	T	TT	PST	Total
Solved correctly	5	8	3	16
Would pose problem to the whole class	9	9	10	28
Would give the problem in examination	1	2	0	3
Encountered the problem in textbooks or math courses	0	0	0	0

Findings indicated that almost half of the teachers solved the problems incorrectly. Nevertheless, most of them after realizing the correct solution were willing to pose the problem to their entire class. However most teachers would definitely not pose the problem in an examination, in order to avoid unnecessary difficulties for their students during exams. None of the teachers had encountered such a problem in any of elementary schools' textbook.

The analysis of the other ten research problems draws much a similar picture. The TT teachers solved more problems correctly than the other teachers did. In addition during the interviews, TT teachers expressed much more the kind of beliefs which we would like and expect math teachers to hold. This might indicate the importance of in-service teacher development programs.

LEARNING MATHEMATICS BY PROJECTS USING WEB PAGE

SEP – SSEDF – DGENAMDF
Yolanda Campos – Centro Siglo XXI
Teresa Navarro de Mendicuti – BENM

Objective and description: In this experience we have elaborated one prototype project which represents an interinstitucional effort to produce some kind of material that encourage the critical and creative incorporation of computer technologies in the area of teachers training as part of an Academic Programme of Computer for Education in Mexico D.F.

The objective of this prototype is to promote the learning of Mathematics in elementary school based in projects, to stimulate teachers and students to use computer technologies critically and creatively as a didactic assistance and elaborate a Web page as an integrative element within the multimedia elements generated during the projects process. Concerning the level of teachers training we intend to promote the active participation of teachers and students the use of computer technologies as a support for educational projects that can be applied to elementary education after being introduced to the prototype.

Among the computer technologies used we have: productivity tools and structured educational software elaborated specially for the prototype, Logo, software for exploration, Internet, and the elaboration of a Web page. This Web page integrates the project description, the software, book and notebook exercises, participation in learning circles and discussion forum. Didactic suggestions are offered as well as a teachers manual, parental advice and lines of investigation. It is our wish to prepare the teachers trainers together with the students so that they can apply the project working model in elementary school and generate new projects with the assistance of the prototype.

Some Results: Until now in the experimental phase of the prototype, teachers in training involved have acknowledged the agreement between the project and the focus of the new plans and study programs within Primary School Study Licence. For the moment we have not yet gotten personal project production but we hope to achieve this in 99. Working with the children in open participation within the pilot phase we have observed the way they have advance not only in Math but also in their attitude towards school according to their parents. We were able to capacitate teachers from the Valle Arispe Primary School on the project focus and collaborative learning around the prototype; each teacher managed to produce a personal project that was included in the Web page. We successfully organised a direct workshop of Web page project elaboration with the National Association of Teachers of Mathematics.

We have considered pedagogic follow up for the learning circles for children, teachers, parents and researchers as well as discussion groups with other interested teachers. It is our intention to document every action realised and generate lines of investigation to sustain the thesis proposed in the corresponding section. Developmental courses for training and actualising, as well as other higher studies have been organised for teachers in service to be innovated and reflective in this new system.

A Study of Second Semester Calculus Students' Notion of Covariation

Marilyn P. Carlson
Arizona State University

Research has shown that calculus students possess weak understanding of impor aspects of the function concept, with particular difficulty understanding covariant aspects function relationship (Carlson, 1998; Thompson, 1994). The present study investigate calculus II students' understanding of covariation.

Imagine this bottle filling with water. Sketch a graph of the height as a function of amount of water that's in the bottle.

On the above problem, 14 of the 20 students constructed a graph that was str concave up or concave down, conveying that "as more water is added, the graph should r However, when asked to explain why, most appeared to be responding with a memor phrase. When prompted to discuss the changing shape of the graph, fewer than half mention of the changing rate, and when further probed, did not appear to understand varying magnitude of the variables represented in this situation. Few students attended to "rate change" from positive to negative. Although these students had successfully complet course that emphasized rate and covariation, most did not appear to possess deep-se understandings for applying this knowledge in fairly routine settings.

LEARNING CONSTRUCTIVIST TEACHING BY DOING: A COURSE FOR IN-SERVICE TEACHERS

Chang, Ching-Kuch

National Changhua University of Education, Taiwan

E-mail: macck@cc ncue.edu.tw

A problem-centered and investigation-based course on teaching for in-service mathematics and science teachers has been developed in a summer program. The purpose of this course was to learn how to teach mathematics or science from the constructivist perspective. The course development was based on constructivism, especially social constructivism (Ernest, 1991). Major adjustments concerning the structure, contents, and the ways of teaching have been made on this course. The course not only introduced constructivism, but also taught according to its principles, letting the teachers construct their teaching knowledge by doing, talking, presenting, and writing. Furthermore, the course also had the teachers investigate their own teaching problems. During investigation the teachers have processes experiences such as exploring, searching, formulating, planning, testing, justifying, conjectures, reflecting, and generalizing. It was found that the new course was more effective than traditional course—by lecturing. Teachers' learning was illustrated by excerpts from their journals.

THE COMPLEMENTARY ROLES OF IDEA INITIATOR AND INQUIRER IN MATHEMATICS CONJECTURING ACTIVITY

Ing-Er Chen
Kaohsiung Normal University

Fou-Lai Lin
Taiwan Normal University

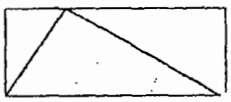
We had developed a thinking model of mathematics conjecturing. Evidence in our research had shown that two different thinking paths in this model conforming to the functions of conjecturing and refuting respectively could keep the fluency of one's thinking. Thus, we applied this model to design mathematical conjecturing activities to develop students conjecturing abilities.

This paper reports the discourse between two students in the activity conducted in a Taiwan eighth-grade mathematics class. All students were encouraged to guess a conclusion and judge the correctness of a proposition. Their performance in this activity could be divided into four stages: making conjectures, judging reasonably, refuting arguments, and comment and reflection. Some learning materials were quoted or rewritten from Mason (1989) and Polya (1954). Data was obtained from classroom observations, interviews, transcription of videotapes and audiotapes of the lessons, and students' booklets.

According to the episodes of their discourse, one student can be identified as an idea initiator, and the other as an inquirer. The idea initiator was an active conjecturer. Her contribution in the class is to provide some vague but good ideas followed by others. The contribution of the relative role, idea inquirer, is to arouse everybody's thinking. She got benefit from the activity by absorbing the initiator's ideas and her query could help the initiator to put her thinking in order.

Our evidences show that successful conjecturing needs two roles, idea initiator and idea inquirer. One student may play these two roles spontaneously. But most students could only play one of these two roles. Thus, the interaction between initiator and inquirer, who both offered complementary scaffolding by each other and conformed to the functions of conjecturing and refuting respectively, made the conjecturing activity successful. Based on this phenomenon, we suggested that cooperative learning and social construction might be the appropriate way of developing conjecturing activitiy.

THE HETEROGENEOUS CHARACTER OF THE STUDENT TEACHERS THOUGHT



Climent, N.; Contreras, L.C. & Carrillo, J.
(University of Huelva, Spain)

Teachers usually consider their students as a *group* (*homogeneity* tendency), but every student builds their own *individual* knowledge in their personal way, based on their previous knowledge and their beliefs on mathematics and its teaching and learning. Their mathematical abilities and their own logic come also into play in every situation they approach.

Problem solving emerges as a challenge for students. They, when tackling problems, apply their mathematical abilities and views. Hence, problem solving is a very appropriate realm in which one can analyse knowledge as well as beliefs.

We have posed to related statements (C1 and C2) of the Dickson et al. Problem to two groups (A, B) of student primary teachers (C1 to group A and C2 to group B).

C1	C2
Find the area of the triangle of the picture, given 20 cm^2 as the area of the rectangle.	What part of the rectangle is the triangle of the picture, given 20 cm^2 as the area of the rectangle?

Inspired in Dickson et al. (1984) *Children Learning Mathematics: A Teachers Guide to Recent Research.* London: Cassell.

The students were asked to solve it at home and to write the process in as detailed a way as possible. After that, we analysed their protocols and we chose one representative of each different way of solving. Each student was interviewed twice (individually, to light some aspects of their processes and, in groups, to promote sharing and further discussion, comparison and revision of the solutions). Our analysis focused on main global processes and perspectives, as well as major errors, to find some differences related to students' beliefs and knowledge organisation.

We conjectured that there would be different approaches depending on the numerical or geometrical character of the statement. It happened, nevertheless almost all the students seemed to be keen to give numerical support, making explicit some aspects of their mathematical beliefs. In addition, we found an absence of reflection on what is being done in each moment of the process.

With these comments we want to highlight the importance of metacognitive knowledge and beliefs in teacher education. The metacognitive features go beyond the specific mathematical knowledge towards the students' current and future professional knowledge (metacognitive knowledge lies in the basis of professional knowledge, supporting it).

AUTHENTIC LEARNING IN MATHEMATICS: A REAL POSSIBILITY OR AN ACADEMIC'S FANTASY ?

Anne D. Cockburn,
University of East Anglia, U.K.

Kindergartens and elementary classrooms tend to be full of brightly coloured tools and toys which are rapidly produced when the children are introduced to the early stages of mathematics. Unfortunately, as the students grow older and the work becomes more formal, there is less and less evidence of apparatus - let alone everyday objects - to develop skills and promote understanding. Thus, in effect, the quality of 'authentic learning' (Desforges, 1995) is diminished leaving mathematics as an abstract series of equations and problems which appear to have little, or no, relevance to the real world.

I am certainly not the first to advocate that learning from everyday experience is effective (see Froebel, 1887; James, 1899; Dewey, 1933; Kamii, 1985 and so on) but it may be that (1) it is an unrealistic aspiration when one is endeavouring to teach thirty children or (2) only fairly simple mathematics lends itself to the use of real examples which may be familiar to the children.

This poster focuses on the second of these possibilities. It will include some examples of mathematical concepts which have been presented in an everyday manner in order to aid pupil insights and understanding. It will also encourage delegates to explore the possibility that more complex mathematics might be presented in such an accessible way and invite them to express their opinions on such an approach.

DOES THE AUTHENTICITY OF THE CONTEXT AFFECTS THE TENDENCY TOWARDS IMPROPER PROPORTIONAL REASONING?

Dirk De Bock* **, Lieven Verschaffel* and Karen Claes*
University of Leuven* and EHSAL, Brussels**; Belgium

Two recent studies by De Bock, Verschaffel and Janssens (1998) revealed a very strong tendency among 12 to 16-year old pupils to apply the linear model in non-linear scaling problems (such as "Farmer Carl needs 8 hours to manure a square piece of land with a side of 200 m. How many hours would he approximately need to manure a square piece of land with a side of 600 m?"). However, these studies did not explain why so many pupils improperly made use of this model. One possible explanation for pupils' misuse of the linear model is the inauthentic or unrealistic nature of the problem situations. Some evidence for this hypothetical explanation can be found in Treffers (1987), who realized a design experiment in sixth graders on the influence of linear enlargement on area and volume that was built around the context of "Gulliver's travels", and claimed that, in this realistic mathematics education approach, pupils have no difficulty with a problem like "How many Lilliputian handkerchiefs make one for Gulliver?". However, the facilitating power of realistic and attractive contexts on pupils' ability to solve non-linear scaling problems has – as far as we know – never been investigated in a systematic way.

To investigate the influence of authentic contexts on pupils' well-documented tendency towards improper proportional reasoning, we executed a new study. In this study, 152 13 to 14- and 161 15 to 16-year olds were matched in two equivalent groups. A paper-and-pencil test, consisting of two proportional and four non-proportional scaling problems was administered to all pupils. In the first group, the test was preceded by an assembly of well-chosen fragments of a film version of Gulliver's visit to the isle of the Lilliputians, and all experimental items were linked to these film fragments. In the second group, an equal number of mathematically isomorphic problems was presented in the form of a series of non-related traditional school problems, without any contextual support.

In this poster, we present a selection of the materials and the main results of this research. In addition, we exemplify the different correct and incorrect strategies pupils applied to represent and solve the non-proportional problems in both experimental groups.

VISUALISATION AND THE INFLUENCE OF GRAPHICAL CALCULATORS

Sally Elliott, Brian Hudson. Sheffield Hallam University, Sheffield, UK.
Declan O'Reilly. The University of Sheffield, Sheffield, UK.

Visualisation is increasingly being accepted as a fundamental aspect of mathematical reasoning. Indeed many researchers stress the importance of mental imagery in the construction of meaningful mathematics (Presmeg, 1995; Wheatley and Brown, 1994). Zimmerman and Cunningham (1991) further argue that visual thinking needs to be linked to other modes of representation in order for students to learn optimally.

The potential of utilising graphical calculators to promote and encourage visualisation skills has been recognised in numerous studies. In particular, graphical calculators can be used to enable students to develop a deeper insight into functions and their graphs (Carulla and Gomez, 1997, Ruthven, 1990). Borba (1996) suggests that the use of graphical calculators mediates both teacher-student relationships and interactions between students.

This study investigated ways in which the graphical calculator mediated students' powers of visualising functions. The findings indicate that this occurred in three distinct ways. Firstly, it appeared that the graphical calculator enabled the students to access graphical images of functions quickly and easily, when perhaps they may have had difficulty otherwise. This in turn allowed them to see the problem more clearly and proceed towards a solution. Secondly, it seemed that the graphical calculator influenced students' perceptions in a positive way towards the validity of visual methods in mathematics. Thirdly, the observations suggested that the graphical calculator was instrumental in improving levels of student confidence surrounding functions. It did so by providing scaffolding for student-student interactions, which enabled students to make connections between visual and symbolic modes of representation more easily.

"*MANOR PROJECT*": PREPARATION OF TEACHER-LEADERS AND IN-SERVICE TEACHER EDUCATORS

Ruhama Even, Hasida Bar-Zohar, Orly Gottlib, Nily Hirshfeld, Naomi Robinson, Josephine Shamash, Weizmann Institute of Science, Rehovot, Israel

The *Manor Project* is used as a vehicle for the preparation of teacher-leaders and inservice teacher educators whose role is to promote teacher-learning relevant to mathematics teaching as part of effecting changes in school mathematics. The poster presents the central aspects of the *Project* in an attempt to expand and enrich understanding about professional preparation of teacher-leaders and teacher educators.

The aims of the *Manor Project*: 1) to prepare promising mathematics educators to serve as teachers, leaders and guides for secondary school teachers and provide support in the process of studying mathematics teaching and introducing changes in school mathematics, 2) to prepare resource materials for project participants and other mathematics teacher educators relevant to their work with teachers.

The preparation program is in the framework of a two-year intensive course whose central aims are: 1) to develop an understanding about current views in mathematics teaching and learning; 2) to develop leadership, mentoring knowledge, skills and work methods with teachers; 3) to create a professional reference group.

The program focuses on cognitive, curricular, technological and social aspects of teaching different mathematical topics, such as: algebra, analysis, geometry, the real numbers, probability and statistics. It also examines critical educational issues, such as assessment and teaching in heterogeneous classes, enhances mathematical knowledge, emphasizes the development of leadership skills and methods for working with teachers, encourages discussion of practical difficulties and dilemmas. The program also focuses on educational initiatives whose purpose is to effect changes in school mathematics teaching and learning.

The resource materials focus on central subjects in mathematics teaching and learning and are field-tested. Three resource files have so far been developed: Algebra, Functions and "π". The major themes in these files are: historical aspects of the central subject, selected mathematical topics relevant to the subject matter of the file, students' conceptions and ways of learning and thinking, aspects of mathematics teaching relevant to the central subject.

All resource files contain detailed suggestions of activities for teacher-development meetings and provide examples of different models for such meetings, intended to serve as a guide to teacher-educators and teacher-leaders.

The Use of Images in Primary mathematics texts

Tony Harries, Bath Spa University College
Rosamund Sutherland, Graduate School of Education, Bristol University

This presentation represents part of the work from a larger study which compared mathematics text books used in primary schools in 5 different countries – France, Hungary, Singapore, United Kingdom, United States of America. Text books play an important role in influencing the ways in which primary teachers think about teaching and learning mathematics. We take the view that what appears in a mathematics text book does not appear by chance. It is influenced by the multifaceted aspects of an educational culture. In this way mathematics text books provide a window onto the mathematics education world of a particular country. A full consideration of the results of the study, which included a comparative analysis of the use and consistency of use of multiple representations, are presented in the final report (Harries, Sutherland 1999). A number of ways have been developed for classifying illustrative representations in texts. But one of the most useful for our purposes is developed from Botsmanova (1972). Three categories are used: **Objective-illustrative**, **Object-analytical** and **Abstract spatial diagrams and sketches**.

Using these categories the presentation will contain illustrations from a range of text books showing in particular the way in which images are used to introduce pupils to the concepts which underlie multiplication and division. We suggest that it is important to make more explicit the principles influencing text book design and development so that consistency in the way in which concepts are represented and developed can be pursued and theory and practice can develop in an iterative way.

SOLVING ALGORITHMIC PROBLEMS ASSISTED BY THE COMPUTER

Ronit Hoffmann,
Kibbutzim College of Education, Israel

The main consideration leading to the development of the above mentioned course was the **need** to use the computer as a tool for solving mathematical problems. In the current situation, most college students in Israel do not know how to program. We believe that the future mathematics teacher should know how to build algorithms and computer programs. The concept of the algorithm is essential both to computer science and mathematics. The Harari Committee (1992) and the NCTM standards (1989) recommended it to be among those topics that should be expanded and emphasized in the mathematics curriculum. Therefore we decided to develop an educational unit about algorithms, in which the emphasis is on writing algorithms for a given mathematics problem, and 'running' them on a computer.

While solving problems in the suggested way, the students are exposed to new mathematical thinking (for them) - **algorithmic thinking**. They are exposed to another facet of mathematics, and different aspect of integrating computers in its teaching.

Mastery in the course, which deals with **discrete algorithmic mathematics,** invites further opportunities of integrating the computer in mathematics classes in all the learning stages, and gives the opportunity to solve complex problems, assisted by the computer, even in more advanced mathematics courses. During our study, this course served us as an introduction to that of Computer Oriented Numerical Mathematics. The fact that the students (176 students during the four years of the experiment) who had not known any programming language, were successful in tackling the numerical problems in the later course, demonstrates that the aims of the introductory course were achieved, and within a relatively short time.

The poster will demonstrate a sample problem, one of several problems that are dealt within the above-mentioned course. The problem is followed by a variety of different solutions that are presented in a gradual way. It will emphasize how the students, while solving the problem, are exposed to several kinds of algorithms - due to different problem solving strategies, and how they learn to perform each of them in the computer, using the spreadsheet.

A Study on Students' and Teachers' Conception of the Effects of Dynamic Geometry Software

Kyoko Kakihana *, Katsuhiko Shimizu **, Nobuhiko Nohda ***
*Tokyo Kasei Gakuin Tsukuba Women's University,
**National Institute for Educational Research, ***University of Tsukuba

Dynamic geometry software (DGS) has been used in schools for about ten years in Japan. DGS such as Cabri Geometry, Geometric Constructor and etc. are commonly used. Workshops/ seminars for the use of DGS have been held for teachers for its implementation. As a result of these works, DGS started to be disseminated in many classes. On the other hand, the possibility that researchers identified as merits of the use of DGS seems to be realized in a limited extent, in these classrooms [(1)]. The reasons why this limited realization might due to the purposes for what teachers use DGS and the recognition of actual effect of DGS by teachers and students.

Purpose: The purpose of this research is to identify students' and teachers' conception of effects of DGS and to find similarities and differences between these conceptions of effects and research findings.

Method: The opinions/ impressions from 23 reports of Cabri classes were categorized and analyzed: # of students: 164,sentences labeled: 270, # of teachers: 15, sentences labeled: 106

Result

(1) By using DGS, students recognized they could learn and enjoy geometry more actively. There were 44% of students' sentences and 26% of teachers' sentences on affective effects. These affective effects are coincident with the research finding of the effects of using Cabri[(2)].

(2) Some teachers' expectations were recognized also by students. Some teachers expect explanatory works/motivating to proof in DGS as researchers' finding [(3)]. And teachers recognized that students were motivated to make a proof through exploration/discovery.

(3) The problems on situation/ timing when to use DGS, on development of drawing ability, on the task designation for DGS and on teachers' over expectation were pointed by teachers themselves. These obstacles are also pointed out by researchers like Laborde C. [(4)] and others. These obstacles explain the limited realization of merits of DGS mentioned above.

THE FUNCTION AND THE STUDENTS OF ASETEM/SELETE: A CASE STUDY

Athina Katalifou, University of Athens, School of Philosophy,
E-MAIL: akatal@cti.gr

This study is an exploratory activity (teaching experiment) for the teaching of functions involving a multi-representational software «Function Probe» (Confrey, 1992) in ASETEM/SELETE, a teacher's college.

The aim of this study was the observation of the way students understand functions and especially transformations, using one more tool: the computer (Kynigos, 1995).The main questions of the study concerned: the attitude of the students towards the software, the way they deal with mathematical problems and the impact of technology in the problem solving stragedies they used.

The teaching of transformations, that mainly concerned the parabola $y = x^2$, started with the visual and graphical forms and was extended to data table and algebraic equations. It should be noted that the experiment consisted of four parts:

1. **phase 1**: the students had to match different parabolas starting from the prototype $y = x^2$ and using the transformation icons of Function Probe.
2. **phase 2**: using the graph and the data table of some parabolas the students were asked to try to think out the algebraic equations.
3. **phase 3**: the students studied the relationship between changes in different graphs and changes in coefficients of their algebraic equations.
4. **the task**: it concerned the possibility to use the tool demanding an exploratory behaviour from the students.

The data, and especially the observed talk, were analysed qualitatively (Cohen and Manion, 1997). According to recent research emphasis is placed on the joint construction of knowledge (teacher-learner, learner-learner).Though the time available was insufficient for differentiating the already established concepts of the students, formed through a traditional environment, the results pointed our that the utilisation of Function Probe leads probably to a better understanding and suggests more research on the function concept.

A GEOMETRIC APPROACH TO BUILD INEQUATION MEANING

Estela Kaufman Fainguelernt — IEM, Santa Úrsula University,Brazil

Franca Cohen Gottlieb — IEM, Santa Úrsula University, Brazil

The data has been collected since 97, students from a public high-school, a low income group working with a teacher-researcher, Alzir Fourny Marinhos, in Rio de Janeiro, Brazil. He is working in his master thesis advised by the authors.
Our main question: What is the role of graphical representation in the process of build inequation meaning?
To answer this question we suppose that through the visualization process students could have a better understanding of the algebraic solution for inequations.
For example, the majority of our students solve inequations following rules:

$x-1>0$ $\quad -x>1$ $\quad x>-1$

They use a single technique, without connection with the relation order nor with functions. It is a kind of ritual and before, when they used the same technique to solve equations, "it works".
Using a geometrical approach they begin represent intervals, after that they plote functions as, $f(x) = ax + b$.
Using the example above, $f(x) = -x-1$, the function is ploted and students observe when the function is positive and when it is negative.
Comparing the graphic solution with algebraic solution they easily understand that the first solution is not the right one.
Seems to us a certain unhappy circularity, which states that inequation is badly taught because is misunderstood and it is misunderstood because it is badly taught.
Several kinds of mathematical concepts are tied to similar situation. The conceptual field provides a framework for this research, Vergnaud (1991).

"A conceptual field is defined as a set of situations, the mastering of which requires mastery of several concepts of different natures"

The research mastery historical evolution of relation order, algebraic aproach through daily-life situation, and a geometric aproach.

Complementary Strategies To Cognitive Analysis:
The Case Of Mathematically Successful Populations

Evgeny Kopelman
Hebrew University of Jerusalem, Israel

It is not a surprise that the less researched school populations in mathematics education are those at more advanced levels of studies and who generally had no problems in passing standard evaluations. This doesn't say that they may not have any difficulties with basic mathematical notions. In fact, they do - as has been shown elsewhere (Vinner & Kopelman, 1998; Kopelman, 1996). While understanding their difficulties is very instructive for mathematics education, it poses a real challenge before a researcher, since standard methods seem to be not easily applied in this case.

First, those who do such research run a risk to fall out of the research tradition, since they can't draw on the known theoretical frameworks and results, which, as a rule, tend to speak about an average student. For a researcher studying mathematically successful populations it is useful to

ask instead, whether he or she may imagine a chosen model being applied also to oneself.

Secondly, a researcher analyzing responses to questionnaires delivered to these populations or transcripts of conducted interviews will rarely find there flaws in logic , inability to think in abstract terms or to appreciate the idea of the mathematical proof. On the contrary, the

explanations will bear the unmistakable qualities of experienced learners of mathematics and the researcher will have to look for the extra-cognitive reasons which had brought the respondents - often unanimously - to their certain line of thinking and, eventually, to wrong answers. Whereas

traditional cognitive studies focus on student's cognition grappling with a certain mathematical notion, for this type of research neither of them is certain; the responses of the students often make sense only in the context of the didactic tensions which accompany the teaching of that notion.

The poster presents examples from research which revealed difficulties of mathematically advanced students when they had to apply some notions of school algebra and geometry. The examples are accompanied by historico-didactical deconstruction of the corresponding notions, which may be also used in teacher education.

THE RICE VIRTUAL LAB IN STATISTICS: A WEB RESOURCE FOR TEACHING STATISTICS

David M. Lane, Rice University

The Rice Virtual Laboratory in Statistics is an integrated combination of a set of simulations/demonstrations, an electronic textbook, case studies, and a data analysis program. The lab currently contains 16 simulations and demonstrations designed to make abstract concepts concrete and allow students to investigate various aspects of statistical tests and distributions. Topics such as how the choice of bin width affects a histogram, sampling distributions, restricted range, and repeated measures designs are illustrated. Example results of the sampling distribution simulation are shown below. The left portion of the figure illustrates the effect of sample size on the sampling distribution of the mean; the right portion shows how the sampling distribution of the mean differs from the sampling distribution of the median when the sample size is 10 and the parent population has a uniform distribution.

The electronic textbook covers topics typically included in an introductory course in statistics and contains over 2,000 links among related topics. The case studies demonstrate the real-world applicability of statistics and illustrate many methods of descriptive and inferential statistics. They include the raw data so students can perform their own analyses if they wish. The data analysis program can create boxplots, histograms, stem and leaf displays, and scatterplots as well as basic statistical analyses such as correlation, regression, and simple analysis of variance.

The four components of the lab are closely integrated. The textbook has links to simulations that illustrate concepts in the text and the simulations have many links to the textbook. When data from case studies violate an assumption of the inferential test performed, simulations are used to assess the practical effect of these violations. Many of the graphs and analyses presented in the case studies were produced by the statistical analysis program.

REINFORCING TEACHERS UNDERSTANDING OF LIMITING PROCESSES BY CONSIDERING SEQUENCES OF PLANE FIGURES

J. Mamona Downs & Martin Downs
University of Macedonia

In our presentation we will indicate what sequences of plane figures and their limits are. The topic is not commonly familiar and, partly because of this, has not been "institutionalised". This helps in raising the following issues of educational interest:

(1) It is well known that many students have cognitive problems with limits of real sequences (e.g. [1]). It would be of interest to know how these problems may change with limits of figures.

(2) It has been remarked often in the literature (e.g. [2],[3]) how difficult it is for teachers who have assimilated a complicated concept (say, that of the limit of a real sequence) to understand the problems a student has when (s)he first faces it. In teachers training, the introduction of a "parallel" concept (but new to the teachers) may prompt better understandings towards these problems of students in the original concept.

(3) The exercise of forming definitions may provide a way of partially dissipating the "Platonic" bias found in many people towards Mathematics. (Whereas the importance in regarding Mathematics as a product of the human mind is widely acknowledged in research). As with limits of figures we have several different approaches to take for our definition, we have much room in our paradigm for debate and criticism, activities rarely found in pedagogical practices in maths.

With these issues in mind, we designed a fieldwork to use in a pilot study. This involved 16 maths. secondary school teachers with varying teaching experience. The fieldwork consisted of one three - hours session, where at different stages the teachers were asked to examine given tasks concerning limits of sequences of plane figures and to address their thoughts publicly to the whole audience and hence to invite open discussions.

The study revealed many phenomena of diffuse character and its results suggest some particular avenues worthy of further research. The poster presentation will largely consist of diagrams of sequences of plane figures and (when appropriate) their proposed limits; these will be carefully selected to illustrate some of what we feel are our more significant findings.

ON DYNAMIC SOLUTIONS OF THE QUADRATIC EQUATIONS USING A COMPUTER

Matumoto Yosifumi
Nishinippon Institute of Technology,kandamati,Fukuoka,Japan

A solution of a quadratic equation is obtained by factoring decomposition or the quadratic formula algebraically.The solution is explained as the intersections of the parabola and the x-axis.The purrpose of this communicationis to construct the solutions on the computer display by using parallel lines and circles dynamically.

We consider a quadratic equation with real coefficients

$$(A) \qquad ax^2 + bx + c = 0 \quad , \quad a \neq 0$$

such that the graph of quadratic function $y = ax^2 + bx + c$ with vertex (r , s) and passing through a point (p , q). Then $b = -2ar$,$c = ar^2 + s$ and $q = a(p - r)^2 + s$.

We regard the display as the orthogonal coodinate plane . The solution points are constructed step by step by using parallel lines and circles .In order to the constructions can be seen dynamically , we present a program with the following properties.

(i) Through the process of constructions, when a figure is constructed in a step,data need for later remain and others are wipe out and go to next step.

(ii) Drawing of parallel lines : Drawing of a parallel line m through the point P which is parallel to the given line L. Starting from L, we construct the family of lines m(t) which is parallel to L such that when a line m(t) is drawn , then next line is drawn and m(t) is wiped out . Thus, we can imagine a parallel line m(t) approch to m from L dynamically.

(iii) Drawing a circle : A dotted point moves continuously and draw a circle.

Following our program ,a student can easily construct the solutions of a quadratic equation on the display.The construction is visual and dynamic, which means that the student can imagine the solutions geometrically.And we believe he also understand that a real solution and complex solution has the same character essentially.

Exposure of "Self Knowledge" in Solid Geometry among Mathematics Teachers Through Reflective Process

Shosh Millet – Achva Academic College
Dorit Patkin –Kibbutzim College of Education

The teacher's "self knowledge" is an element in his or her pedagogic-practical knowledge (Zuzovski 1998, Patkin & Millet 1997, Clandinin 1987). This study exposes the "self knowledge" of mathematics teachers in primary schools regarding solid geometry, through reflection. Children are exposed to solid geometry on various levels, from kindergarten age up. Previous studies have testified to the fact that pupils encounter difficulties - aversion and fear engendered by geometry. A good number of teachers have aversions to solid geometry, as well (Ben-Haim 1987). Therefore, those engaged in teaching the subject must address the problem and try to overcome these difficulties. In this poster we have introduced the reflective process among teachers, including application of this process to the Van-Hiele Theory in solid geometry.

In order to expose the "self Knowledge" of a group of teachers enrolled in the enrichment courses in solid geometry, a two-stage reflective questionnaire and a post-intervention questionnaire regarding application were employed. The intervention plan involved an encounter with the Van-Hiele's theory in plane geometry and adaptation and adoption of this theory to spatial concepts.

Sample: 18 primary school teachers certified to teach math, with at least five years teaching experience, enrolled in the enrichment course

Results indicate that 50% of the teachers evaluated themselves to be at the third level, 6 teachers rated themselves at the final level, and the rest rated themselves at the second level.

The rationale and examples of findings and evaluations expressed by course participants will be presented in the poster.

MAGIC CIRCLES: AN INVITATION TO EXPERIENCE CAS TECHNOLOGY FROM A DIDACTICAL POINT OF VIEW

Esther Openheim and Nurit Zehavi

Weizmann Institute of Science, Israel

In order to prepare teachers to teach with modern technology, Balacheff ('?93) suggested that teachers be provided with opportunities to experience mathematics from a mathematician's point of view, and to experience technology from a didactical point of view. We have provided such opportunities by introducing a relatively new technology, Computer Algebra Systems (CAS). The teachers learned to use the CAS software *Derive* in rich problem-solving situations and explored the didactic strategies that make effective use of this technology. One of the problems that the teachers encountered in the course was *Magic Circles.*

Magic circles involve a rich variety of mathematical structures, concepts and ideas, such as composing linear functions, inverse functions, fixed points, group theory, complex numbers, and vectors. Given a closed circle of 10 linear functions, we begin at the top of the circle and substitute a number of our choice. The outcome is substituted in the next expression and so on, proceeding clockwise, until we complete the circle, and the final output turns out to be the same number with which we started. We posed several problems. For example:

1. If we break the circle at any other function, substitute a number, proceed clockwise and complete the circle at the new point of entry, will we always finish with the same number with which we started?
2. Is it possible to construct *magic circles* such that if we traverse them in either direction, the output is the same as the input?

To answer the first question, "the breaking of the circle", it should be realized that the whole circle reduces to the identity function, function composition is associative, and a linear function has an inverse. Thus,

$$(F_6 \circ F_5 \circ F_4 \circ F_3 \circ F_2 \circ F_1) \circ (F_{10} \circ F_9 \circ F_8 \circ F_7) = I(x) = x$$

In using a CAS, the input requires a particular forced way of viewing things and expressing relationships and the output needs to be interpreted similarly. The poster will include a variety of approaches to a series of problems related to magic circles, demonstrating the expressive power of the technology in integrating mathematical concepts, methods, and visual representations.

ELEMENTARY CHILDREN AS REAL-WORLD PROBLEM SOLVERS: THE IMPLICATIONS OF GROUP WORK

Andrea Peter-Koop
University of Münster, Germany

The study-in-progress reported in this poster was initiated with the concern that little is known about elementary students' real-world problem solving competencies and strategies as related to the dynamics of group problem solving. Although we are reasonably well aware of the individual capabilities of single students, the complexity of the 'normal' classroom in terms of mixed abilities, and the variety of socio-cultural (out-of-school) experiences of children as well as their quantitative and qualitative participation in classroom interaction have been almost completely neglected (Pehkonen 1991). The objective of the research is to identify the collaborative and individual mathematical problem solving strategies and competencies that groups of third and fourth graders (8- to 10-year-old children) apply with respect to open real-world related tasks.

The following criteria guided the development of the open problems used in this classroom based study: the problems should be 'open-beginning' as well as 'open-ended' real-world tasks that provide 'reference contexts' for elementary students; the wording of the problems should not contain numbers in order to avoid that the children immediately start calculating without first analysing the context of the given situation and in order to challenge the students to engage in estimation and rough calculation and/or the collection of relevant data.
To date, four such problems have been posed in both grade 3 and grade 4 classes which were subsequently divided into working groups of 4-5 children. Each group was videotaped while solving the problem.

The methodological framework of the project is based on an 'Interpretative Classroom Research' approach (Bauersfeld et al. 1988) following a strict analytical procedure for the interpretation of the video data.
As the analysis of the data is not yet completed, this poster will show examples of students' solutions and excerpts from their discussions which illustrate some of their strategies and difficulties, focussing on their estimation and/or rough calculation strategies and the forms of visualisation they developed in order to represent sub-problems/aspects which arose during group discussion.

What is the relationship between the teaching and learning of early addition in the primary classroom?

Alison J. Price

Oxford Brookes University, OX33 1HX, UK

Background

Young children's development in the learning of addition has been extensively researched and minutely documented (see for example Nunes and Bryant 1996) so that we know that there is a development through 'counting all', 'counting on', 'known facts' and 'derived facts'. However it would seem that not all children progress through these stages, as Gray and others (Gray and Tall 1994) have identified older children still using elementary counting strategies to attempt to solve more complex addition. The effect of teaching on the children's development has been little researched. In England children begin full time schooling at the age of four or five and encounter formal arithmetic very early. What effect does this early teaching have on their understanding?

The Study

This study therefore investigates teaching and learning, in terms of how the teacher presents and represents mathematics to the children and the sense that the children are making of their work. Participant observation carried out in four classes (four teachers and 121 children aged four to six years) during one lesson a week over a period of six months, provided 60 teaching episodes for analysis. The teacher's representation of mathematics was analysed using an adaptation of a model from Lesh, Post and Behr (Lesh, et al. 1987) which identifies the inter-relationships between manipulative materials, real world scripts, pictures, spoken language and symbols. Analysis of the children's responses defines the way in which their previous social, linguistic and mathematical understanding affects their learning. Analysis of this data is still continuing.

The poster

The poster display will further explain the process of data analysis. Details of initial findings from this research will be presented, with emphasis on the role of written recording and the use of symbols in identifying the children's thinking. This will be illustrated with examples of children's work.

CONSTRUCTING INQUIRY QUESTIONS BY STUDENTS

T. Resnick M.Tabach

Weizmann Institute of Science.

Compu-Math project is a development, implementation and research project for middle school and high-school mathematics. The learning environment includes tasks organized around large-scale problem situations, which can be investigated using various approaches. The students, as investigators, are involved in mathematical thinking processes, such as looking for appropriate strategies, posing hypothesis and accepting or rejecting them, monitoring, asking questions, etc. Students have at their disposal computerized tools such as multi-representational software. They are encouraged to decide which representations to use, when to switch from one to another, when and how to link them, and in which medium to work (e.g., paper and pencil, technological tool, discussion in teams).

One type of activity, *The Problem of the month*, is open-ended, and includes most of the topics that the students have learned recently.

Our poster will illustrate an example of *The Problem of the Month* called *The Animal Park*, in which we present a situation, without any questions. Each part of the situation is presented in a different representation (words, table, graph or algebra). The students are required to construct inquiry questions. We give a collection of words, concepts and expressions, connected with the situation, to help and guide the students. In their responses, most students refer to more then one part of the situation. Hence, they have to deal with more than one representation, and to perform transitions between them. They does these transitions deliberately, and the construction of the questions involves all the mathematical thinking processes that were mentioned above.

Teachers and Computers: Teachers Cultures

Elvira Santos - Escola Básica de Álvaro-Velho - Portugal

This research intends to contribute to a better understanding of teachers cultures, related with the use of computers in the classroom.

The study's framework draws from "teaching cultures are embodied in the work-related beliefs and knowledge, teachers shared - beliefs about appropriate ways of acting on the job and rewarding aspects of teaching, and knowledge that enables teachers to do their work" (Feiman-Nemser and Floden, 1986, p.508). The content of teacher cultures consists "of the substantive attitudes, values, beliefs, habitats, assumptions and ways of doing things that are shared within a particular teacher group, or among the wider teacher community. The content of teacher culture can be seen in the way teachers think, say and do." (Hargreaves,1995,p.166)

In this research we studied how teachers use their knowledge about computers and their practice. The conceptual framework this study is shown in Figure 1.

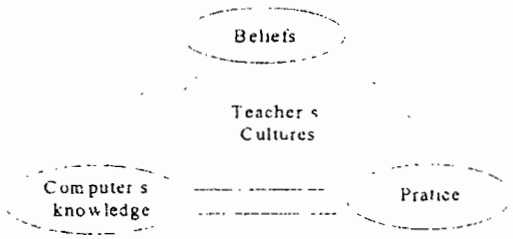

Figure 1

In this poster we will show and compare teacher's cultures of three mathematic teachers: i) one teacher who use the computer in classroom; ii) another that had abandoned the computer's use with pupils; iii) and, finnaly, one teacher who never used it.

CAN YOU TELL ME WHETHER THIS IS A PROOF?

Annie Selden
Mathematics Department
Tennessee Technological University
Cookeville, TN 38505 U.S.A.

John Selden
Math Ed Resources Co.
P.O. Box 2781
Cookeville, TN 38502 U.S.A.

Eight mid-level university mathematics majors, the entire cohort in a "transition to abstract mathematics" course, were interviewed individually and asked to think-aloud as they determined whether four "proofs" of a theorem, generated by similar students, were proofs. All eight students considered the "proofs" carefully line-by-line, finding some notational and computational anomalies; however, they apparently often did not notice or check structural difficulties, such as the proof of the converse being offered.

First, the students were asked to read the theorem, give examples, and attempt a proof on their own. Then each of the four "proofs" was presented separately. At this stage, the students were only able to judge correctly about half the time, with some saying they were "unsure." Next, students were given all four "proofs" and asked whether they would like to rethink their judgments. As the interviewer continued to probe over the hour to hour-and-a-half interview, they gradually came to make more correct judgments, eventually being correct in about 80% of the instances. At the close of each interview, students were asked several questions about how they read proofs. All said they read proofs very carefully and checked all steps to make sure everything followed logically. However, their actual ability to tell whether the four "proofs" presented in the interview were correct was initially no better than chance.

Since all but one were preservice secondary mathematics teachers, this calls into question their ability to judge the correctness of secondary pupils' proofs. Perhaps validation of proofs, that is, the process of checking them, which is now only a part of the implicit curriculum of most mathematics departments should be made part of the explicit curriculum.

The Statement and One of the Four "Proofs"

For any positive integer n, if n^2 is a multiple of 3, then n is a multiple of 3.

(a). Proof: Assume that n^2 is an odd positive integer that is divisible by 3. That is $n^2 = (3n + 1)^2 = 9n^2 + 6n + 1 = 3n(n + 2) + 1$. Therefore, n^2 is divisible by 3. Assume that n^2 is even and a multiple of 3. That is $n^2 = (3n)^2 = 9n^2 = 3n(3n)$. Therefore, n^2 is a multiple of 3. If we factor $n^2 = 9n^2$, we get 3n(3n); which means that n is a multiple of 3.?

ANGLES IN TRIANGLES AND PRALLEL LINES - WHAT ARE THE DIFFICULTIES AND MISCONCEPTIONS?

Behiye Ubuz
Middle East Technical University, Ankara, TR

The concept of angle is one of the more basic ideas in understanding all geometrical concepts and further mathematics such as calculus. This study investigated 10^{th} and 11^{th} grade Turkish students' learning of the concept of angle given in triangles and parallel lines and the difficulties in finding its measure. In addition to that this study also dealt with whether and how the gender issue could influence learning. A diagnostic test including 11 open-ended questions was administered to 67 students from a private college at the end of the second semester of 1998. 34 of these students were 10^{th} grade and the rest were 11^{th} grade students. There were 23 female and 11 male students for the 10^{th} grade, and 11 female and 22 male students for the 11^{th} grade. The test was administered in the usual classroom conditions. The time allowed was about 50 minutes.

Geometry as a separate course is given starting from 10^{th} grade. While geometry I in grade 10 includes Lines, Angles and Triangles, geometry II in grade 11 includes Polygons, Circles, Vectors, and Solids. Time allowed for Geometry I and Geometry II is two and four hours a week respectively.

The analysis of the written responses given to the diagnostic test questions revealed that: (i) the percentage of students answering correctly increased with class grade level (maturity, experience, or both). On the contrary, misconception or errors had the same pattern of overall incidence from one grade level to another; (ii) questions including angles in parallel lines are much easy than questions including angles in triangles for both sexes; (iii) the comparison of "no answer" and "incorrect answer" categories for both gender, for almost every questions, showed some differences. It seems that the female students, because of their initiative, made much more errors and the male students.

Also it was noticed that the errors made were due to: 1) incorrect choice of angles as the base angles of a isosceles triangle; 2) thinking that the base angles of each isosceles triangle should be the same; 3) incorrect application of exterior angle theorem in a triangle: incorrect choice of angles; 4) not knowing the meaning of traversal line cut two parallel lines; 5) assuming something which is not given.

During the presentation the results mentioned above will be shown on the examples of questions.

An in-depth analysis of Japanese elementary school mathematics teachers' manuals: A preliminary report

Tad Watanabe, Towson University, USA

The recent results from the Third International Mathematics and Science Study (TIMSS), specially the videotape study, showed that the Japanese mathematics classrooms are organized very differently from those of the US and Germany. Although the TIMSS videotape study focused on the 8th grade level classrooms, other researchers' reports indicate that these differences are also present in elementary school classrooms.

On the other hand, some researchers have reported that many elementary school teachers, both in Japan and in the United States, rely heavily on their textbooks (for example, Shimahara & Sakai, 1995). Although textbooks have been analyzed previously, most of the time, the focus was to identify the contents of mathematics curricula. However, if teachers are to 'rely' on textbooks, the books they will use is most likely the teachers' manuals.

In this session, I will present the results from a study that is analyzing the contents and organization of Japanese elementary school mathematics teachers' manuals. The questions the study addresses are: What information is provided in the teachers' manuals? How are the teachers' manuals organized? How consistent are the contents and organization of the teachers' manuals with the nature of mathematics teaching in Japan reported in the existing literature.

RESEARCH REPORTS

TEACHER PROFILE IN THE GEOMETRY CURRICULUM BASED ON THE VAN HIELE THEORY

Afonso,C; Camacho, M. and Socas, M.M.
University of La Laguna. Tenerife. Spain

Abstract

In this paper we present a study of six in-service teachers. Using various instruments such as diagnostic tests to assess the level of the teachers' geometrical reasoning, structured interviews, learning unit notes and class session video recordings, we study the teachers' experiences and behaviour regarding the teaching/learning of geometry and we analyze whether the profile of the teachers in question is or is not in keeping with the profile of the ideal type of teacher who, according to current Educational Reforms (MEC 1989), is presumed to be prepared for successfully teaching the present innovative Matehematics curriculum which is based on an interpretation of the Geometry curriculum set forth in the Van Hiele model of geometrical reasoning. We conclude that, in order to implement these curricular innovations with some measure of security, it is necessary to set up in advance comprehensive teacher training programmes. These programmes should not be an isolated part of the curriculum nor a series of recipes about how to put Van Hiele programmes into effect, but rather an interpretation, justification and orientation arising from the teachers' practice itself.

Introduction

The role played by Geometry in the compulsory education curriculum has been under discussion throughout the school Mathematics community for the past few decades. Its importance within the curriculum has been clearly reflected in the various documents which at an international level outline the path to be followed in Secondary School Mathematics teaching (NCTM 1991); NRC, 1989). Among these discussions (Freudenthal, 1973; Clements and Battista, 1992) the van Hiele model of Geometric reasoning constitudes a theoretical framework that enables us to design and restructure the Geometry curriculum in compulsory education (Geddes, 1992; Geddes and Fortunato, 1993; Burger and Culpepper, 1993).

This frame of reference means our accepting a major curricular change in Geometry that has multiple effects, especially with regard to the subject (Geometry), the students and the teachers.

To date, research on Geometry from the van Hiele perspective has focused more on the structure and organization of contents and on a better understanding of the students' knowledge and behaviour (Clements and Battista, 1992) than on the those problems the teacher faces when putting this curriculum into practice.

According to followers of the Van Hiele theory, mathematical thought follows a concrete model made up of two parts. Firstly, a descriptive part whereby a sequence of types of reasoning ("levels of reasoning") can be identified; an individual's mathematical reasoning progresses through these various levels from the moment s/he begins learning until s/he reaches the maximum degree of intellectual development in

this field. Secondly, an instructive part whereby teachers are given guidance about how they can help students most easily attain a higher level of reasoning as they pass through "learning phases".

As is well known, the Van Hiele model (Fuys, Geddes and Tischler, 1984) is made up of five levels of reasoning –recognition (visualization), analysis, classification (informal deduction), formal deduction and rigour; and five learning phases – information, directed orientation, explication, free orientation and integration.

The aims of this empirical, descriptive study are as follows.

a) To compare the situation of a group of in-service teachers regarding their experiences and behaviour in Geometry teaching/learning situations.

b) To analyze whether the profile of the teachers in question is or is not in keeping with the profile of the type of teacher who, according to current Educational Reforms (MEC 1989), is presumed to be ready to teach successfully the present innovative Mathematics curriculum based on an interpretation of the Geometry curriculum set forth in the Van Hiele geometrical reasoning model.

Research Context and Methodology

The present study was carried out in six public schools in Tenerife during the academic year 1996-97. Six in-service teachers took part, all of them with more than 10 years of experience. These teachers taught Mathematics at Year 7 level (11-12 years old) and their places of work were distributed as follows: Teachers B and D (urban area), Teachers A and C (suburban area), and Teachers E and F (rural area).

An essentially qualitative methodology was used. Test instruments enabling us to determine the teacher's level of reasoning (Usiskin, 1982; Jaime, 1993) and structured interviews with closed protocols were employed together with instruments that allow us to undertake studies through a purely interpretive analysis of video-taped classroom sessions and an examination of the learning unit notes used by the teachers. We have considered that it is the suitable methodology to use because the research problem has to do with aspects related to teacher's thinking. That presupposes that we have to obtain data, not only from the teacher's geometrical knowledge but also from his oppinions and decissions in a giventeaching situation

Instruments

The data collection instruments used were:

1.- Structured interviews with closed protocols and open-answer questions These enable us to obtain information about individual differences (D.I), institutional limitations (L.I), the nature of the task the teachers set their Geometry students (N.T.), their opinions of their students (J.P.E), the geometrical contents (J.P.C.) and the kind of decisions the teachers must make regarding teaching and learning (D D.), as adapted from the model proposed by Shavelson and Stern (1981).

In the teaching decisions category (D.D), Geometry teachers' didactic practices are analyzed and are then related to their classroom styles. In order to identify the various styles of the teachers under study, we adapt the terminology used by Porlán (1993): traditional style (excessive concern with contents in their formal logical

aspect); technological style (excessive concern with operative and behavioural objectives); spontaneous style (excessive concern with the activities carried out by the estudents), and investigative style (concern to integrate desirable scholarly knowledge and the students' knowledge and interests). However, in this study we fuse together the "spontaneous" and "investigative" trends and call this amalgam simply "investigative", this being the term used in current Educational Reform programmes in the Mathematics field, as we do not possess enough elements to differentiate the amalgamated terms with the instruments we use.

2.- Tests to assess teachers' geometrical thought (Usiskin, 1982 –TU and Jaime, 1993-TJ). Although there are other diagnostic instruments to assess reasoning levels (Mayberry, 1981; Crowley, 1987); which have been used with more or less success in various research projects, we opted to choose both these tests for two reasons:

a) To determine the degree of acquisition attained by the teachers, in accordance with the continuity hypothesis set forward in the Van Hiele Theory.

b) To compare the information provided by two different diagnostic instruments deriving from contradictory theories (the discrete and the continuous) and thereby contrast results.

3 - Class notes required from the teacher before s/he performs in class. Taking into account these notes, we are able to study the type of decisions the teacher has to take during the class. The structure of the notes enables us to examine the type of organization the teachers make beforehand. We can identify two different tendencies towards either conceptual or curricular organization. By conceptual organization we mean the type of organization that treats contents as a basically instructive element which are then organized from the point of view of the internal logic of geometry. By curricular organization we mean the type of organization that treats contents as a basically educational element and which are then organized from a curricular point of view. In other words, contents are considered epistemologically and phenomenologically as an educational tool in order to attain skills that also require a pedagogic and didactic organization (Methodology) and an organization of the assessment process designed to measure the skills acquired.

4.- Video recordings of two one-hour sessions taken by the teachers and the observations made by an external observer in the classroom. The classroom study made by the external observer and the analysis of the transcriptions of the video recordings are carried out using the observation guidelines adopted by Walker (1984). In the present work we consider the following categories: students (groupings, motivation and participation in tasks), teachers (suitable mathematical vocabulary, teachers' answers to students's questions and class work distribution), resources (textbooks, written materials, graphic materials, manual materials and other resources) and performance of the learning unit (what is taught –concepts, procedures or attitudes; how the task is organized and what the role of the teacher is when the task is carried out).

Results analysis.

We should point out that it has been difficult to find teachers prepared to carry

out educational experiments which imply the implementation of innovations as proposed by Van Hiele. So we cannot claim that selection of the 6 teachers taking part in our research was random.

Based on the data shown in Table 1 we can see that the teachers use different teaching styles in the classroom: Teachers A, C and F usually employ an investigative style rather than the traditional, while Teachers B, D and E use the traditional style rather than the investigative. Except for Teachers B and E, the technological style is hardly ever used.

such as that proposed by Jaime (1993), as this is quite hard and implies a great deal of work on the part of the respondent. In our study, one of the 6 teachers did not answer the last five questions in the Jaime test; so, with only the results from the Usiskin test to go on, this teacher (Teacher C) is placed, not very reliably, at Level 1, which is not very reliable. With regard to the remaining teachers, two of them (Teachers A and D) are placed at Levels 3 and 4, their results from both tests coinciding for the most part, while the other three teachers are at Levels 2 and 3 (Teachers B, E and F). The results of the tests are shown in Table 2. In the first column (TU) we give the number of correct answers/total number of questions for each teacher, and in the second column the degree of acquisition for each level according to the corresponding percentage (Complete acquisition = C, High acquisition = H, I = Intermediate acquisition, Low acquisition = L, No acquisition = N). To interpret the degrees of acquisition, see Gutiérrez and Jaime (1995).

LEVEL 5	4/5	-	0/5	-	0/5	-	3/5	-	1/5	-	1/5	-

Table 2. *Geometric Reasoning Tests*

The Geometry taught in the Mathematics curriculum for students aged between 9 and 13 years involves levels of attainment of between 1 to 3 on the Van Hiele geometrical reasoning scale. Accordingly, as the subjects of our research teach the final two years of Primary and the first two years of Secondary education, we can see that only Subjects A and D attain the geometric reasoning levels deemed appropriate for carrying out the tasks at these stages of education.

The classroom notes handed in by the teachers (see Table 3) show a greater tendency towards conceptual organization (Teachers C, D, E and F) than curricular organization.

Based on analysis of the video- recorded sessions, groupings for undertaking tasks confirm the tendency towards group work in the case of Teachers B and C, and the tendency towards individual work in the case of Teachers A, D, E and F, in other words, most of the teachers involved in our research However, the tendency expressed in the interview was group work (Table 1). Also, there is a greater tendency towards individual work (A, D, E and F) than group work (B and C).

Generally speaking, the teachers are quite rigid and exercise excessive control when it comes to class dynamics; nonetheless, they adopt more flexible postures when communicating course contents, suitable vocabulary and correct answers to students' questions and doubts. Although there is a tendency in teachers' answers towards an homogenized treatment rather than individualized treatment (Teacher F), the other teachers tend to answer the whole group (A, B and C) or establish some balance

between individual and group answers (D and E).

Teachers A and B organize classroom tasks from an investigative focus when carrying out the learning unit, and these teachers also play the role of guides in this area. The other teachers (C, D, E and F) set tasks in a routine fashic playing the role of transmitters of knowledge. In these cases, although to a lesser deg in the case of Teachers A and B, organization is fundamentally curricular, as we have noted before.

Worthy of note is the way in which Teachers A, D and E confirm the expectations they expressed in their respective interviews, while the other teachers (B, C and F) fail to live up to these expectations.

Conclusions

The reforms in the Spanish education system (MEC, 1989) involve major changes in teacher training and imply significant direct effects on teachers' classroom work. Such is the scope of these reforms that curricular proposals made on the basis of Van Hiele theories require a teaching community possessing certain skills and attitudes (teacher profile) that might lead to major changes in teachers'epistemological outlook, which can be summarized as follows:

1. Scientific training in Geometry to at least one level higher in geometric reasoning than the level teachers will work on with their students.
2. The concept of learning in terms of guided investigation.
3. Ability to work with sets of student with very different basic skills, interests and necessities as far as Geometry is concerned.

4. The idea of the Geometry curriculum as an educational tool that enables students to attain the various levels of geometric reasoning.
5. Positive valorization and use of group work.

The present research work forms part of a broader project we are undertaking in conjunction with in-service teachers (Afonso, Camacho and Socas, 1995 and 1997), which is designed to find out whether there is any relationship between the styles of teachers working in our education system and the profile of the ideal teacher capable of carrying through the curricular proposals based on Van Hiele's theories. Our aim is to establish the means for teachers to change their attitudes and help understand better the dynamics of the processes involved in curricular changes of this nature.

On the basis of the various instruments used in our research work, we have interpreted teacher profiles in the terms set out in Table 4. The data are taken from geometric reasoning tests (Table 2) and classroom notes and video recordings (Table 3). In Table 4 we do not refer to the data obtained in the structuredinterviews because of the contradictions apparent in the data obtained from the various instruments.

We can see that Teacher A would have the ideal profile for carrying out a curriculum designed from the Van Hiele persepective if we could aid him to foster group work and repect class dirrerences, though his teaching is effective and highly individualized.

Teacher profile	A	B	C	D	E	F
1. Scientific training (Table 2)	3-4	2-3	(TU) 1	3-4	2-3	2-3
2.Guided research (Table 3, items 4 and 5)	Yes	Yes	no	no	no	no
3.Respect the heterogeneity of the class (Table 3, item 3)	no	no	no	Yes-no	Yes-no	Yes
4 Organization of Geometry from a curricula (Table 3, item 1)	Yes	Yes	no	no	no	no
5. Team group (Table 3, item 3)	no	Yes	Yes	no	no	no

Table 4. *Teacher profile*

In spite of having a suitable level of geometric reasoning (3-4), Teacher D sets about classroom activities in a routine way, thus becoming no more than a transmitter of knowledge. Also, the teacher puts little value on group work, over-standardizes his classes and manifests an excessively conceptual idea of the curriculum. Such a teacher would appear to have difficulties in carrying out curricular proposals in the terms set out by Van Hiele.

The results we have obtained for the rest of the teachers lead us to believe that these teachers' epistemology might be a major obstacle when it comes to implementing a Geometry curriculum based on Van Hiele's theories. There are various imbalances between the five categories that go to make up the ideal teacher profile.

In order to implement these curricular innovations with some measure of security, it is necessary to set up in advance comprehensive teacher training programmes. These programmes should not be an isolated part of the curriculum nor a series of recipes about how to carry out Van Hiele's idea, but rather an interpretation, justification and orientation arising from practice itself (immersion). The term immersion should be understood as the performance and discussion on the part of the teachers of those very activities that they will later propose for their students in class.

as well as their knowledge of the most relevant aspects of research into the present area.

DOING ALGEBRA TYPE STUFF: EMERGENT ALGEBRA IN THE PRIMARY SCHOOL

Janet Ainley
Mathematics Education Research Centre
Institute of Education
University of Warwick, Coventry, U. K.

There is a large body of research about the early stages of algebra which attempts to identify and explain pupils' difficulties. In this paper I take a different approach, exploring the potential of spreadsheets to provide new ways for children to be introduced to, and to appreciate the need for, an algebra-like notation, and illustrating 'emergent algebra' in primary school children familiar with spreadsheets.

Introduction

There is a large body of research about the teaching and learning of the early stages of algebra (sometimes referred to rather confusingly as 'pre-algebra') much of which seems to be about trying to explain why algebra is hard, identifying which bits of it are hard, and exploring pedagogic approaches which offer ways of overcoming the difficulties. A theme within much of this research has been to identify when 'real' algebra begins; to define a boundary between algebra and arithmetic. Filloy and Rojano (1989) define a 'didactic cut' between linear equations which contain only one use of a letter to represent the unknown and can thus be solved by essentially arithmetic approaches, and those equations in which the unknown appears more than once, so that arithmetic approaches have to be replaced by algebraic ones, involving the manipulation of symbols.

Other researchers have focused on the cognitive obstacles pupils encounter in the early stages of algebra. Herscovics and Linchevski (1994) argue that the divide between arithmetic and algebra lies not in the mathematical structures, but in the cognitive structures of pupils. They define the 'gap' as occurring when pupils are required to operate on or with the unknown. Many other researchers (too numerous to list without the risk of serious omissions) have explored in detail particular cognitive obstacles, sources of misinterpretation of algebraic symbols, pedagogic approaches which may introduce, or alleviate, potential difficulties, and theoretical models of learning processes which may illuminate our understanding of why algebra is hard, and when the hard bits start.

Brown et al (1998) draw on the work of Ricoeur to offer a critique of this research in early algebra as an example of research based on the notion of transition from one state (of knowledge) to another. They propose instead the need for multiple narratives in order to capture the complexity of the learning process. In the spirit of Brown et al., but with not drawing directly on Ricoeur's work, I intend in this paper to offer a

narrative of what I shall call *emergent algebra* in children in the last year of primary school, within the context of the use of spreadsheets.

Re-viewing the problem

In offering this narrative of children's emergent algebra, I want to take a view of the whole area which differs from that of many previous researchers in a number of w: This may prove to side-step some difficulties, and to introduce others. In contrast to attempts to define the boundaries of algebra, I want to work within a fuzzy description of 'algebra type stuff': an expression given to me by a ten year old pupil. I take this view partly because I am unconvinced that a clear definition of what is and isn't algebra is particularly useful in looking at what pupils do, say and write, and partly because the use of technology, and particularly spreadsheets, may affect the kinds of algebra type stuff which are important and interesting. As I discuss in more detail in the next section, spreadsheet environments produce some interesting ambiguities in the ways algebraic ideas can be seen and used.

A different view of what makes the early stages of algebra hard is that it is very difficult for pupils to have any sense of the purposes of algebra, of what it is that algebra is useful for. Lave and Wenger (1991) have drawn attention to the important characteristic of out-of-school learning contexts, in which, '*learners, as peripheral participants, can develop a view of what the whole enterprise is about*'. Sutherland (1991), in a discussion of what she saw as some outstanding research questions in the teaching and learning of algebra called for '*a school algebra culture in which pupils find* ***a need*** *for algebraic symbolism*' (my emphasis). However the current school curriculum offers few genuine opportunities for pupils to develop a view of the whole enterprise, or a sense of the need for algebraic symbolism.

Investigations of number patterns in practical contexts are often used as a starting point for the introduction of algebraic notation. But, although it may seem clear to the teacher that a general algebraic expression arises naturally from such investigations, for pupils this may seem pointless. If you already have a rule for finding any term in the sequence, what is the point of expressing it again algebraically? An alternative approach often proposed as a way of providing meaningful contexts for algebra is the use of word problems (for example, Stacey & MacGregor (1997), Sutherland & Rojano (1993)). In practice, such problems can often be solved by arithmetic approaches, or the contexts themselves are largely ignored by pupils as a distraction (Ainley (1997)), so the usefulness of algebraic notation remains unclear for pupils.

One of the features of technological environments which use algebra-like notations (e.g. spreadsheets, graphic calculators, Logo or Basic programming) is that when the notation is used, it does something: there is an immediate point and pay-off for using it. This feature can be incorporated into the design of meaningful activities in ways which give opportunities for pupils to gain at least a glimpse of the purpose of the

whole enterprise (Ainley (1996), Ainley, Nardi and Pratt (in press)). Furthermore, computers and calculators will only accept inputs in particular forms without and capacity for interpretation, and so there is an additional need to adopt the conventions of notation. This opportunity to use an algebra-like notation in an active way, to produce results of various kinds (a Logo drawing, a numerical output from a Basic program, a spreadsheet of data which can be graphed), is in stark contrast to the more passive use of algebraic symbolism in more traditional pedagogic approaches, where the only feedback accessible to the pupil may be the teacher's approval.

The spreadsheet as an algebraic environment

Spreadsheets, which are becoming increasingly available both in and out of schools, offer an environment with some interesting algebraic opportunities. However, as spreadsheets are designed as commercial, rather than pedagogic, tools there are also some significant differences between what can be done on a spreadsheet, and what might be done in formal, pencil-and-paper algebra. In this section I will explore both the opportunities and some of the limitations of spreadsheets as an environment for learning about and using algebraic ideas[1].

Spreadsheets use an algebra-like notation, in which the cell reference is used ambiguously to name both the physical location of a cell in a column and row, and the number that the cell may contain. The spreadsheet thus offers a strong visual image of the cell as a *container* for a number, which may or may not be present in the cell when the cell reference is used to create a formula elsewhere on the sheet. The image of a variable name as a container whose contents can be changed is one which has been used successfully as a pedagogic device in a number of settings (see, for example, Tall and Thomas (1991)). However, the image offered by the spreadsheet is ambiguous in another powerful way: when a formula is entered in a column, it can be 'filled down' to operate not just on a single cell, but on a range of cells in a column. The cell reference can then be seen as both specific (the particular number I am going to enter in this cell) and general (all the values I may enter in this column).

When a cell reference is used within a formula, the cell in question may contain a number, or another formula, as shown in cell B2 in Figure 1. This means that operating on an existing operation or function, a well known area of difficulty for many pupils, is easy and intuitive. The spreadsheet notation allows the encapsulation of the operation as a single cell reference, but at the same time disguises what has happened (as in D2 in Figure 1).

Figure 1

[1] Although there are some small technical differences between particular pieces of software, I shall ignore these in favour of concentrating on common features

Spreadsheets lend themselves to activities in which the focus is on creating expressions to represent relationships. It is less obvious how they may be used to create equations, and since there is no facility, or need, for symbol manipulation on a spreadsheet, solving equations can only be done indirectly through trial and improvement approaches. Whilst I am aware that some researchers might claim that this is sufficient reason to disqualify activities on a spreadsheet from being 'algebra', I wish to propose a different view. Spreadsheets provide a powerful environment for what Kieran (1996) refers to as *Generational activities*: expressing general relationships arising from a variety of sources. Because of the ease with which large quantities of data can be generated and explored, they are also powerful for some aspects of *Global, meta-level activities*, such as problem solving and awareness of constraints in problem situations (Kieran (1996)).

Starting algebra type stuff with spreadsheets

Much of the research and curriculum development with spreadsheets in secondary school algebra which has been reported, even the inventive work of Sutherland and Rojano (e.g. 1993), has focused on using spreadsheets to tackle traditional problems. However, the cognitive accessibility of spreadsheets also offers exciting opportunities to introduce pupils to different kinds of activities which are essentially algebra-like, and thus to meet algebraic ideas in new ways. Within the Primary Laptop Project, children regularly use spreadsheets as tools within mathematical and scientific activities. Pupils currently in Year 6 (aged 10-11; the final year of primary school), have had access to spreadsheets during the last four years. Their work has included entering formulae for 'function machine' or 'guess-my-rule' activities, collecting and graphing data in problem solving activities, and entering and copying formulae to generate data. Within the primary school, the children have not been introduced to any 'formal' algebra, such as the use of letters in equations to represent specific unknowns, but they have had opportunities to use spreadsheet notation for representing unknown numbers, generalised relationships and ranges of numbers, in the context of meaningful activities. In the last part of this paper I report on the preliminary stages of research on how these experiences are translated into work with formal algebraic notation as children move from primary to secondary school.

Talking about Algebra Type Stuff

To provide a starting point for conversations with these Year 6 children about their algebraic ideas, I have used some of the questions selected by MacGregor and Stacey (1997) in their study of secondary school pupils' understanding of algebraic notation. Using these questions offered the opportunity for comparison with results from a large scale survey. Because of the experience the children, I decided to present the questions in both a standard algebraic form (as in MacGregor and Stacey's study) and in a spreadsheet version. While designing the question sheets, it also occurred to me that some of the questions could be expressed in 'everyday' language, without any use of a formal notation, and I designed a third sheet of questions phrased in this way. All the Year 6 children were asked to complete the three question sheets; first the

everyday version, then the spreadsheet questions, and finally the algebraic form. In the following discussion I shall focus on just one of these questions, HEIGHTS[2].

everyday version	algebraic version
David is 10 cm taller than Ellie. If you knew Ellie's height how could you work our David's height?	David is 10 cm taller than Ellie. Ellie is h cm tall. What can you write for David's height?

In the interviews, I introduced an extension to this: the *Christmas tree question.*

Let's imagine that David is a little boy, and he is going shopping with his mother (father) to buy a Christmas tree. He says, "I want a Christmas tree that is twice as tall as I am". What could you write down for the height of the tree?

From the written responses, it was clear that most children found the everyday version of HEIGHTS unproblematic, and the results for the algebraic version were comparable to those MacGregor and Stacey obtained for children who had had some introduction to algebra in the first year of secondary school. My main interest , however, was to use the written responses as the basis for interviews exploring the children's ideas. I made the selection for interviews on two criteria: I was interested to talk to some of the children who had apparently completed both the spreadsheet and algebra sheets correctly, and also to some of those who had given idiosyncratic responses. There is space here to give examples from only four conversations.

Livy had completed the everyday and spreadsheet questions correctly, but had left the algebra sheet blank except for one question. However, her explanation of this answer indicates that she is comfortable with using a letter to stand for an unknown number.

Res: ... you did this one with the triangle. Can you explain what you meant there? [**n x 3**]
Livy: Well, is it like a sort of algebra sort of thing, so [...] so, using n would be like having a number, would be some equivalent number, so that, what n is it's times by 3. [...]
Res: Let's just have a look at these others that you didn't try before. [We look at HEIGHTS.]
Livy: It would just be h add 10 or something.
Res: OK, you write it down, write it down how you think it might go. [Livy writes: **h+10**].

After looking at the rest of the page, I asked Livy the Christmas tree question.

Livy: Just do... Well you times David's height by 2, but would you put um a letter, 'cause you don't know what it is?
Res: Well we've got something written down for David's height.
Livy: Oh, he's 10 cm taller.
Res: Mmmm. ..... Can you think of a way we could write down David's height times 2?
Livy: times 2 on the end.
Res: OK have a go, write it over here in this space, how you think you might write it.

Livy immediately wrote **h + 10 x 2**, and without prompting correctly added brackets. Notice that Livy is familiar with the term 'algebra', and seems to have a reasonable notion of what this means.

---

2 In trying to devise a version of this question involving sensible use of a spreadsheet, I produced something unnecessarily complex, which I will not include here

Wen was more tentative in his responses, completing the everyday sheet, but leaving the spreadsheet page blank. For the algebra version of HEIGHTS he had written **h 10cm**. He too had clearly heard of algebra.

Res: Tell me what you were thinking about if you can remember when you wrote that.
Wen: I was thinking of algebra, whatever, something ...
Res: OK good. [...] So what did you mean when you wrote that?
Wen: Ellie is h cm tall and if David is 10cm taller than Ellie, then you must do h 10cm. [...] It's 10 cm taller than h.

Wen did not see that he needed to add an operation to link h and 10; it was already clear to *him* what his answer meant. However, when I wrote **h + 10 cm**, he was happy to accept this notation, and said, '*It means a number add 10.*' At the end of the interview Wen confidently used this notation to write **(h+10) x 2** in response to the Christmas tree question. I asked him about his use of 'algebra'.

Res: You knew that name 'algebra'. Where did you learn that from?
Wen: Murderous maths. [A comic-style book]
Res: What do you think algebra means?
Wen: um it's a bit, it's where you use a letter for an unknown number.

Emm gave detailed and correct answers to the everyday and spreadsheet questions, but seemed to have fallen into a well-documented error in trying the algebraic versions. Her response to HEIGHTS was **i**, followed in small writing by the comment **including each letter adds 10cm**. This seemed to indicate that she was not simply seeing the letters as a code. As the following conversation shows, this was actually her way of trying to write 'h plus 10'.

Res: Can you explain what you meant here? I wasn't quite sure what you meant.
Emm: I'm not quite sure. I said if every like a, b, c, d if in between that letter was 10 cm, if Ellie was h it would be i next.
Res: Oh I see,[...] Can you think of any other way we might be able to write down something for David's height?
Emm: I couldn't quite think of anything, because that seemed kind of strange, because I didn't understand the h.

After discussing some other questions, I decided to simply show Emm the standard notation for David's height. Her face immediately lit up.

Emm: Oh! of course! (laugh and huge grin)
Res: Do you like that?
Emm: Yes, it's much easier, 'cause my mum says I work things out really hard, the hard way.
Res: Right, so you think that's an easier way to write it? Now you've seen that, could you think of a way to write some of the other questions?

Emm went on quickly and confidently to complete the rest if the questions on the page, and the Christmas tree question. She seemed to accept the need for this new notation to express her ideas, and her pleasure in using it was clear.

Kit responded to the everyday version of HEIGHTS by writing = **x - 10 cm.** Although he had got the wrong operation, he was clearly trying to give an algebraic response.

Res: Tell me about what you wrote here and why you wrote it. [...]
Kit: Well x ... we say x means any number so we, so if David is 10 cm taller than Ellie, Ellie would be the x, no, David would be the x and Ellie would be the answer, would be what came out, so we were doing like er function machines and stuff
Res: I see. [...] Where you put 'equals x'?
Kit: I did it as a formula.
Res: Right, so what you really meant was Ellie's height equals x minus 10?
Kit: No I meant if David's 10 cm taller ... David's, well I think I went wrong there, I think I should have put plus 10.

During a lengthy discussion of Kit's responses to the other everyday questions (all answered on the same style), and the spreadsheet questions, it was clear that he had some understanding that letters could be used in similar ways to cell references, to stand for any unknown number. His use of an equals sign at the beginning of his answers also indicated that he was thinking in terms of spreadsheet formulae in his algebra-style responses. However, when we got to the algebraic version of HEIGHTS he appeared to have changed his approach to use an 'alphabetic code'.

Res: 'What can you write for David's height?' You put a G
Kit: Yeah, I was doing it in like in algebra type stuff.
Res: Well, what we were doing here is certainly algebra type stuff! Why did you choose G?
Kit: Well I just thought um ...
Res: ... you'd just choose another letter?
Kit: No, I actually did something and like went through the stages but using letters instead of numbers.
Res: Oh ... Can you remember why you wrote G?
Kit: Erm, probably because ... actually it's wrong because it should be higher than H.
Res: OK, [...] Can you think of another way that we could write down David's height?
Kit: Well maybe h could have been like the same as n [n was used in a previous question]
Res: We could use h instead of n. What this is telling us really is to use h to stand for ...
Kit: ... yeah, a number
Res: ... a number, but we don't know what the number is, [...] but we're allowed to call that number h, to use h to stand for that number, just like you were using x before.
Kit: Yeah and then we used n, and now were going on to h.
Res: [...] So could you write like the formula for David's height, using h and saying what you have to do to h?
Kit: Yeah, you could put like just h plus 10.

Despite his apparent confidence when he had the freedom to choose a letter to represent an unknown number, Kit seemed to be confused when a *particular* letter was assigned in the question, perhaps feeling that this must have some significance. At one point in the interview he said in two consecutive statements that '*n means just the same as x*', and that '*n is nothing*'. He still seemed uncomfortable about the use of particular letters when he tackled the Christmas tree question.

Res: How would we write down the height of the Christmas tree?
Kit: n times 2, or 2 times n.
Res: Well, where's this n come from?
Kit: n is just his height.
Res: OK, we've got something that means his height

Kit: h, so it will be ...

Res: Well we've got, all of that [pointing to **h+10**] means his height. h plus 10 means David's height.

Kit: Yeah, so it will be h + 10 brackets, bracket it times 2. [...] That's how I would write it [...] if I didn't know. I'd probably put x actually.

The picture that emerges from these interviews is not of children who are confused by, or failing to use, algebraic notation and ideas. These children are reasonably comfortable with talking about and representing unknown quantities, and with the idea of operating mathematically with them. They also accept the need for a way of expressing these ideas in writing. Many of them were clearly aware that this was a legitimate part of mathematics, and knew the name 'algebra' from sources outside school. Their written representations do not always match those expected in formal algebra, but this seems to be because they do not yet know the conventions, rather than because they cannot grasp the ideas. Once they were shown the notation, or reassured about their attempts to use it, all four children went on to use it confidently, even to express the more complex answer to the Christmas tree question.

Their position seems to me to be similar to that of young children who are learning to write their native language: they can already communicate in a limited spoken form of that language, and understand the purposes for which written language is used by adults. Young children's spontaneous attempts at writing are often described as *emergent writing*. By analogy, rather than using the term 'pre-algebra', I would like to describe much of what the children produced as *emergent algebra*, arising from their attempts to imitate and invent a written notation whose function they already, at least partially, understand. This has the enormous advantage of enabling me to see their attempts not as errors or misunderstandings, but as attempts to get it right.

THE RIGOUR PREFIX

Lara Alcock and Adrian Simpson

Mathematics Education Research Centre, Institute of Education
University of Warwick, Coventry, CV4 7AL, UK.

This paper defines the rigour prefix, a way of dealing with mathematical categories in contrast to general cognitive categories. Illustrative episodes from interviews with beginning university students learning about convergent sequences highlight the contrast between students who are beginning to develop this prefix and those who continue to work with mathematical objects using general cognitive strategies. The importance of the parallel development of the object and rigorous ways of dealing with the object are discussed.

Introduction

Human beings categorise the world in order to deal with it. In this paper we shall be concerned with two different types of human categories; object categories and situational categories. Here "object" covers both concrete and abstract objects, although our principal example will be the mathematical object "convergent sequence". Situational categories are akin to frames (Minsky, 1975; Davis, 1984) in that they determine our expectations of, and our normal behaviour in a given situation. In order to deal with mathematical objects in an educational setting, learners develop situational categories which we call personal "maths frames".

Situational categories frequently act as prefixes in the sense of Lakoff (1987). Important aspects of a concept may be overridden by a prefix to the word denoting that concept, for example the prefix "white" in "white lie" overrides the idea that a lie is usually intended to be harmful. In a similar way finding ourselves in a situation belonging to a particular category may cause us to deviate from our usual behaviour. We will contrast expert maths frames, which act as a significant prefix, with non-expert maths frames which deviate less from general cognitive behaviour.

While our situational categories in general enable us to deal with the world, they do not necessarily always work to our advantage. Schoenfeld (1987) describes some common beliefs students have about doing mathematics problems, including that there is one and only one way to solve any given problem, and that none should require more than a few

minutes' work to complete. These are examples of expectations in the maths frame which may well inhibit a student's progress.

The Rigour Prefix

General cognition involves dealing with categories which are not "classical"; their membership is not dependent solely on some given common property (Lakoff, 1987). If categories were classical then there should be no gradience of membership, and categories should have well-defined boundaries. Instead categories can have "better" and "worse" members, for example the robin is generally considered a better example of a bird than the ostrich, and some have fuzzy boundaries, for example the category "tall man". This means that we are rarely consider any given category in its entirety. In order to reason about it we are compelled to operate on representative members of the category and then assume a generalisation to a large part of the category. Since efficiency is valued over accuracy (Balacheff, 1986), this strategy, which we call the "general cognitive strategy", causes few problems.

However, contrasting this with the formal work of expert mathematicians we find that they operate quite differently. Mathematical objects (at least at university level) belong to defined categories. By the nature of definitions the membership of such categories depends solely on common properties and therefore they *are* classical. In a formal mathematical sense there is no such thing as a "good" or "bad" example of a convergent sequence, and the category has well-defined boundaries. This means that in mathematics whole categories can be dealt with at once by working exclusively with the definitional properties. This is necessary if unambiguous communication between mathematicians is to be possible.

We claim that expert mathematicians have, as part of their maths frames, an encapsulation of this idea, which some call "rigour". This acts as a prefix, in the sense that it overrides the individual's general cognitive strategies in formal mathematical situations. The "rigour prefix" is essentially a directive in the maths frame allowing those who have it to exploit the classical nature of defined categories by using only the definitional properties in formal work.

Mathematicians who have developed the rigour prefix are thus able to access two ways of working: they can work with representative examples to develop intuitive ideas about object structure, but they are also aware of the need to work with the whole category. Those who have yet to develop the rigour prefix only have access to the former way of working.

At the beginning of a university mathematics degree, students are required to develop mathematically in two distinct ways: they learn new object categories (such as "convergent sequence"), but also need to enhance their maths frame as a situational category in order to cope with formal deduction and proof.

We can infer the different levels of development of the rigour prefix in beginning university students from the contrast in the kind of objects they use. In examining students' initial reasoning with convergent sequences, we can see a qualitative difference between those whose immediate reaction is to deal with the whole category (through the definition) and those who deal with an exemplar.

The Rigour Prefix in Action

The following excerpts are taken from interviews with students taking a first course in Analysis. Some were attending a standard lecture course (with three hours of lectures per week and a weekly assignment to be completed for credit), and others were attending a new course based on Burn (1992). Those on the new course had only one lecture per week and in addition attended four hours of classes; a class of 30-35 students worked in groups of about four to complete a weekly "workbook", with the assistance of a teacher (a member of staff or a graduate student) and second year students who had been successful on a similar course the previous year. The workbooks aimed to lead students through a carefully structured sequence of questions covering inequalities, sequences and series. These students proved most of the main results of the course for themselves.

Students from both courses were interviewed fortnightly, in pairs, throughout the term when the course took place. The interviews included a mathematical task-based section related to their recent work.

In both cases the students were asked to work on the question:

> For a sequence (a_n), which of the following is true?
>
> a) (a_n) is bounded $\Rightarrow (a_n)$ is convergent,
> b) (a_n) is convergent $\Rightarrow (a_n)$ is bounded,
> c) (a_n) is bounded $\Leftrightarrow (a_n)$ is convergent,
> d) None of the above.
>
> Justify your answer.

We present excerpts of interviews with two pairs of students whose behaviour is illustrative of the contrast between having and lacking the rigour prefix.

The first two students were taking the question-based course. Having decided that b) is true and produced a counterexample to reject a) and c), Adam and Ben immediately had the following exchange:

B: Right, b) is convergent. Right, our definition of convergence is that...well, there exists an N such that when n is greater than big N, there, modulus of a_n is less than

epsilon. So that leads to epsilon being a bound...plus or minus epsilon being a bound, about a. a_n. Is it?

A: Yes go on do you want to write that down? Right the, you have it bounded by, the plus or minus epsilon, thing, and that shows it's eventually bounded and then it is, bounded. By sort of, an earlier result, sort of thing.

[Ben then writes something down and is asked to read it out]

B: It's only sort of, vague. But, modulus of a_n will be less than epsilon if it's converging, when n is greater than big N. Hence minus epsilon is less than a_n, is less than epsilon, therefore epsilon is a bound. Since (a_n) is eventually bounded, therefore (a_n) is bounded by, whatever various proofs that we've done in the book!

I: Mm. What were you going to say, Adam?

A: If it's convergent, rather than converging, or tending to zero...that, the modulus of a_n you've written, should be modulus of, a_n minus a. And you have to say, if, the sequence (a_n) tends to a, then...and that needs to be the modulus of a_n minus a.

While their speech was informal, Ben's immediate recourse to the definition of convergence allowed them to make rapid progress. They went on to prove that a sequence which is eventually bounded must be bounded and wrote down and explained their whole proof without any significant difficulty. We claim that this is evidence of the development of a rigour prefix - the use of the definition means that the conversation is about *all* convergent sequences. It is not claimed that either had a fully functional rigour prefix at this stage; they may not have an explicit idea of why formal definitions are used in Analysis, but they certainly seem to know *that* they are used.

This contrasts with the behaviour of Wendy, a student on the lecture course. In the first excerpt she and Xavier had just established that they think b) is true, and Wendy had drawn a picture of a monotonic increasing convergent sequence:

W: It's convergent...yes so if it's convergent it's always, or, say it could be the other way round it could be, going down this way. It converges, so it's always above that limit.

X: Could you do, a_n minus l, mod is less than epsilon...thing? That goes to...

W: I wouldn't have done that, but you can have a go if you want!

[There follows a discussion in which they generate counterexample to disprove a) and c), and then Xavier comes back to his idea, and Wendy agrees.]

X: Erm, well the term in the sequence a_n, er minus the limit, or the bound, the modulus of that is less than epsilon, where epsilon is, any, er, real number, positive real number...

W: So that shows it's convergent. You've got a...(writing).... And therefore it's between those, and therefore it's bounded.

[They are asked to explain this in more detail which they do, and then to consider what happens "before big N". (There is some confusion here as they speak of "bounded" meaning only bounded above or below.)]

W: Yes if it's an increasing sequence, the limit'll be, up above. It'll be increasing up...so, what happens before big N doesn't really matter because it'll always be below that. And then if it's decreasing sequence it'll er...(*draws*)

X: Mm. So it doesn't matter what happens before, big N. It's what, after, what happens after,

W: As long as you know whether it's an increasing or decreasing,

X: Sequence.
Short pause.

I: What if it's neither of those things?

W: You're in trouble.

I: Oh dear...
Pause.

X: So if it's oscillating...(drawing)

[The interviewer then clarifies the meaning of "bounded" and the fact that a sequence cannot "shoot off to infinity" at any particular term, and suggests that the terms before a_N are our current problem and asks if we can fix that.]

W: Find out what the points before that point are...

I: Can we do that?

W: When you've found big N, yes.

I: Yes. And what would you do then?

W: You'd have to check that erm...well you could find out whether it was an increasing or decreasing sequence,

I: What if it wasn't either?
Pause.

Throughout this discussion (which lasted approximately 15 minutes) Wendy appears to be employing what we earlier termed "general cognitive strategies" in her reasoning about convergent sequences, based around the idea that a monotonic sequence is a good representative example of that category. It may be suggested that she does have a

version of the rigour prefix and is using this as intuitive work prior to introducing the definition. However we argue against this. Not only does she return to the monotonic sequence idea several times, despite repeated suggestions from the interviewer that other kinds of sequences also be considered, she also sidesteps Xavier's attempt to bring part of the definition into the discussion.

In Xavier's case we can see a contrast between his developing maths frame (which is beginning to show signs of a rigour prefix in his attempts to introduce part of the definition) and his development of the object category for "convergent sequence" which appears to be no more developed that Wendy's: both seem to have access to a very limited number of representative examples.

This highlights the relationship between mathematical object categories and the rigour prefix; the two may influence each other but they are not entirely dependent on each other. A student may have well developed object categories, for instance be able to cite many varied examples from a category without apparently assuming any extra properties or weighting them differently. However, such a student may not work with these categories in the way determined by the rigour prefix. Equally it is possible to have the rigour prefix in the maths frame but have a poor understanding of what any particular mathematical object category contains. We claim that changes to object categories are easier to make than changes to situational categories.

Discussion

Category change has many similarities to Skemp's ideas of how concepts come to be learned (Skemp, 1979). Skemp claims that concepts are altered as the learner acknowledges the importance of different examples of the object. In Wendy's case the examples of convergent sequences that she has been exposed to appear to have led her to believe that a good representative example of that category is monotonic. She is by no means atypical of those on the lecture course in this respect. We suggest that while a teacher may choose to exhibit a particular example on the basis of its simplicity of expression, intending it to serve as illustrative of the general principles under discussion, a student may attach inappropriate weight to it as a member of a category. Exposure to more varied examples may discourage this tendency to consistently work with one particular representative example, and increase the student's number of prototypical members. Using more representative examples enables the student to cover more of the category. However, this is not the same as developing the rigour prefix, without which the general cognitive strategy of working with representative examples is the only available option.

The rigour prefix is defined as a directive in the maths frame allowing those who have it to exploit the classical nature of defined categories by using only the definitional properties in formal work (although their informal reasoning may still rest on

representative examples). We claim that situational categories are modified in the same way as object categories, that is by the learner acknowledging the importance of different instances of the situation. This may be why the question-based course is more successful in encouraging students to develop the rigour prefix. These students are regularly put into a situation where they are asked to prove general results for themselves: the general cognitive strategy is not likely to lead to consistent success in producing such proofs. They are likely to find their current maths frame is no longer efficient and to be ready to explore alternatives to the general cognitive strategy.

We do not suggest that the development of the rigour prefix will be smooth. An interim stage for many in Analysis seems to be a period of manipulating definitional statements in order to please the authorities rather than as a reasoned alternative to the general cognitive strategy. The next stage in development may be a realisation that the definition corresponds to their own category for that object. As was put by one girl in the pilot study for this research:

> "I didn't see how it [the definition] related to what I thought, and I thought what I thought was a lot better than how they'd written it on the page, and then the more I saw how it, sort of works, the more I can see that that is actually just what I thought anyway, and it's just said better than I could say it."

This idea has obvious connections with those of concept image/concept definition (Tall and Vinner, 1981). A student without the rigour prefix works solely with some piece(s) of their concept image, although they may be able to state the definition quite accurately. In addition such a student may well display a propensity towards "proving by example", having what Harel and Sowder (1998) call inductive or perceptual proof schemes.

Conclusion

The way mathematics has evolved has led to experts in the field working with defined (and therefore classical) categories. These offer huge scope for generality and accuracy, but their use requires a maths frame which can override general cognitive strategies.

The development of the maths frame occurs in all learners throughout their mathematical education. However, the development of the rigour prefix is essential to the transition to advanced mathematical thinking. Prior to this, the learner may be able to cope with school mathematics by using a combination of a specialised version of the general cognitive strategy as their maths frame and by being able to create and modify object categories. At university, the student not only needs to be able to continue to create and modify object categories at increased levels of abstraction, they also need to develop a new and fundamental aspect to their maths frame: the rigour prefix.

THE PROBABILISTIC THINKING OF 11-12 YEAR OLD CHILDREN

Gilead Amir, Liora Linchevski, Hebrew University, Jerusalem
Malka Shefet, Lewinski College, Tel-aviv

Abstract

This research explored the probabilistic thinking of 11-12 year old children in Israel. A questionnaire was developed, including scales that explore children's estimations of probabilities. 294 children completed the questionnaire, and 32 of them were also interviewed. Some of the main findings include: 'representative' sequences got higher estimations of chance than other sequences; most of the children did not discriminate between single sequences and classes of sequences; several new examples of children's use of the 'representativeness' and the 'availability' heuristics were identified.

1. Literature and theoretical framework

Piaget and Inhelder (1975, original in French, 1951) analyzed children's thinking about probability into the usual stages (pre-operational, concrete operational, etc.), culminating in a formal understanding of probability through combinatorics. Green (1982), in a survey of 3000 children aged 11-16 showed how their development followed a hierarchy which was consistent with Piaget's stages.

A focus of criticism of much of Piaget's research has been the gap in communication which may develop between researcher and child (see for example Donaldson, 1978). Borovcnik and Bentz (1991) similarly cast doubt on common interpretations of answers to commonly used probability questions.

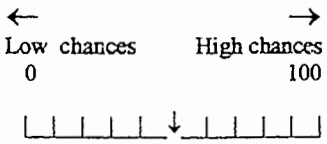
Another focus of criticism on Piaget is in not taking enough into consideration non-formal, intuitive lines of thought. Fischbein (1975) showed that some intuitions in young children's thinking are important in helping (and hindering) their pre-formal probabilistic thinking. Kahnemann, Slovic and Tversky (1982) showed how adults reason in situations of uncertainty using intuitive 'heuristics', rules of thumb which seem to be developed to guide our behavior in daily living. Shaughnessy (1981) asked college students to compare the likelihood of two sequences of births of six children. Only 27% of them answered that there is about the same chance for each. 70% thought 'BGGBGB' is more likely than 'BBBBGB', probably applying 'representativeness' (expecting a sample to be similar to its parent population). Two heuristics we have found (Amir, 1994, Amir & Williams, 1994, Amir & Williams, 1995) relevant also to children: 'representativeness' and 'availability' (estimating odds according to memories of similar past

experiences). Beliefs also influence children's interpretations of probabilistic situations (Amir, 1994).

This knowledge of chance and probability that the child acquires informally, mainly outside school, is relevant to the learning of probability (see Fischbein, Nello & Marino, 1991). Unfortunately, our knowledge of children's preconceptions of probability is not systematic and not precise (Shaughnessy, 1992). This research intended to contribute to this knowledge both in methodology and in substance.

Thus, the aims of this research were:

1) To develop tools for research of probabilistic thinking.



2) To develop insight into probabilistic thinking of 11-12 year old children.

2. Method

Two questionnaires were used: the first is a translation of part of Green's questionnaire (1979) into Hebrew. The second questionnaire is new, aimed at mapping children's probability language, and quantitative estimations and comparisons of probabilities. The instruments' validity and reliability were checked by piloting them both in writing and in interviews.

Use was made of scales, which are frequently used in research of attitudes, beliefs, etc, but are not commonly used in estimations of chances. An example of a question:

3. On each of the scales mark the chances of the event.
For example:
What are the chances of 'Heads' when tossing of a usual coin?
If we think the chances are even we mark the number 50:

A fair coin is tossed 6 times. Tick the chances to get the following results:	
a. 6 'Heads'	
b. 6 'Tails'	
c. 5 'Heads' and 1 'Tails'	
d. 1 'Heads' and 5 'Tails'	
e. 4 'Heads' and 2 'Tails'	
f. 2 'Heads' and 4 'Tails'	
g. 3 'Heads' and 3 'Tails'	

A similarly structured question with scales asked about chances for specific sequences:

A coin is tossed 6 times. Tick the chances to get the following results (in that specific order):

	0 — 100
a. 'Heads', 'Heads', 'Heads', 'Heads' 'Heads', 'Heads'	
b. 'Tails', 'Tails', 'Tails', 'Tails', 'Tails', 'Tails'	
c. 'Heads', 'Heads', 'Heads', 'Tails', 'Heads', 'Heads'	
d. 'Tails', 'Tails', 'Tails', 'Heads', 'Tails', 'Tails'	
e. 'Heads', 'Heads', 'Tails', 'Heads', 'Tails', 'Heads'	
f. 'Tails', 'Tails', 'Heads', 'Tails', 'Heads', 'Tails'	
e. 'Heads', 'Heads', 'Tails', 'Tails', 'Heads', 'Tails'	
f. 'Tails', 'Heads', 'Tails', 'Heads', 'Tails', 'Heads'	

A question with equivalent items dealt with series of births:

In a family of 6 children mark the chances of the following sequences (in that specific order):

	0 — 100
a. boy, boy, boy, boy, boy, boy	
b. girl, girl, girl, girl, girl, girl	
c. boy, boy, boy, girl, boy, boy	
d. girl, girl, girl, boy, girl, girl	
e. boy, boy, girl, boy, girl, boy	
f. girl, girl, boy, girl, boy, girl	
e. boy, boy, girl, girl, boy, girl	
f. girl, girl, boy, boy, girl, boy	

Other questions dealt with classes of sequences in families (such as '3 boys and 3 girls'), and with dice tossing.

When piloting these questions, in writing and in interviews, we found that the pupils used the scales without difficulties, and understood their meaning. Obviously the pupils, with no formal knowledge of probability, were not expected to offer precise values, or even rough values, of the probabilities. What the scales did enable is comparison of their various estimations: Does the pupil see different sequences in a specific question as having equal chances? Is there a trend in his estimations? Does the pupil give similar chances to a specific sequence (such as 'H,T,H,H,T,H') and to the unordered event (in this case '4 'Heads' and 2 'Tails'')? How similar are the chances the pupil gives to equivalent events in different contexts? Do the pupil's responses suggest an application of a certain heuristic? Data that emerged from the questionnaires was validated through interviews.

BEST COPY AVAILABLE

After finalizing the instruments the questionnaire was administered to 294 11-12 year old pupils from central Israel, chosen randomly. 32 of these children were also interviewed. Results were analyzed both quantitatively and qualitatively.

3. Results

3.1 Probability of sequences

When giving an estimation of the probability of the result '2,2,2,2,2,2' when tossing a die 6 times on a scale in the questionnaire the average was 0.24 (n=294), the lowest probability for the sequences in the question. The average estimation for the sequence '6,6,6,6,6,6' was close ($\bar{x}$=0.25). The highest probability in the question was for the sequence '6,5,3,6,2,4' ($\bar{x}$=0.59). As previously explained, the significance of the results is not in the absolute values of the probabilities, because the pupils have no tools for estimation of the correct probabilities. The results' significance is in the comparison between them: although mathematically each sequence has the same probability, the pupils assign to the second sequence a much higher probability. The same results were received also when dealing with coin tossing: 'H,H,H,H,H,H' and 'T,T,T,T,T,T' were the sequences estimated with the lowest probability ($\bar{x}$=0.26 and $\bar{x}$=0.25) when tossing 6 times a coin, and 'H,T,H,T,H,T' was the sequence estimated with the highest probability ($\bar{x}$=0.57). In the domain of birth series, the sequence 'B,B,B,B,B,B' received the lowest probability ($\bar{x}$=0.36), only slightly lower than the sequence of 6 girls ($\bar{x}$=0.36). The sequence 'B,B,G,G,B,G' received the highest probability ($\bar{x}$=0.63).

One possible explanation is that pupils expect different sequences to have different chances because they apply the 'representativeness' heuristic (a detailed discussion of this heuristic is in section **3.4**). Another possible explanation deals with communication: maybe the pupils understand wrongly the question. Maybe they treat each sequence as a **type** of result, a representative of a class of sequences, rather than a specific sequence. If so, then although the answer is formally wrong, it is based on the correct line of reasoning: when tossing dice, receiving 5 different numbers with one repetition, and with no specific order, has a higher probability than receiving 6 times the same number!

This explanation can be checked by comparing estimations of probabilities of specific sequences with estimations of probabilities of unordered events including several possible sequences. For example – comparing the estimation for the probability of the sequence 'B,B,G,G,B,G' with the estimation for the probability of the event ' 4 boys and 2 girls in a family of 6 children'. This comparison is possible with the following table, containing results of sequences

and the matching classes of sequences of 6 coin tosses, and equivalent questions dealing with the order of births in families of 6 children.

Table no 1: Average estimations of probabilities for specific sequences versus classes of sequences of 6 coin tosses and of birth order in families with 6 children (n=294)

Tossing a coin 6 times				A family with 6 children			
CLASS OF SEQUENCES	AVE-RAGE	SPECIFIC SEQUENCE	AVE-RAGE	CLASS OF SEQUENCES	AVE-RAGE	SPECIFIC SEQUENCE	AVE-RAGE
6 HEADS	0.341	H,H,H,H,H,H	0.256	6 BOYS	0.359	B,B,B,B,B,B	0.357
6 TAILS	0.351	T,T,T,T,T,T	0.253	6 GIRLS	0.365	G,G,G,G,G,G	0.358
5 HEADS, 1 TAIL	0.420	H,H,H,T,H,H	0.357	5 BOYS, 1 GIRL	0.450	B,B,B,G,B,B	0.427
5 TAILS, 1 HEADS	0.419	T,T,T,H,T,T	0.346	5 GIRLS, 1 BOY	0.454	G,G,G,B,G,G	0.450
4 HEADS, 2 TAILS	0.579	H,H,T,H,T,H	0.488	4 BOYS, 2 GIRLS	0.549	B,B,B,G,G,B	0.503
4 TAILS, 2 HEADS	0.550	T,T,H,T,H,T	0.489	4 GIRLS, 2 BOYS	0.554	G,G,G,B,B,G	0.520
3 HEADS, 3 TAILS	0.604	H,H,T,T,H,T	0.556	3 BOYS, 3 GIRLS	0.649	B,B,G,G,B,G	0.632
		H,T,H,T,H,T	0.568			B,G,B,G,B,G	0.582

3.2 Probability of sequences versus complex events

The pupils' responses from the table indicate a high similarity when comparing the estimations for sequences with the estimations for classes of sequences.

This low discrimination was also supported by part of the interviews. For example, in a discussion of coin tossing, D. was asked if there is a question similar to 'H,H,H,T,H,H'. She answered that "1 'Tails' and 5 'Heads'" is similar, and that, yes, she would give each the same estimation. Similarly, A. claims that there is no difference between the question about the probability to get the sequence '6,4,5,3,1,2' and the probability of "to get 6 different numbers" when tossing dice. "It is the same, this is also 6 different numbers".

These results suggest that many children do not discriminate between ordered sets and unordered sets in probability. For these children the comparison between the probabilities of the sequences 'H,H,H,H,H,H' and 'H,T,H,T,H,T' is the same as the comparison between the probabilities of the events "getting 6 'Heads' when tossing a coin 6 times" and "getting 3 'Heads' when tossing a coin 6 times". These differences are especially small when dealing with birth orders. A possible explanation is that in families the relative frequencies of boys and girls are seen as important, and not so much the order.

Although, as previously stated, results of sequences and matching classes of sequences were similar, most children did give the unordered event a slightly higher probability than the sequence, i.e., there is some discrimination between the two, but it is low, and has no relationship with the number of sequences in the class of sequences.

3.3 Probability in different domains

Table 1 enables comparison also between answers about coin tossing and about order of births. Similarity in answers to equivalent questions is high, although in general results of birth orders are higher, especially when dealing with specific sequences. Perhaps the context of children in the family is more familiar, and so estimations for these questions are higher. In this case, the pupils are applying the 'availability' heuristic (offering higher estimations for familiar situations).

Interviews confirmed that while part of the pupils thought there is no difference between equivalent questions in different contexts, others thought there is some difference. For example, part of an interview between the child A. and the interviewer I.:

A.: "The questions are different. Because, everything depends on God, like, what he gives man."
I.: "And with coins?"
A.: "With coins it is luck."

A. attributes order of birth of children to God, and results of coin tosses to luck. Questions that are equivalent mathematically do not seem so to children, due to their beliefs. For similar results see Amir (1994).

Or in another interview, with D.:

D.: "No, this is really not the same question."
I.: "Why?"
D.: " Because it is a fact that last week a girl was born to a woman with 11 boys."
I.: " And with coins, to get 11 times 'Heads'?"
D.: "It is impossible."

The explanation of this pupil is based on memory: the pupil does recall memories of families with many boys, but does not have similar memories of long sequences of 'Heads' or 'Tails' when tossing a coin -- perhaps because he

does not often toss coins! This type of generalization based on memories is, as mentioned before, an application of the 'availability' heuristic.

And with K.:

K.: "The two questions are different ... A coin you toss, here [i. e. with births, G. A.] you can get what you want ... With a coin you can control only if you cheat ... With children you do not compete."

3.4 Representativeness

Previous literature (for example Konold et al, 1993), and our pilot interviewing, suggested that the heuristic 'representativeness' includes two distinct and independent dimensions when applied within probabilistic situations: the tendency to expect a sample to reflect the numerical proportion of the parent population; the tendency to expect a sample not to be too orderly, i.e., to look 'random'. Order seems to be more special, thus with less chance to happen. These dimensions lead us to identify four types of responses that seem to reflect application of the 'representativeness' heuristic. A problem used in this research that can exemplify these different types is: tossing 6 coins.

Most of the pupils thought (correctly) that getting 3 'Heads' and 3 'Tails' has the highest chances of all given possibilities. A group of these children applied this view also when analyzing sequences: they gave all sequences with 3 'Heads' and 3 'Tails' a high chance, without taking into consideration the order.

Another group of children thinking 3 'Heads' and 3 'Tails' has the highest chance – when analyzing sequences expected the ordered sequence 'H,T,H,T,H,T' to have the highest chances.

A third group of the children thinking 3 'Heads' and 3 'Tails' has the highest chance – when analyzing sequences expected the 'randomly' ordered sequence 'H,H,T,T,H,T' to have the highest chances.

Another group of the children thought the highest chances are for a case which is **near** the expected numerical value, but not the exact value. In the case of tossing 6 coins they expect "4 'Tails', 2 'Heads'", or "2 'Tails', 4 'Heads'" to have the highest chance. When asked about the result with the highest chances when tossing 30 times a coin, these children answered that "14 'Tails', 16 'Heads'" or "14 'Heads', 16 'Tails'" have the highest chances.

4. Conclusions

1. New instruments based mainly on scales provided useful information about children's concepts of probability.

2. Children gave sequences different probabilities. 'Representative' sequences got higher estimations of probability.

3. Discrimination between sequences and classes of sequences was low.

4. Equivalent probability questions in different domains gave close results, although differences existed, especially when comparing order of birth of children to tosses of coins.

5. The 'representativeness' heuristic includes two distinct and independent dimensions: the tendency to expect a sample to reflect the numerical proportion of the parent population; the tendency to expect a sample not to be too orderly, to look 'random'. These dimensions led to the identification of 4 variations of 'representativeness'.

WHAT CAN BE LEARNT ABOUT FRACTIONS ONLY WITH COMPUTERS

Ilana Arnon, Pearla Nesher, Renata Nirenburg, CET, Tel Aviv

In this report we will present the software "Shemesh", designed for the learning of mathematical concepts through concrete representations that can not be constructed by the students without the computer. The concept of ***Equivalence Class*** *plays a significant role in the structure of Rational Numbers. In a discrete Cartesian system an equivalence class of fractions is represented as a line through the origin. Other fraction concepts also have concrete representations in such a system. Fifth-graders who used "Shemesh" in their learning process were clinically interviewed several months later. It was found that they remembered these representations and could use them for solving conventional arithmetic fraction-problems.*

To compare two fractions means to find the order relation between them, such as the following problem: "Of $\frac{3}{4}$ and $\frac{7}{10}$, which fraction is larger, or are they equal?" How do we usually approach such problems in elementary schools? One way is to teach some algorithm, to be learned by heart. If we aspire to some meaningful learning, we might choose more lengthy methods. For example, we might teach the following method:

Find two new fractions: One equal to $\frac{3}{4}$, the second equal to $\frac{7}{10}$, yet both having the same ("a common") denominator. Compare the new fractions.

Some will argue that the easiest common denominator to find would be 40 (the product of the two given denominators). In this method, we expand each given fraction by the denominator of the other, to deduce that $\frac{3}{4}=\frac{30}{40}$, $\frac{7}{10}=\frac{28}{40}$, and hence, according to a previously learned rule of comparing fractions with common denominators, $\frac{28}{40}<\frac{30}{40}$, hence $\frac{7}{10}<\frac{3}{4}$.

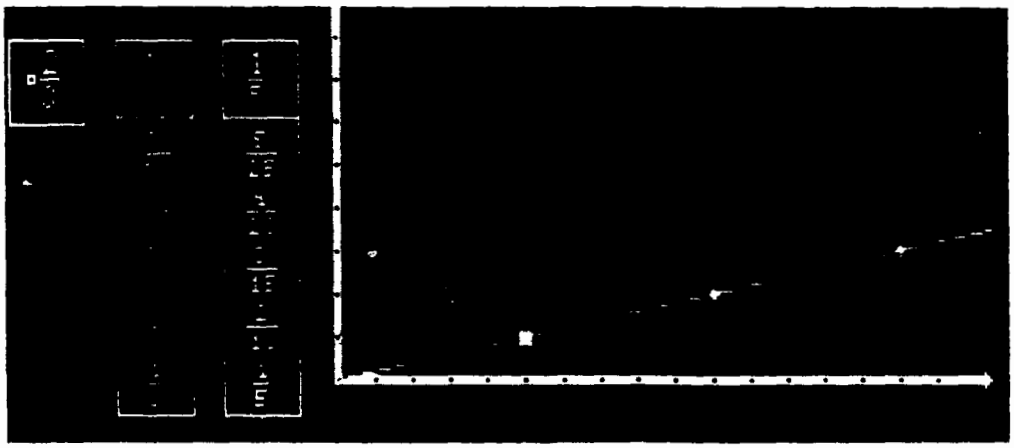
Others will argue that there exists a simpler common denominator, to work with - namely 20. The followers of the first method will argue that 20, being a smaller integer, might be perhaps easier to use for the calculation, but not at all easy to find. To obtain it involves either using complex ideas of whole-number-theory, such as decomposition into prime factors and smallest-common-multiple, or else constructing lists of fractions equal to the original ones until hitting fractions with a common denominator: $\frac{3}{4}=\frac{6}{8}=\frac{9}{12}=\frac{12}{16}=\frac{15}{20}=$, $\frac{7}{10}=\frac{14}{20}=$ Hooray! All these methods lead the student to believe that he had found **the** appropriate common denominator (and respective representative solution), and not **one of several.**

Working on fraction concepts with 4-, 5-, and 6- graders we found that it was extremely difficult for students simultaneously to conceive of the components of this complex situation: The two given fractions, the equality of each of them to the members of its own list, and the three significant characteristics of the fractions with common denominator: that their denominators are equal, that each of them equals

one of the original fractions and that they usually do not equal each other. (On the contrary, we have to determine which one is larger and deduce from that the order relation between the original fractions).

The same holds for other arithmetic operations on fractions, such as addition and subtraction. If we do not wish to teach an operation as a technical algorithm, the solution always begins by searching for a replacement for each given fraction; We search for the replacement in the set of the fraction's equals. We choose the replacement according to convenience; the same arithmetic problem can often be solved by means of more then one choice. The idea that the solution of the problem does not depend on the choice we make (on the individual replacement we used in the solution-process) is very crucial for the understanding of fraction-operations, and too much neglected, in our opinion, in school mathematics.

There is a fundamental mathematical idea behind all these methods, namely, that a fraction is not a single pair of integers (numerator and denominator), but a class of equivalent such pairs. The arithmetic operations executed between pairs of fractions are in fact defined in terms of their equivalence classes. Here is an example of a definition of this idea:



> *Let R be a commutative ring without zero-divizors.*
>
> *(a) We define a relation on* $R \times (R \setminus \{0\})$ *by* $(a,b) \sim (c,d) : \Leftrightarrow ad = bc$. *This is an equivalence relation. The equivalence class of (a,b) is denoted by* $\frac{a}{b}$.
>
> *b) The set* $Q(R) := \{ \frac{a}{b} \mid a \in R,\ b \in R \setminus \{0\} \}$ *of equivalence classes, endowed with the operations* $\frac{a}{b} + \frac{c}{d} := \frac{ad + bc}{bd}$ *and* $\frac{a}{b} \cdot \frac{c}{d} := \frac{ac}{bd}$, *is a field, called the* **quotient field** *of R.*
>
> (Spindler, 1994, V. II, p. 40).

Teaching fractions as equivalence classes means more than teaching the equivalence of two elements of a given class. It means getting the students to operate on the classes as **objects**. So, while the concept of fractions as equivalence classes remains difficult and very abstract it is essential that it be taught. Piaget taught us that students of this age develop abstract mathematical concepts by reflecting on their own **concrete** activities (Piaget, 1976). What if we find concrete representations for equivalent classes of fractions? Will that enable the teaching of this concept?

Resnick (1987) emphasized the necessity of strict and explicit **mapping** between a concrete representation and the mathematical ideas it represents. Nesher (1989) emphasized the need for well defined and (mathematically) closed **knowledge domains**, to be taught by the use of isomorphic concrete exemplification domains. Dubinsky (1991) emphasized that the development of a new mathematical concept

begins by an **action**, and Arnon (1997) investigated the improvement of the development of fraction concepts by the use of **concrete actions**. Arnon (1997) also showed the necessity of another condition: the ability of children to operate the concrete actions, after due interiorization, **in their imagination**.

We chose to represent fractions as equivalence classes of ordered pairs of integers in a discrete Cartesian coordinate system. An ordered pair is represented by a point whose vertical coordinate is the numerator and its horizontal coordinate - the denominator. The ordered pairs of each equivalence class are situated on a straight line passing through the origin (Kalman, 1985; Kieren, 1976):

Drawing 1

The use of computers is indispensable for this exemplification, because of the need for accuracy in drawing the different lines. The software "Shemesh" ([1]) was developed with a screen consisting of two separate parts: A number-domain and a drawing-domain. An equivalence class is represented in the number-domain as a list of fractions $\frac{a}{b}$, and is referred to as a "class". In the drawing-domain it is represented as a line through the origin together with all the points of the "class", a point for each numeral $\frac{a}{b}$ (see drawing 1). Users can construct points representing individual pairs of numerator and denominator and lines representing equivalence classes. Other options of the software are: The construction of additional types of fraction sets, the performance of arithmetic operations such as addition, subtraction, comparison, and more. The software and its optional activities were constructed according to the necessary conditions established by the researchers that were quoted above. Even so, the use of this representation for elementary school students poses the following questions:

- To what degree is this representation really **concrete** for young children?

1) "Shemesh", Fractions as Equivalence Classes, CET - Center for Educational Technology, Tel-Aviv, Israel

BEST COPY AVAILABLE

- Does the use of this software enhance the development of the concept of fractions as equivalence classes?

We set out to investigate these questions. In a preliminary experiment, thirty fifth-graders attended between one to four lessons a week. The sessions took place in a computer laboratory, in addition to the normal school schedule, and participation was voluntary. Some of the students dropped off along the way. Others were persistent and attended up to 30 lessons. The lessons consisted of group-work, individual work and large group discussions.

Three months after the teaching experiment was over we interviewed 21 students (those available at the time). One student dropped out because she was quite unable to work with the specific representation. We will present the data collected from the remaining 20 students in two parts, concerning the construction of the concept, and its further use.

A. The construction of the concept of equivalence class

1. The representation of a numerator and denominator pair as a point in the Cartesian system

All 20 students handled this representation correctly (although some needed a few "recollection" exchanges): Using pencil and paper drawings they drew points representing given fractions, and vice versa, and successfully accomplished even more sophisticated assignments.

2. The relation between the members of an equivalence class

All 20 students knew that the fractions whose points were on a line passing through the origin were equal to each other. They also knew that the fractions that appeared on a list in the number domain equaled each other.

S8: "*...actually they are in the same class... because they are equal.*"
S19: "*Because they are in the same class, and they equal each other.*"
S20: "*First of all, they are all on this line. Second - they are all equal.*"

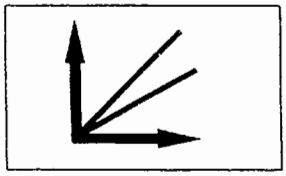
3. The link between a list on the number-domain (a "class") and a line on the drawing-domain

19 students expressed their certitude about the link between such a list and its line:

S8: "*Because usually in the computer, when we have a line, and we have a class, then usually they belong to each other.*"
S17: "*All the fractions of a class are on the line.*"

S10 expressed the integration of all three ideas:

"*They* [refers to the list] *are all fractions of* $\frac{2}{3}$, *it is a line of* $\frac{2}{3}$ *and they all are expansions of* $\frac{2}{3}$"



B. The use of lines in solving arithmetic fraction-concepts.

1. The use of lines for the comparison of fractions

In this representation the order relation between fractions is determined by their **lines**, and not by their individual **points**: The fraction whose line is higher is the larger fraction (see drawings 2 and 3). This rule is valid in the first quarter of the Cartesian system, and needs refinement with neg ive fractions (which was tried out with older populations, but will not be reported here). In the interviews we dealt with three situations of fraction-comparison, which denote a hierarchy in the development of students' ability to use the lines as problem-solving tools:

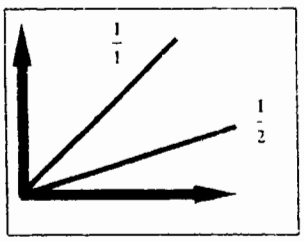
1a. The fractions were presented by their lines

The students were presented with a drawing of two lines in a Cartesian system devoid of points:

Drawing 2

The problem was:

"Here are the lines of $\frac{1}{1}$ and of $\frac{1}{2}$. Write each fraction next to its line."



$\frac{1}{1}$ and $\frac{1}{2}$ were chosen because we believed that most students knew which of them is larger. We expected students who had interiorized the representation of the relation ">" in the Cartesian system, and knew that $\frac{1}{1} > \frac{1}{2}$ will ascribe $\frac{1}{1}$ to the higher line, and $\frac{1}{2}$ to the lower. We found that 15 of the 20 students did so, and relied on the order relation between the fractions in their explanations:

S1: "*Because this is a whole, and it is larger than a half, therefor its line is higher.*"

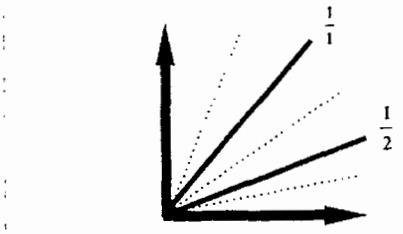
S10: "*Half is smaller. It is a fraction smaller than one over one. And the lines that are higher, which rise upward, are the lines that are larger.*"

1b. The given fractions were presented as lines while the answers were requested as points:

The students were presented with this Cartesian system and were requested to draw points of fractions:

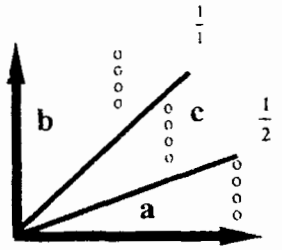
Drawing 3

a. Smaller than $\frac{1}{2}$;



b. Larger than $\frac{1}{1}$;

c. Smaller than $\frac{1}{1}$ **and** larger than $\frac{1}{2}$.

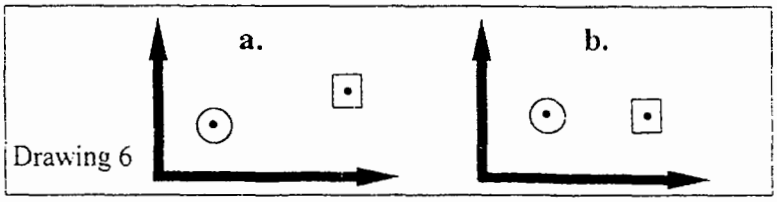


The same 15 students who succeeded to solve the previous problem, succeeded here too. S10 (for question c):

"*It can't be above the line of one, but it will be above the line of half.*"

2 students used lines for their answers:

14 students spoke of **zones of the plane:**



Drawing 5

1c. Both fractions represented by points

The students were presented with two Cartesian systems devoid of all but two points:

In each system the students were asked to mark the point of the larger fraction.

Drawing 6

In order to solve the problem they had to know that the order relation was determined by the relative position of the **lines**, and not of the points. 14 students used lines to solve the problem correctly. 4 of them actually drew the lines. 10 answered correctly with no visible action. When asked to explain they refered to lines in their explanations:

S4: "*If we take a line and we drew it from the origin-point up to the fraction, and we draw it, then we will find that the square will be beneath the line, so it will be smaller than it* [no line drawings, only hand gestures of imaginary line drawings in the air, accompanying the explanation].

S5: "*If I took a ruler and drew a line from here to there, the line would be higher than if I drew a line from here to there* [draws while explaining his answer] *and the higher the line, the larger it is.*"

S8: "*Because here if one draws of the circle, an imaginary drawing of the line, then the line is higher than the... if one draws an imaginary line of the square* [with each reference to a line "draws" with his finger in the air a line via the origin]."

S17: "*It has to do with the lines, not the fraction itself.*"

One might say that for these students the concrete action of comparing fractions by means of their representative lines was interiorized to a degree where they performed it in their imagination.

One student estimated the fractions corresponding to the given points numerically, and then compared them correctly. One student thought that the further the point was from the vertical axis, the larger the fraction. The others either could not solve the problem, or were not asked to.

2. The density of the rational numbers

The question was:

> "Find fractions (as many as possible) that are larger than $\frac{1}{5}$ **and** smaller than $\frac{1}{3}$: $\frac{1}{5} < \square < \frac{1}{3}$ "

16 students started with $\frac{1}{4}$. That was the only solution for 3 of them. Others added expansions of $\frac{1}{4}$. 2 students added ("*from my head*") a fraction that was not an expansion of $\frac{1}{4}$ ($\frac{3}{13}$ and $\frac{3}{10}$) and used the software for checking. The last 11 used the Cartesion system in their search for more solutions: They drew the lines of $\frac{1}{5}$ and of $\frac{1}{3}$ (see drawing 1), and wrote many fractions whose points were located between these two lines. As for how many such fractions exist, they all answered "*many*" or "a.*lot*" or "*infinite*":

S9: "[Draws the lines] *"All that is between this line and that line*" [writes $\frac{4}{13}$, $\frac{4}{14}$, $\frac{5}{16}$, $\frac{5}{17}$. Then she expands the drawing-domain to reach more fractions].
In.: "*How many are there?*"
S9: "***Up to infinity***".

S21: [draws the lines and writes $\frac{2}{7}$. Strolls with the cursor among the points within the lines, and continues to write: $\frac{2}{9}$, $\frac{3}{10}$, $\frac{3}{11}$, $\frac{3}{12}$, $\frac{3}{13}$.] "*there are a lot*".

Summary of findings:
The findings we described suggested answers to our two research questions. As to the question about the concreteness of this representation, we have shown that fifth-graders worked with the different components of the discrete Cartesian system - points, lines, axes, origin and zones. These were concrete to them to the extend that they were able to draw sketches by hand when needed.

As for the second question, about the development of the concept of fractions as equivalent classes, we have shown that:

- Students understood the mapping between the mathematical language and this representation (Resnick, 1987; Nesher, 1989): They could identify a fraction given by its point or line, draw sketches of a line or point of a given fraction, and even find the correspondence between sets of fractions of a given characteristic, and zones of the Cartesian system.
- The students knew the term "equivalence class of fractions" and its concrete representation - a line through the origin. They were also aware of the equality of any two elements of such class.

- The students used this concept and its representation to solve arithmetic problems. They did so when the **problem was presented by drawings**, such as when they found fractions smaller than $\frac{1}{2}$ beneath the line of $\frac{1}{2}$. They also did so when the problem was presented in formal **mathematical language**, such as when asked to find fractions larger than $\frac{1}{5}$ and smaller than $\frac{1}{3}$, they drew the lines of these fractions and found the required fractions between these lines. They could even make deductions about the abundance of such fractions.

Further findings, relating to the connections students make between this representation and other common concrete representations of fractions, will be reported in the presentation.

Conclusions

The findings of this research indicate that fifth-graders can develop the concept of a fraction as an equivalent class, provided that appropriate concrete representations and activities are used. Such development was made possible by the software "Shemesh".

The findings also indicate that this concept develops gradually. Further research is needed to obtain more insight into the nature of this development.

DECISION-MAKING STRATEGIES IN PROBABILITY EXPERIMENTS: THE INFLUENCE OF PREDICTION CONFIRMATION

Paul Ayres
University of Western Sydney Nepean
Australia

Jenni Way
University of Cambridge
UK

Two groups of grade six students observed a video-recording of coloured balls being drawn from a box (sample space unknown). After every fifth selection, students were required to predict the colour of the next ball drawn. One group observed a sequence where the most frequently occurring colour (white) was drawn 80% of the time following prediction, whereas for the second group, a white only appeared 20% following prediction. Even though the accumulated experimental probabilities prior to prediction for both sequences had been manipulated to be identical, the former group chose white, more consistently than the latter group. Consequently it was argued that children may be influenced in their probability judgements by confirmation or refutation of their 'predictions'.

One focus area of probability research, particularly in the context of education, has been inappropriate decision-making strategies, or *misconceptions* in situations involving random events (for example: Peard, 1995; Shaughnessy, 1981; Tversky & Kahneman, 1982). Several of these strategies are attributed to the effect of sequences of randomly generated outcomes from probability experiments on the subject's expectations regarding the 'next' outcome. One such strategy that has received considerable attention is *representativeness* (Fischbein & Schnarch, 1997; Kahneman & Tversky, 1972; Shaughnessy, 1981), which is the expectation that a random set of outcomes should be representative of the composition of the known sample space. Related to representativeness is the type of thinking known as *negative recency* or *gambler's fallacy*, where there exists the expectation that as the frequency of a particular outcome increases the probability of that outcome occurring decreases. For example; when repeatedly flipping a coin, a run of heads would lead to the expectation of the next flip being a tail. The opposite and less common strategy (Fischbein & Schnarch, 1997) is referred to as *positive recency* (in this case, predicting a head because that's the trend).

Much of this research has been conducted with adults, using written tasks or 'tests', in which preconceived sets of outcomes have been presented to the subjects. However, it is quite common for researchers working with children to use real random generators to accommodate children's need for concrete experiences (for example: Truran, 1992; Way, 1996). Often in this type of study the children, following a number of experimental outcomes, are asked to state what they consider to be the most likely outcome of the next random event. This context gives rise to a little studied, possible influence on decision-making; that of the confirmation or refutation of the 'prediction' by the actual next outcome.

Truran (1996), working with a *known sample space*, analysed the changes in prediction of primary and secondary students in regards to the next outcome. One

finding was that when the more-likely outcome was predicted, it didn't really matter whether the next outcome confirmed or refuted that prediction. However, if the less-likely outcome was predicted, the subject was highly likely to change the prediction, particularly if the following outcome refuted the less-likely prediction. Similarly, Ayres & Way (1998b) working with *unknown sample spaces*, found evidence that upper primary-aged students would change their prediction patterns according to how successful they were in their predictions. Although, students would choose the most frequently occurring colour under specific conditions, they would change strategy if their predictions were not rewarded.

The findings (not directly tested) by Ayres & Way (1998b) suggest that children may be influenced in their probability judgements by confirmation or refutation of their 'predictions' rather than the overall picture. Consequently, this study was designed to explore this theory directly. Because random generators naturally produce sequences which vary, a video-recorder (see Ayres & Way, 1998a) was used to control the outcome sequences and provide a realistic medium for children.

METHOD

Participants. Fifty nine grade six students from a primary school in the state of New South Wales, Australia, participated in this study. Students had not been formally taught any chance and data topics in their mathematics classes.

Apparatus. A video recording of coloured balls being chosen from a box was made according to the following procedure. Ten coloured table-tennis balls (6 white, 3 blue and 1 yellow) were placed in an opaque brightly-coloured box (18cm x 18cm x 14cm) with no lid. To ensure that particular outcomes occurred, the box was fitted with three cardboard compartments which were not visible from the camera angle. Within each compartment was placed a ball so that the three colours were represented once only. In addition, the box was fitted with a false bottom in which the remaining seven balls were placed. Hence when the box was shaken (before each selection), the noise was consistent with a box containing a number of balls. Furthermore, the compartment design made it possible for a researcher to select a particular coloured ball at will, but give the appearance that the ball was selected at random. In this fashion, thirty selections were made, with replacement, and consequently a particular colour sequence of outcomes was made to occur. The researcher (positioned in front of a white board) was filmed making the selections. As each selection was made, a second researcher recorded the "colour" on the whiteboard in a 6 x 5 array format. At all times, the researcher making the selections and the box was visible, as was the record of the colours previously selected. In order to make the video as authentic-looking as possible (see Ayres & Way, 1998a), a clock was positioned close to the whiteboard to indicate a continuous time passage and avoid possible suspicions of video-splicing. After five selections, the researcher paused and asked for a prediction to be made. This process was continued a further five times and a prediction was made after every fifth selection.

Ayres & Way (1998b) found that students of this age are more likely to select the most frequently occurring colour if a high percentage of the sample space is represented by that colour. Consequently, the particular sequence selected included 19 whites (63%), 7 blues (23%) and 4 yellows (13%). To create a situation where the most frequently occurring colour (white), appeared consistently on prediction, four of the first five prediction were manipulated to be white. This sequence was called the *Typical Outcome* sequence (see Table 1). The positions where predictions were made are underlined in Table 1.

Table 1: Colour sequences developed for the Typical and Non-typical groups.

Outcomes	Typical Outcome Sequence	Non-typical Outcome Sequence	Experimental Probabilities (%) W : B : Y
First five	WYWBW	WYWBW	60 : 20 : 20
Second five	WWBWY	BWWWY	60 : 20 : 20
Third five	BWWWB	WBWWB	60 : 27 : 13
Fourth five	WYBWW	YWBWW	60 : 25 : 15
Fifth five	WBWWW	BWWWW	64 : 24 : 12
Sixth five	WYWBW	YWWBW	63 : 23 : 13
	W	Y	

Note: Underlined positions indicate where predictions were made.

In the same fashion, a second video-recording was made. In contrast to the first, the less likely outcomes (blue and yellow) appeared consistently at the prediction locations. This sequence was called the *Non-typical Outcome* sequence (see Table 1). To achieve this effect, the underlined colours in the first sequence were rotated with a different colour within the same subset of five colours. As a result, only one white appeared in the first five prediction positions. Students who predicted a number of whites would therefore not be very successful. Furthermore, the accumulated experimental probabilities after each set of five outcomes (see Table 1) for both sequences were identical, and approximately matched the theoretical probabilities (60: 30:10). Consequently, if students viewed either sequence and were guided by experimental probabilities alone, they would choose white as the most likely outcome in both situations. However, depending upon which sequence was viewed, students' success rates would vary considerably. It was therefore anticipated that this design would cause the two groups to adopt different selection strategies.

Procedure. Students were randomly assigned to two groups. One group was shown the typical outcome sequence (Typical Group), whereas the second group viewed the non-typical outcome sequence (Non-typical Group). The experiment was conducted with small groups of students each time. As an introductory instructional

phase, a student was asked to select a ball from the box (used in the video) with the partitions removed, show it to the rest of the class, before returning it to the box. The class was then asked to predict what colour would occur the next time if another ball was selected. This procedure was repeated twice, so that students became familiar with the idea of making predictions following a random selection. The experimenter used the following statement: "What do you think the next colour will most likely be?" The wording "most likely" was used to encourage students to make decisions based on their concepts of chance; however, it should be noted that children may interpret words, such as "likely", differently to what is expected (Konold, 1991). They were also informed that there were some white, blue and yellow balls in the box, but no clue was given to the proportions. Additionally, the students were told that it was a game and students should try to predict as many correct colours as possible. When the experimenter was satisfied that the students understood the nature of the task, they were shown one of the videos according to which group they had been assigned. The video recording was shown on a large TV monitor positioned at the front of the classroom. After each selection a record of the colours was also recorded on the classroom chalkboard. After the first five colours were observed being drawn, the video was stopped and students were asked to make their predictions, then given time to record them on answer sheets. This procedure was then repeated for five more subsets. The language used by the researcher was identical for both groups, as was the task that the students were required to complete.

RESULTS

For each student, a sequence consisting of six colour predictions, was recorded. Given the nature of the prediction tasks in this study, of particular interest was the number of whites chosen. If students were guided by experimental probability then it was expected that a high percentage of whites would be chosen. To investigate this, the mean number of whites chosen for each group was calculated (see Table 2). In addition, the number of whites chosen in the first and last three predictions was also recorded (see Table 2). Ayres and Way (1998b) found that students may not necessarily choose the most frequent colour after a small number of observations and may need more information before committing to a strategy. By comparing predictions over the two halves it was possible to analyse the extent to which students refined their strategies as more selections were observed.

Over the six trials, the mean number of whites predicted by the Typical Group (2.73) was not found to be significantly greater than the Non-typical Group mean (2.65) under a two-tailed t-test ($t(57) = 0.26$, $p > 0.05$). Although, there was no difference in overall means between these groups, substantial differences can be found in the prediction patterns. By comparing the change from the first three predictions to the final three predictions there was a significant difference between the Typical Group (+0.61) and the Non-typical Group (-0.24) under a two-tailed t-test of differences ($t(57) = 2.44$, $p < 0.05$). For the Typical Group, a significantly

greater number of whites was chosen in the last three predictions (1.60), compared with the first three (1.13), under a paired t-test: $t(29) = 2.31$, $p < 0.05$. As the mean number of predictions for white was greater than 50 % (1.6 out of 3) for the final three, there was a clear indication that this group had started to favour the most likely outcome. Nineteen of the thirty students chose at least two whites. In contrast, the Non-typical Group chose less whites in the latter half (1.21) compared with the first (1.45), although the difference was not significant under a paired t-test: $t(28) = 1.16$, $p > 0.05$. A value of 1.21 out of 3 indicates that the group was less likely to favour the most likely outcome in their predictions. Only six of the 29 students chose at least two whites. The above analysis indicated that by the end of the prediction sequence there were significant differences between the groups. The group, which was being rewarded with correct answers by choosing the most likely outcome, was increasing the use of this strategy; whereas, the group which was not being rewarded was moving away from the strategy.

Table 2: Mean number of whites predicted by the two groups

	Typical Group (n=30)	Non-typical Group (n=29)
Mean number of whites chosen on first 3 predictions	Mean = 1.13 SD = 0.73	Mean = 1.45 SD = 0.79
Mean number of whites chosen on last 3 predictions	Mean = 1.60 SD = 0.81	Mean = 1.21 SD = 0.86
Mean number of whites chosen over 6 predictions	Mean = 2.73 SD = 1.08	Mean = 2.65 SD =1.20

Prediction Patterns

To gain insights into the type of strategies employed, prediction profiles for each group were found by calculating the frequency of each colour selected at each prediction point (see Table 3). The profiles indicate that many students changed their choice of colour. For both groups the most frequent colour chosen for the first prediction was yellow. This may be example of the *negative recency* effect as the other two colours had more recently occurred (see Table 1). Following the first prediction, the group profiles changed considerably. For the Typical Group, white was the most frequent (61%) colour chosen on the second prediction. As a white occurred at the first prediction point and because of the high proportion of whites occurring, this group may have been influenced by experimental probability in this instance. However, these students were not rewarded with a correct prediction, as a white did not occur when the colour was drawn. This failure may have also influenced the third prediction, as yellow was the most frequently (55%) chosen colour in this position. Again, this may be an example of negative recency as a

yellow had not occurred for five selections. For the remaining three predictions, white was the most frequently chosen colour, with 84% of the students choosing white for the last prediction. Overall, white was chosen by more students than any other colour except for the first prediction (when a sequence had barely been established) and on the third prediction (following the only non-white occurrence at a prediction point).

In contrast, the Non-typical Group, only had a clear preference (41%) for white on the third prediction. As this followed a white occurring at the second prediction point, it may have been the group's only majority attempt to use experimental probability. Although there are some other notable preferences for this group, namely 66% blues on the fourth prediction and a high number of yellows on the second and fifth predictions, it is unclear why these preferences occurred. It could be argued that both negative and positive recency effects occurred at particular points. Equally, it may be argued that these profiles are just random. However, what is clear is that this group was reluctant to predict white.

Table 3: Colour selections (%) at each prediction point

	Typical Group			Non-typical Group		
Predictions	W	B	Y	W	B	Y
First	29	16	52*	38	21	41
Second	61	32	3*	41	3	55
Third	23	19	55*	41	28	31
Fourth	42	26	29*	31	66	3
Fifth	42	23	35	31	21	48
Sixth	84	6	10	34	34	31
Overall	47	20	31	36	29	35

* Note: a red selected by one student at these positions

The above analysis, based on the data reported in Table 3, indicated that students in both groups changed the colour of their predictions considerably. The extent of these changes was investigated further by calculating the changes of colour made by each student in their prediction sequences. For example, a student in the Typical Group predicted the following six colours- W B Y W W B. This sequence involves four changes of colour from one prediction to the next The maximum of number changes possible is five. The mean number of changes made by the Typical Group and Non-typical group was 3.52 (SD = 1.06) and 3.38 (SD = 1.32) respectively. Both means indicate considerable colour changing. However, there was no significant difference found between groups on this measure under a 2-tailed t-test: $t(57) = 0.13$, $p > 0.05$.

To investigate the extent to which changes are influenced by previous successful predictions, changes were categorised according to whether they followed confirmation or refutation of predictions. For each student the number of changes made following either outcome was calculated as a proportion. For example, if a student made four correct predictions which were followed by a total of one change in colour following these successes, then the student had a ratio of 0.25 changes per successful predictions. For the Typical Group, the mean ratio of changes made (0.92, SD=0.47) following successful predictions was significantly greater than the mean ratio (0.46, SD = 0.46) following unsuccessful predictions under a paired t-test: $t(28) = 3.15$, $p < 0.01$. For this group, the students changed colour twice as many times following an unsuccessful prediction than a successful one. For the Non-typical Group, no significant difference was found between the mean ratio (0.62, SD = 0.42) following successful predictions and the mean ratio (0.71, SD = 0.46) following unsuccessful predictions under a paired t-test: $t(27) = 0.77$, $p > 0.05$.

CONCLUSIONS

The main objective of this study was to test the hypothesis that a subset (consisting of student predictions) of a sequence of "random" outcomes, can affect selection strategies. Even though the accumulated experimental probabilities prior to prediction for both sequences were identical, the Typical Group chose white, more consistently than the Non-typical Group, especially in the latter half of the trials. The experimental design was therefore instrumental in forcing measurable differences between the groups. Consequently it was argued that children may be influenced in their probability judgements by confirmation or refutation of their predictions. Certainly students in the Typical Group were less likely to change colour following a successful prediction, than following an unsuccessful colour. In contrast, students in the Non-typical group consistently changed colour. These changes for the latter group may well have been caused by an underlying conflict between the overall observed experimental outcomes and the lack of white occurring in the prediction locations.

To a certain degree, this study has shown that children this age, without any formal probability schooling, can make decision based on likelihood. However, probabilistic reasoning may not be well developed as decision making seems to be highly influenced by unexpected outcomes. Consequently, any teaching activity in this domain needs to make a focus on this issue. The study has also shown the effectiveness of using a video-recorder as a research tool. No student doubted the validity of the videos. In fact, all students enjoyed the activity. From the perspective of future research, the study will be expanded to investigate other age groups and to include experiments when the sample space is known. In addition, interviews will be conducted to find out if their given reasons support the data trends.

THE DEVELOPMENT OF MATHEMATICS EDUCATION BASED ON ETHNOMATHEMATICS: THE INTERSECTION OF CRITICAL MATHEMATICS EDUCATION AND ETHNOMATHEMATICS

Takuya BABA
IDEC, Hiroshima University, Japan

Hideki IWASAKI
IDEC, Hiroshima University, Japan

Abstract

Ethnomathematics so far has gained a certain degree of momentum in the developing countries, and some developed countries with multicultural backgrounds as well. On the other hand, critical mathematics education which originated from a developed country, has highlighted critical points of ethnomathematical research. In order to connect ethnomathematics to school mathematics as a part of educational endeavor, the complementary relation between critical mathematics education and ethnomathematics has been deliberated in both ways. Subsequently the foundational framework has been proposed to strengthen the critical nature by means of reciprocity and to develop mathematics education based on ethnomathematics.

1. Introduction

'Ethnomathematics', which was named by D'Ambrosio at ICME 5, in 1984, has resonated among researchers who tried to engage in cultural aspects of mathematics education, and has formed a productive field of research to enlarge the interpretation of mathematics education. Some examples shown in such as Ascher (1991) and Gerdes (1988, 1990) have gradually added concrete images to its general characteristics and materialized its abstract existence. However, the clearer its characteristics become, the more criticisms are made against its potential and applicability to mathematics education.

> 《Ethnomathematics does not amount to a set of general thinking tools since the mathematical activity is 'locked' into this practice , of which it is part, and it cannot function as a tool or basis to criticize that practice itself. Being critical towards the use of mathematics in the context of practice requires viewing that practice from an external perspective in a way that allows the mathematics to be distinguished in some way from the remaining aspects. It is this complete integration of mathematical activity with practice which marks it as distinct from the mathematics of the classroom.》 (Keitel, 1997, p.19)

In other words, her criticism is equivalent to the observation that ethnomathematical activities are closely linked with practices and there is no

necessity for the practitioners to explore the implication and method of their activities. On the other hand, the 'general thinking', which forms a core of school mathematics, demands the completely opposite direction, that is consideration of the reason and method of activity. Thus, the critical points in her words can be summarized as follows.

"Ethnomathematics cannot express itself in its own words."

"The practitioner of ethnomathematics is not necessarily conscious of its implication."

"The objectives of ethnomathematics and school mathematics are different in nature."

Since these points are taken from the perspective of critical mathematics education proposed by Keitel, the first objective of this research is,

① to consider the relationship between both ethnomathematics and critical mathematics education.

Applying this result, the second objective of this research is,

② to consider the preconditions such that ethnomathematics may provide some perspectives for the foundational reconsideration of mathematics education.

2. Critical Mathematics Education (CME)

Keitel has referred to Skovsmose from various perspectives in CME and Skovsmose has developed this theory more overtly and radically. In this research, therefore, the focus of consideration is upon the theory of Skovsmose.

CME is an educational theory which reflects critical theory of Frankfurt School and develops educational practice for the formation of critical citizenship. Its systematization is being made in northern Europe and Germany. The subject, mathematics, had a tendency of being excluded from the practice because of its formal and objective nature, but Skovsmose pointed out the importance of critical aspect which should be incorporated into mathematics education, as follows.

《It is necessary to increase the interaction between ME and CE, if MT is not degenerated into one of the most important ways of socializing students (to be understood as students or pupils) into the technological society and at the same time destroying the possibilities of developing a critical attitude towards precisely this technological society.》 (1985,p.338)

Here, we would like to clarify the objective of CME through the verification of its three key terms, instead of trying to define directly the meaning of 'critical'. These three key terms, which are listed below, play a central role for the fulfillment of the objective of CME.

(1) critical competence (2) critical distance (3) critical engagement

More concretely, (1) critical competence means that students need capability to think and judge by themselves what is important and they are presumed to have it for the active participation in the educational process. This is a human element of the educational process. (2) critical distance is to keep a distance from the given subject or curriculum, and the teacher and students are not supposed to take it for granted. This regards an element of curriculum in the process. (3) critical engagement means to direct the educational interest of classroom towards the outside of school and to relate it to the existing social problems. This concerns how to set the objective in the educational process.

> 《I conceive a majority of the developed examples of concrete materials to be used in mathematical education as being abstract from a social point of view, even if they are concrete in a physical sense.》 (1995,p.63)

Skovsmose pays much attention to the social implication of teaching material and what it realizes in mathematics education. Any practical examples in CME aim at the formation of critical citizenship through thematization and projectization strategies beyond the subject framework at present. Thus when the children are asked if it is reasonable to do something in order to get pocket money or what is a reasonable salary, they are naturally stimulated to deliberate on the issue of money more socially.

This perspective is very indicative when we consider the fact that many children just learn to do calculation without knowing the reason and yet this technological society is supported to be productive by high level mathematics. However, there seems to be little consideration from the viewpoint of mathematics in particular and this aspect will be discussed after the two-way consideration of ethnomathematics and CME.

3. Ethnomathematics

The term, 'ethnomathematics', sometimes causes confusion in terms of whether the definition refers to a single mathematical activity, a set of mathematical activities in each culture, or the research to analyze these activities. We think it is not very productive to adapt a narrow definition, and that awareness of multi-aspects of the definition should underpin the discussion.

> 《'ethnomathematics' can refer to a certain practice as well as to the study of this practice. In what follows we use 'ethnomathematics' in both senses, although we primarily think of ethnomathematics as including certain educational ideas and a research perspective.》 (Vithal, Skovsmose, 1997, p.133)

In this study, we will not differentiate these two 'ethnomathematics', as

practice and its analysis. The more explanatory terms, 'mathematical activities' and 'ethnomathematical research', will be employed to make a clear distinction only when necessity arises.

While many mathematical activities have been identified and unified into ethnomathematics, Bishop (1994, p.15) and Vithal, Skovsmose (1997, p.134-135) have recently tried to clarify the structural relationship among some strands of the ethnomathematical theme. Their classifications have similarities from the historical and socio-cultural point of view except that the latter has the additional category as a research to focus on the relationship between ethnomathematics and mathematics education. Naturally Bishop as a mathematics educator knows its importance but Vithal, Skovsmose state clearly that this has potential to integrate other strands.

The intention of this paper relates to this category which is to lay a foundation for the relationship between mathematics education and ethnomathematics. The ethnomathematics emerged as 'objection' from the developing countries against the predominance of Western mathematics in schools, but the fulfillment of this goal requires ethnomathematics to be self-referential, which will be discussed in depth in the next section.

Here we would like to take one example for further discussion. Gerdes (1990) deliberated on the application of sand drawing, Sona, to the mathematics curriculum.

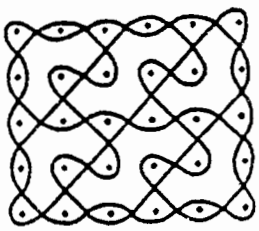

Fig.1 Sona

The Sona drawer has to draw efficiently and beautifully by any means. The method was invented to mark a set of equidistant points with a fingertip on the wiped-up ground and make a drawing by use of these points as reference. Many Sona drawings are done under the restriction of symmetry and in one stroke. And the laws such as symmetry and repetition incarnated in the drawing can represent arithmetic relation, sequence, symmetry and similarity in mathematics education.

Gerdes attempts to resurrect a cultural value with introduction of this Sona. Accordingly this creates a new research field by means of applying mathematical activities, immanent within African culture, to the curriculum development.

4. Bilateral Consideration of Ethnomathematics and CME

According to Vithal, Skovsmose (1997, p.132), while both ethnomathematics and CME have a common term as a reaction to modernization theory, the former has a cultural background and the latter a political one. In short they share the critical stance against the implicit belief which modern society holds but from different angles. However a further deliberation on this difference exposes the difficulty and complexity of this problem. One person, one group of people, or one society can criticize another party from a certain angle but this fact only exposes half of 'the truth'. Neither ethnomathematics nor CME are immune from criticism. That is why we would like to consider as a next step the relationship between ethnomathematics and CME in both directions and to find a complementary role to strengthen each other structurally.

Consideration of CME by use of ethnomathematics

As discussed earlier, three key terms of CME are critical capability, critical distance and critical engagement, which provide important views to the educational process. As for the first term, it is necessary to retain an inner standard for the criticism, and this standard and critical capability are fortified by the reflection of his/her own mathematical activities.

The second term implies 'to keep a distance from curriculum' and it requires a mathematics different from the one under discussion. Ethnomathematics substantiates this other mathematics in a practical way.

> 《whenever we increase our understanding of other cultures, we increase understanding of our own by seeing what is or is not distinctive about us and by shedding more light on assumptions that we make which could , in fact, be otherwise. Our concepts of space and time are, after all, only our ideas and not objective truth. And, there is no single correct way to depict objects in space, nor one correct way to orient a picture in order to comprehend its contents.》 (Ascher, 1991,pp.186-187)

Fig. 2 Musk-ox hunting on North Somerset Island

Also Ascher has given this picture as an example. It enables us to imagine and investigate a mathematics beyond the horizon of our culture.

The critical engagement as the third term means 'to direct an interest toward the outside world of classroom'. It naturally brings about such awareness to stay within the situation of ethnomathematical practice, because the ethnomathematics is unavoidably intertwined with other activities in the society.

It has been shown from the above consideration that CME provides just the theoretical framework and ethnomathematics can concretize this framework of CME by providing practical examples.

Consideration of Ethnomathematics from the Perspectives of CME

Naturally ethnomathematics takes a critical stance against Western mathematics from its original background, but the first two of Keitel's points require ethnomathematics to verify itself critically. That concerns the expression of ethnomathematics in its own words and the awareness of ethnomathematics practitioners. At this junction, Gerdes offered a kind of solution in his educational consideration.

> 《The artisan, who imitates a known production technique, is, generally, not doing mathematics. But the artisan(s) who discovered the technique, *did* mathematics, was/were thinking mathematically. When pupils are stimulated to *reinvent* such a production technique, they are doing and learning mathematics.》 (1988, pp.140-141)

This means that the artisan of mathematical activities, with little mathematical consciousness, practices his own activity as a part of culture. However, it is this mathematical consciousness, and in other words the objectization of practice in mathematical perspective, that enables the incorporation of ethnomathematics into the educational practice. And this is not the viewpoint of practitioner but the one of creator.

In the example of the Sona, there exists a specific method 'to plot a matrix of points on the sand beforehand' in order to make a perfect Sona drawing without hesitation. This method transforms 'to draw Sona' to 'to plot a matrix of points' and 'to follow an algorithm to travel through these points'. However the repetition of drawing the Sona a thousand times will not automatically give birth to this method, but for this invention it is necessary to consider the process analytically and synthetically. This transformation provides justification for its applicability to education. Therefore, the critical verification of ethnomathematics has a close relationship with the fact that 'ethnomathematics is engaged in mathematics education' and we suppose that the last point by Keitel can find a solution in this connection.

As for this critical verification we would like to examine the Sona further by use of key terms of CME. In this case students are assumed to have critical competence basically and they are encouraged to do mathematics from the viewpoint of being creator. The critical distance from the ethnomathematics is required implicitly here. In other words, this example already includes some key terms of CME. The Sona may be able to cast the question to the applicability and eligibility of school geometrical materials, but in mathematics education its self-critical nature should be scrutinized. To view critically the Sona will induce the students to look around themselves, to analyze the mathematical activities in their environment and to develop these activities into an organized but still somewhat personal tool.

5. Conclusion

The first objective of this paper has been to consider the relationship between ethnomathematics and CME in both directions. As a result, it has been shown that mathematical activities substantiate three key terms in CME, and in return these terms can provide a structure and thus a rationale for the application of ethnomathematics to mathematics education. The second objective of this paper, that is the consideration of prerequisite for ethnomathematics to contribute positively to mathematics education, has also been addressed in this two-way consideration because of their complementary relationship.

So far, ethnomathematics has developed discussion from the viewpoint of critics to criticize the school mathematics, but the perspective of educational application necessitates it to be viewed critically as well. This means the incorporation of 'ethnomathematics as method' with 'ethnomathematics as object' can consolidate a foundation for the research field of ethnomathematics. The following framework will be proposed for the integrated approach in ethnomathematical research.

(1) to reflect critically mathematics education through mathematical activities and ethnomathematical research

a) mathematical implication b) social implication

(2) to reflect critically ethnomathematics from the perspectives of critical mathematics education

c) mathematical implication d) social implication

The distinction between mathematical implication and social implication is important to consider the characteristics of the subject, mathematics. The

mathematical implication here concerns the formality peculiar for the subject and, on the other hand, the social implication means the usage of the mathematical concept in the social context.

In this framework, the first component as (1) has potential to reveal the uncritical nature of the present mathematics education. The students are frequently required to develop mathematical thinking as an objective tool with what they find little meaning, but they are not encouraged to consider the relation between this objective tool and their mathematical activities. Here the integration of CME and ethnomathematics plays an important role to uncover what has been taken for granted. The second component as (2) will invite the students to reflect their activities and develop their thinking from there. Their own activities are the target of reflexive thinking and at the same time the source for higher level of reflection. For this development three key terms of CME will provide a guide in how to develop the critical thinking upon their mathematical activities.

Thus we think this integrated approach by use of the above framework plays a pivotal role in the practical and theoretical development of the ethnomathematical program so that ethnomathematics research will eventually produce a fruitful alternative to the present school mathematics.

LACAN'S FOUR DISCOURSES AND MATHEMATICS EDUCATION

Roberto Ribeiro Baldino
UNESP, Rio Claro, SP, Brazil

Tânia Cristina Baptista Cabral
UNESP and EBP-SP, SP, Brazil

Abstract

In this paper, we use Lacan's four discourses in order to characterise current traditional mathematics teaching and suggest an alternative methodology from the point of view of psychoanalysis theory. The paper is a continuation of "Lacan and the school credit system", Proceedings of PME22, v. 2 p. 56-63.

Introduction

In Baldino & Cabral [1998A] we pointed out that the plenary conference of Shlomo Vinner in PME-21 [Vinner, 1997] highlighted a mismatch between students' discourse and action with respect to the *credit system*. We referred to it as a *mismatch phenomenon*. We remarked that it is in this gap opened by such a mismatch that Lacan places *desire*, and we approached this phenomenon from the perspective of psychoanalytical theory of *Lacan's four discourses* [Lacan, 1973]. This theory has helped us to understand what we have been doing for quite some time, namely learning mathematics as an experience of modification of the *desiring subject* [Cabral, 1998].

In that paper, we referred to discourse as a complex process entailing the participation of the talking subject in three registers: *imaginary* (pre-suppositions of the talking action), *symbolic* (language), and *real* (jouissance). Therefore, the discourse was to be understood as a *joint effort* of the students and the teacher in order to *sustain* a certain relation or statute of actions and utterances. According to Lacan, there are four possibilities for this statute: the *master's*, the *university's*, the *object's* and the *hysteric's* discourses. In the paper mentioned, we introduced four signifiers: the *master* S_1, the *knowledge* S_2, the *lost object* a (petit-a) and the *hysterics* $\$$ and four positions: the *agent*, the *work*, the *production* and the *truth*. The master's discourse is characterised by the distribution of these signifiers through the four positions according to the following diagram (figure 1). We invested the master's discourse in the analysis of a hypothetical traditional classroom. The positions are occupied respectively by the *teacher*, the *student*, the *credit system* and the *castrated* or *ignorant teacher* (figure 2). We also hinted that the three other discourses should be obtained by counter-clockwise shifts of the signifiers through the positions.

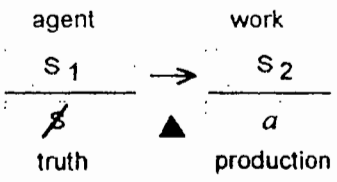

Fig. 1: the master's discourse

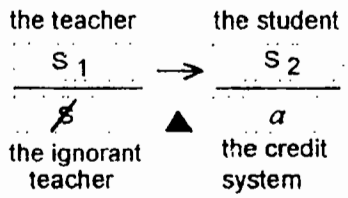

Figure 2: the master's discourse in the classroom

In the present paper, we shall invest the other three discourses comparing a hypothetical traditional classroom with a classroom organised according to an alternative teaching proposition called Solidarity Assimilation Groups (SAG) [Baldino, 1997]. We shall show that, in traditional teaching, these discourses alternate from the university to the object and then to the hysteric, whereas in SAG, this order is reversed. For further references about psychoanalysis, language and mathematics education, see Brown [1997], Atkinson & Moore [1998] and Baldino & Cabral [1997, 1998B].

The University's discourse

If we follow the student's way from elementary to high school and into the university, we shall find that it is not the master's discourse that is present in the classroom any more. The challenge of the teacher's authority has disappeared. In the university, the master's discourse happens only during a very brief initial moment when the teacher states the course's pre-requisites and the goals to be pursued, according to the syllabus. Honours students do not ask questions at this moment. The teacher minimises the discussion of the credit system and refers to it as a minor bureaucracy. He assumes that the student's grades are a consequence of the acquired knowledge. The students seem to readily agree. The teacher makes an effort to hover over the magisterial authority (S_1). He tries to build an image of himself, identifying himself with a scientist or researcher. The lessons are dominated by a continuous word-flux emanating from the blackboard and received by affirmatively-nodding frenetically writing students sitting on the second row. The first row is most of the time empty, since it is reserved for students considered geniuses.

In the mathematics classroom, the students frequently expect clear explanations in a steady voice and watch carefully for the teacher's vacillations. Questions are allowed within narrow limits. Questioning is the risky enterprise by which students establish their position in their ranking. The risk is pays off if the question embarrasses the teacher or reveals that he has made a mistake. Each class starts at the point where the last one stopped, following the thread of organisation of mathematical knowledge established by mathematicians who operate the scientific practice. "*Le savoir est, à un certain niveau, dominé, articulé de nécessités purement formelles, des nécessités de l'écriture, ce qui abouti de nous jours à un certain type de logique*" [Lacan, 1991, p. 53]. We say that an effort of linearisation of the signifiers' chain is evident mainly in mathematics. In order to perfectly understand and dominate this logic the teacher has to talk, to show and practice his ability as a juggler of knowledge. Such is the *scéance magistrale*. The teacher's alibi for putting on this sort of game is to pretend that he is teaching. He actually believes he is and that the students learn by listening to his voice. He believes that his talking can fill the gap in the students' knowledge. Actually, he is the one who is learning the most.

The foundation of this kind of discourse is "*une prétention insensé d'avoir pour production un être pensant, un sujet*" [Lacan, 1991, p. 203]. Indeed, signifiers have rotated one fourth of a lap counter-clockwise (figure 3). The signifier of the castrated subject **$** is now in the place of *production* and exerts the function of *loss*. It points to the students that were lost, either because they gave up the course's credit or because they will never use the acquired knowledge in their future lives, or because they did not actually learn what the institution claims they did.

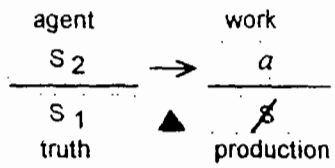

Figure 3: the university's discourse

The *petit-**a***, the cause of desire that was the lost production of the student in the master's discourse, is now on the numerator and exerts a demand that puts the agent into action. Now the *petit-**a*** indicates the students' plenary, the big-Other to whom the teacher addresses. "*L'objet a, c'est ce que vous êtes tous, en tant que rangés là*" [Lacan, 1991, p. 207]. The $\mathbf{S_2}$ must exert its function with respect to desire from the position of the agent.

However, desire is generally the Other's desire. What the teacher desires is what is socially desirable. Hence, it is necessary to go after the teacher's desire on the right of the arrow, in the place of work, from where the Other, in this case the students' assembly, exerts the demand. In this position we now have the object ***a***. As the cause of desire, the ***a*** is hidden in a gap of the Other, where the agent will have to look for it. In order to do that, the teacher tries to guess the student's doubts (or questions and motivations) for the knowledge that he wants to introduce. The arrow indicates that it will be impossible to fulfil this guess, but a renewed attempt has always to be made, in order to sustain the university's discourse. The students, on the other hand, look through the blackboard at their future career or at the admittance door to the math department.

Since the ***a*** is a lost object, its function of demand can only be exerted if a representative of it reaches the front stage and offers itself as a desirable *façade* of the ***a***. This façade acts as a bung of the Other's gap: "*C'est là le creux, la béance que sans doute viennent d'abord remplir un certain nombre d'objets qui sont, en quelque sorte, adaptés par avant* (...) *ils sont priés de constituer avec leur peau le sujet de la science* (...)" [Lacan, 1991, p. 121]. The bung of the gap, the *façade* of the *petit-**a***, is the smart faces of affirmatively nodding students.

In order to sustain the $\mathbf{S_2}$ in the position of the agent, it is necessary to pretend that what the teacher says is true, not because *magister dixit*, but because of a logical reasoning stemming from solid epistemological foundations. The magisterial authority ($\mathbf{S_1}$) must be repressed under the stage where he stands and must never be evoked as an argument. It is necessary to make believe that what is hidden under the stage is the deep secret of knowledge. It is the ***a***-students who actually work, and as workers they have to produce something. The barrier in the denominator indicates that there is no possible contact between the secret of knowledge and the castrated subject. Such a contact would short-circuit the whole scheme. "*Comme sujet, dans sa production, il (**$) n'est pas question qu'il puisse s'apercevoir un seul instant comme maître du savoir*" [ibid. p. 203]. The university discourse is the main expedient used by the State, the Law and the Ideology in order to assure that the labour work-contract is made between equal parts that meet freely in the market.

The object's discourse

In general, at the end of the course there is a final exam. Students are expected to review the course material and organise their ideas in order to show a certain performance, the so-called "mathematical ability". However the exam invariably leads to credit and certificate. The students work in order to prepare themselves for the exam. However, the work is now done by the ignorant subject ($\mathbf{\$}$) who is at home, at the student's house or in the library as the subject who tries to understand the course material. Consideration of classrooms in third-world countries shows that, for many students, the acquisition of the necessary knowledge is an impossible strategy to get credit [Baldino, 1997]. They lack the adequate background and study habits. They resort to several *ad hoc* strategies among which rote learning is the most widespread [Cabral, 1992, 1998]. Vinner refers to such strategies as "pseudo-conceptual" and "pseudo-analytical modes of thinking" [Vinner, 1997, p. 1-70]. The object of desire (***a***) is the credit system, now in the position of the agent. True knowledge ($\mathbf{S_2}$) is repressed and provides an alibi for the credit system to operate. The result is a credit certificate, a meaningless sheet of paper stamped "*passed*" ($\mathbf{S_1}$) without which the student cannot move into the next course. The certificate is just as

void as a king's signet, a mark without which the profession cannot be practised. The arrow indicates that no pseudo-learning strategy can assure that the student will pass. The black triangle indicates that a direct connection between the certificate (S_1) and the true knowledge (S_2) would invalidate the whole pseudo-learning strategy and substitute true knowledge for rote learning (figure 4).

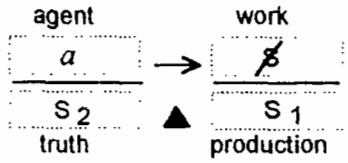

Figure 4: The object's discourse

The hysteric's discourse

It is evident that the school apparatus cannot function only on the basis of either the university discourse or this kind of object's discourse, since the production of such discourses are respectively the cultural eunuch and a piece of paper. Somewhere else in the university some other kind of discourse must be happening. "*The moment one knows the difference between analytical and pseudo-analytical he or she can reflect about their thought processes, abandon the pseudo-analytical and follow the true-analytical. I say abandon the pseudo-analytical because usually the pseudo-analytical comes first*" [Vinner, 1997, p. 1-74].

Indeed, the *scéance magistrale* is followed by the class of *travaux dirigés*. Later in the exam the students will be asked to reproduce this sort of work, without the help of the teacher. The students are now expected to ask *What is this? Why does it work? What is the ultimate reason for it?* They are expected to address these questions not to the teacher but directly to the organisation of mathematical knowledge expressed in the books. They are expected to reduce complex developments to symbols of their own. In the *scéance magistrale* the teacher has showed them that he can do it, hence this is possible. They are told: *Don't you see that now it is your desire that moves the process? What do you want from school? Your production should now be your own comprehension*. This means that now each student has to work ($\$$) in order to supply his/her ignorance with respect to a small piece of mathematical knowledge (a) generally in the form of a problem to be solved or a proof to be understood. Placing oneself in the position of the one who does not know ($\$$) is the fundamental condition for learning. The condition of possibility for this to happen is that this piece of knowledge becomes a representative of his/her private object of desire. In their effort, the students are comforted by the idea that there is an ultimate reason for each mathematical result to be true, since it fits into the organisation of mathematical knowledge (S_2).

The student knows that the exam questions will not be mere application of ready formulas and that some kind of extra difficulty will be involved. S/he will have to resort to the history of his own knowledge acquisition to be found in the under-pressed S_2. The effort is paid off by the *Aha! I got it!* This "aha" (S_1) means nothing, except that something has died in the subject. Indeed, an old (ignorant) subject has died and another one who dominates this piece of knowledge, has been born. Comprehension has no weight. The arrow means the impossibility of fully supplying the subjects demand for understanding. Some residue is always left. The triangle means the isolation: if there would be a passage between S_1 and S_2 in these positions, there would be no possibility of a *aha*, since S_2 is already complete (figure 5).

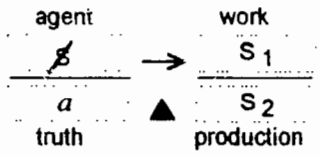

Figure 5: the hysteric's discourse

However, things do not generally happen as expected. The day before the exam the student is at home reviewing the course's subject-matter. Since s/he lost a long time as a good *a*-student, studying the *a*-theory for the exam of another course, s/he finds out that there will not be enough time, neither to do the exercises and understand the proofs nor to accomplish any fast rote learning. Many obscure points remain. S/he dangles completely lost between the notes in the binder and the textbooks. *Somebody please tell me what to do*; s/he asks herself. At mid-night s/he is tired. At this moment the exam loses its meaning, either as a warranty of knowledge for the future courses or as a means to pass this course. The Other's demand becomes concentrated on a single point. The student simply hopes to be lucky the next day. The exam becomes a pure $\mathbf{S_1}$ that goes to the position of demand of the other in the form of a school's "*honour's code*", reminding the student that there are less honourable strategies.

The cause of desire (a) sustains the agent as the castrated subject whose truth, not to be revealed at any price, is that s/he is a distressed student ($\not{\mathbf{S}}$) who has an exam next day and to whom the institution did not provide enough time and conditions to learn. S/he should not be blamed for such a failure. The final production of this discourse is the last sprout of the traditional school credit system, the inclusion of *cheating know-how* ($\mathbf{S_2}$) among the strategies to get credit. The cheating document is going to be thrown away after the exam, eliminated as if it had never existed. The arrow indicates the impossibility of the above-depicted student to satisfy the divergent school's demand, no matter how hard s/he works. The triangle means that the truth of the hysteric cannot face the know-how that constitutes it as a truth. Knowing how to pass without learning, cannot be admitted as legitimate.

The four discourses in the SAG classroom

It is possible that what we are calling traditional teaching cannot be fully found anywhere. Each classroom has some traces of it. For the sake of the exposition we have assembled all these traces in a single exaggerated cartoon and have labelled it *traditional teaching*. It consists in a sequence of four moments. Briefly, an inaugural moment, based on plain authority (the course's introduction), a second moment dominated by a verbal flux (the *scéance magistrale*), a third moment centred on the credit system, and a final moment where the student only hopes for luck in the exam.

If we want the students to learn anything beyond learning how to get credit, we must do something different from the traditional teaching described above. We propose SAG as one among possibly many alternatives to face the difficulties pointed out by the preceding analysis of the school apparatus. It can certainly be said that such an analysis was biased. Which one is not? We explicitly admit that differently biased analysis would lead to other propositions.

In the alternative didactical and pedagogical SAG proposition, the four moments alternate in the reversed order: we go from the master's discourse to the hysteric's discourse, then to the object's discourse and end with the university's discourse. In addition, some roles that support such discourses will be reversed.

At the first moment of a typical SAG classroom, the master's discourse is present. However, the teacher is the one who knows ($\mathbf{S_2}$). She is informed by everything that we have just written. She knows that the students want to get credit and she resists co-operation. However, she does not display this knowledge. She works to organise the classroom in such a way as to frustrate the (re)production of the credit system distortions. A work contract explicitly including all rules to get credit is introduced and tried for a couple of weeks, before it is put to a vote. The contract is based on some non-negotiable principles. As a characteristic of SAG it includes specific rules to get credit for classroom group work, for collective classroom organisation and for tutorial sessions [see Baldino, 1997]. Insofar as the students are not used to similar work contracts, they show some degree of astonishment. However, they generally end up accepting the contract and abiding by the teacher's proposed classroom organisation. In this way they preserve their position as students (S_1). As the ones who are there to learn, students are ignorant by definition. This ignorance includes ignorance of classroom organisation. Such ignorance supports their consent ($\mathbf{S}$). The production of this discourse is a certain classroom organisation (a). It may take a few weeks to get it going (Figure 6).

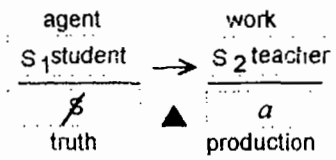

Figure 6: The master's discourse in the SAG classroom

Next, the teacher distributes worksheets to the groups of students or assigns them a specific task from the textbook. The students naturally ask what they are supposed to do. Here is a typical dialogue:

Student: *What do you want me to do?*
Teacher: *Look at the task on the blackboard.*
Student (later): *May I do it this way?*
Teacher: *If it is right, you may; if it is wrong you may not*
Student: *Is it right?*
Teacher: *Check with your peers.*

The teacher deliberately, but only to a certain extent, refuses to assume the function of the supporter of mathematical truth. She stands and observes the class, trying to decide which group she is going to visit next or which general instruction or advice she should write on the blackboard. Since the voted contract is prevailing, the student identifies the watching teacher's eye as a kind of demand ($\mathbf{S_1}$) to him/her from some point of a picture impossible to fully apprehend ($\mathbf{S}$). The students know that credit is at stake in this gaze. However, they also know that the condition to get credit is not displaying mathematical ability. Instead, they are expected to *work-to-learn*, according to the established group work rules. These rules include listening to their peers and being able to explain how they have solved each problem, until a consensus is reached or a clear divergence is established. Rules to get credit for group work explicitly exclude right/wrong mathematical criteria. In order to sustain such a situation, mathematical knowledge has to appear as the hidden object of desire (a). The production of this discourse is the collective elaboration of the solution of the assigned exercises or questions. No possible action can completely free the student from the staring of the teacher ($\rightarrow$). No contact between the production and

mathematical truth is possible (▲); *credit is for working to learn and understand*, not for getting the right solution (Figure 7).

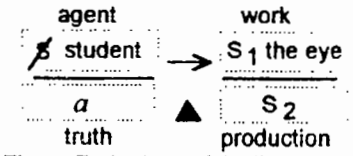

Figure 7: the hysteric's discourse in the SAG classroom

At the end of the class, each group hands in a common worksheet with the result of their work. In the next class, the teacher gives these worksheets back to the groups, with added remarks to be further worked out. Mistakes are pointed out, but they do not weigh negatively on credit. The first task of the group is to correct the mistakes and answer to the teacher's specific remarks. The ignorant student ($) who inquires into the mathematical objects (*a*) settles the demand.

Mathematical knowledge (S_2) is present and assures an underlying function of coherence indicating that this demand makes sense and may in principle be satisfied. The production is the student's exclamation: *Aha, I got it* (S_1). Of course, this situation is a mere hope. It never happens completely, as we would like it to happen (→). The student's "*Aha*" only marks the beginning of a necessary explanation and is not worth it (▲) (Figure 8).

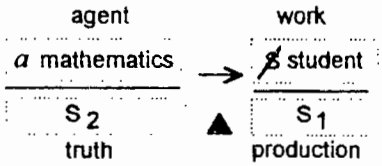

Figure 8: the object's discourse in the SAG classroom

Finally the class is organised in such a way that students go to the blackboard to present the solutions of their groups to the students' assembly or to the peers who attend the tutorial meeting. This is certainly a typical university's discourse, but contrary to the situation described in the traditional teaching, now the speaker is the student (S_2). The demand is put forth by the audience (*a*), as before, but it is does not consist of affirmatively nodding students. The objective of the meeting is to give back to the student at the blackboard a reading of what s/he is saying. Students are instructed to watch for points where the comprehension of the colleague at the blackboard may look frail and to convey their remarks, not through statements of sapience addressed to the teacher, but through questions addressed to the student at the blackboard until s/he realises his/her weak point was. The teacher's authority assures the co-ordination of the process (S_1). The production is the castrated subject ($) insofar as the students in the audience recognise their difficulties in the mistakes of the student who is at the blackboard (figure 9)

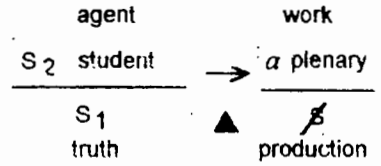

Figure 9: the university's discourse in the SAG classroom

SAG's daydream is the following. If classroom group work is well done, if the students have the necessary pre-requisites for the course and if the assigned tasks are adequate, there should be no need for exams. Students may get credit only on the basis of group work assessment. This is not because SAG assures that the students will learn as much as the institution requires them to learn. It is because we will have learned as much as possible, since we will have engaged them in the tasks best suited for their learning and given them the best possible assistance. In reality, we may also say there is not such a classroom fully organised according to SAG. SAG is a principle to be followed: *credit for group-work, not for mathematical ability*; in one word, for the ethics of work in the classroom [Baldino, 1998]. In practice the work contracts have established a percentage (up to 30%) for group work assessment. This principle is necessary to bring and sustain the object's discourse in the classroom. This is not as easy as is supposed in Vinner [1997]: "*The moment one knows the difference between analytical and pseudo-analytical, he or she can reflect about their thought processes, abandon the pseudo-analytical and follow the true-analytical. I say abandon the pseudo-analytical because usually the pseudo-analytical comes first*" [Vinner, 1997, p. 1-74].

ACTION RESEARCH: COMMITMENT TO CHANGE, PERSONAL IDENTITY AND MEMORY

Roberto Ribeiro Baldino

Antônio Carlos Carrera de Souza

Action Research Group in Mathematics Education, UNESP, Rio Claro, SP, Brazil

ABSTRACT

This paper reports on the activities of a five-year action research group whose goal is to develop a speech community committed to change the failure of mathematics teaching and the classroom routines that support it. Our premise is that accepting or challenging the stories told by newcomers to the community about their classroom experiences will interfere with the formation of their professional identities by preserving some of their recollections in the community's memory and dismissing others. Ms. Daniels, a personage of Borko et al [1992] is brought to the fore in order to provide a guiding thread for the discussion.

Introduction: change, commitment and identity

Taking into account the public concern and amount of investments made in mathematics instruction around the world, one conclusion is inevitable: mathematics teaching is a human activity haunted by failure. If we hope to banish the ghost of failure, *change* becomes necessary. In PME22, a Plenary Panel Discussion was dedicated to it. There are many meanings of this word. In some cases, *change* means to look for a "linguistically and culturally sensitive learning environment" [Khisty, 1998:101]. In other cases *change* means to concentrate on curriculum issues [Jaworski, 1998, Pence, 1995], or to introduce new technologies [Crawford, 1997], or to *change* the classroom norms and management [Cobb&Yackel, 1995, Tomazos, 1997]. It may also mean to *change* teachers' knowledge and practices [Simon & Tzur, 1997], or to *change* teachers' beliefs [Becker & Pence, 1996]. Still in other cases, *change* means to focus on ethnical issues or gender inequity [Breen, 1998] or, simply to improve learning and teaching [Konrad et al, 1998].

However, if the majority of the projects for *change* succeeded in effectively improving the learning of mathematics, there is no guarantee that the minimum standards would not rise automatically, so that the ghost of failure would still be around. If we look at the hundreds of existing teacher formation programs, it seems that all efforts to produce a *commitment to change* as an output also fail. What happens to the student teachers the "day after"? If the program closely follows them as they enter the school system, success can be reported [Shane, 1997]. However, as soon as the effects of the teacher formation program cease, or even before that, there has been dramatic evidence that teachers conceptions and practices are rapidly absorbed by the dominant traditional school ideology, and *change* is invalidated. [Borko et al, 1992, Ensor 1998, Schmidt & Duncan, 1998].

We shall concentrate on the case of Ms. Daniels, who "approaching the end of her student teaching, was still unable to provide a clear explanation of division of fractions" [Borko et al, 1992:209]. When a student, Elise, asked her why to invert the second fraction, she erroneously picked up the diagram for multiplication and got stuck. The authors are perplexed because Ms. Daniels "did not attempt to correct the representation the following day" [ibid. 198] and because she "did not learn the conceptual information and representations that she needed to produce an adequate explanation of division of fractions during the mathematics methods course" [ibid. 218]. She had to compensate her failure in answering Elise's question by drilling the inverse algorithm. "However, despite her realization that 'the explanation wasn't very good', she was basically pleased with the lesson" [ibid. 198].

How strongly can teacher formation programs impose commitments to change on the student teachers? If "teacher preparation programs respond more quickly to calls for reform than school classrooms, perspective teachers' field experiences are inconsistent with the expectations developed in their teacher education coursework" [Van Zoest, 1998:354]. Brown [1998] reports the case of a student, L, who revolted against the teaching methods. This case had a happy ending, since L reevaluated her written stories and reached "the calm, almost detached from the former state, knowingly living in the new realm where the new brand of stories are seen as fitting better" [ibid.]. However, can't we say the same of Ms. Daniels? As a result of her strategy she *got credit* [Vinner, 1997], became a teacher and went on living in school, where her brand of stories are seen as fitting better. Can the constraints of a credit-based system impose emancipatory commitments on the human subjects who constitute its output? Was this the contradiction that L revolted against?

However, suppose that all goes well and we finally obtain a teacher culturally committed to change. Here is an excerpt of a dramatic report.

"Keiko's philosophy of education was developed in Japanese culture and her (...) beliefs about mathematics mesh with the goals of NCTM (1989, 1990 & 1995) but not with the traditional classroom and ways of teaching mathematics in American Schools. (...) By the end of her two week field placement, Keiko concluded that she would not teach in public schools because the cultural and societal differences were too great; they demanded that she give up her *identity*" [Schmidt & Duncan, 1998:310-311, our emphasis].

The question is, should we help Keiko to abandon her *identity* and become a happy, accepted citizen of her new cultural environment? Or are we politically committed to change the school she taught in? Commitment is a consequence of the subject's personal *identity* as a social human being. Arguing from the analysis of a film (Bladerunner) Zizek [1993] has produced evidence that our identity depends on our memories.

"Stories are precious, indispensable. Everyone must have his history, her narrative. You do not know who you are until you possess the imaginative version of yourself. You almost do not exist without it" [Time magazine, quoted by Zizek, 1993 in Brown, 1998].

Brown [1998] asks, how do we build a sense of our own identity through the memories we hold on to? His answer is that our memories "are constructed through

our own particular understanding of the path we follow through the passage of time" [ibid. 2] and then he connects this "with the explicit task of pinning down bits of experience faced by teachers carrying out reflective practitioner research" [ibid. 2]. He finally suggests that the student teachers must find a space where their personal stories about their teaching practices can be told and will be listened to, so that these practices can be reevaluated and finally cast as part of their new teacher's personal identity.

Borko et all's [1992] report on the case of Ms. Daniels is an example where the control of the credit system did not work as expected. The authors are puzzled: why did she not investigate the topic later? For Ensor [1998] there is no puzzle at all; just "a human subject inserted into a range of different contexts, each of which defines competence differently" [286].

From this point of view, Ms. Daniels behavior is coherently human: she told the researcher interviewers what they would like to hear; she reproduced the instructor's demonstration in the exam, and she kept the class under control by drilling the inversion of the second fraction algorithm. One discourse for each occasion. This has nothing to do with faking and gulling but with typically honest human behavior. According to Lacan, we can say that a being is properly human if she fails to abide by what she honestly promises to herself. Such a mismatch is what he calls *desire*. I can't avoid recalling a tale by a famous Brazilian writer from the last Century[1]: a girl fell in love with a sailor and promised to wait for him. When he came back from his six-month trip, she was married to another guy. – *But you swore that you would wait for me*, protested the desolate sailor. The girl tried to comfort him. – *Of course, I did, but please, understand, when I swore it was true...*

This tale refers to a commitment to permanence that meant change. It elicits that the reported cases, with the exception of L's, refer to commitments to change that turned into permanence. We seem to know very well that school does not do what it promises. What we do *not* know is how it reacts to change, especially the change that compels it to do what it promises. Is the discourse for change covering up a desire for permanence? In one word, we have touched the dialectics of *change/permanence*.

Methodology: action research with self-regulated differential intervention

In 1993, guided by reflections like these, we endeavored to simultaneously challenge and produce conditions favorable to student teachers' commitment to change[2]. Somehow we had realized what we can now state clearly: commitment is a consequence of human identity; such an identity develops from recollections of memories; and such recollections are anchored in discourses involving the subject and a context. We also realized that the discourse starts with a demand from the context that precedes utterances and writing: "The discourse is the norm of what fits and what does not fit into the Other's ears, and consequently what can and what cannot be said

[1] Machado de Assis.
[2] At UNESP. Rio Claro, SP, Brazil

by the speaker" [Baldino & Cabral, 1998:58] Hence, the context is productive of discourses:

"(...) in each case the produced text is evoked within a particular context, by a specific invitation to speak. In this sense the *contexts are productive*. At the same time they are constraining insofar as each context, with its audience, both canalizes and silences expression" [Ensor, 1998:283 emphasis added].

So we succeeded in creating a *speech community* whose identity is now supported by a five-year history. The stories told by the newcomers about their classroom experiences are listened to and discussed from the point of view of the understanding of the community members. Our premise is that accepting or challenging such discourses interferes with the process of formation of the student teachers' professional identities by preserving some of their recollections in the community's memory and dismissing others. What is at stake is the feeling of belonging to this community or not. The objective is not to graft commitment onto this or that student, but to provide an identity for the community of students and in-service teachers committed to change.

Of course, this community has to be based in the university but should not be subjected to bureaucracy so as to keep its critical stand with respect to both school and academy. In particular it has to be free from any obligations to the credit system. Participation should be only on a volunteer basis. The task of constructing this community clearly required an action research method:

"Action research is small-scale intervention in the functioning of the real world and a close examination of the effects of such intervention (...) the ultimate objective being improvement of practice in some way or other" [Cohen & Manion, 1994:186].

Our project is both decision and conclusion oriented. Our two research questions are: 1) how to face the general failure of mathematics teaching at all levels? 2) What are the school and classroom routines that sustain this failure? There are no formalities for admittance; everybody who is touched by these questions are welcome to our Saturday-morning meetings. At the beginning of each semester we split into several subgroups according to the interests of participants. Each sub-group defines a project connected to the research questions involving some kind of classroom action. Projects may last for one semester or for several years. Every Saturday all projects report their weekly progress and get advice from the other community members. Themes have varied from children's songs and stories to the teaching of analysis, from games for integers to ecology and garbage collection. Evaluation of these projects consists of submitting their results to specialized reviewers. There are almost one hundred publications, including dissertations and papers in specialized journals and conference proceedings.

During these years we have counted on an average of 25 people in these meetings: professional teachers, graduate students in mathematics education, and undergraduate student teachers who are simultaneously taking courses in mathematics methods and pedagogy. Most of the classroom interventions employ the technique of *differential intervention*: once in the classroom, either as a regular, a

temporary or experimental placement, the teacher or teaching team does not do exactly what is expected from him/her/them but introduces some *change* that makes the school system uneasy and against which tradition does not find any ready available argument: introduction of group work, new topics, new instructional material, new classroom norms, new forms of evaluation, etc. We do not go to observe the student teachers' classrooms. Data is collected from the reactions of the school system to such changes as reported by the student teachers who decide what *change* should be made. We say that the *differential intervention* is *self-regulated.*

Research report and discussion

One way to report on the five-year production of this action research group would be to select one group and report fully on it. Another way would be to report on a hypothetical "average" group. We shall follow the second way, using an expedient: we shall suppose that Ms. Daniels has joined us in the beginning of this semester. In this way we will be able to accurately describe what has actually happened in most of our sub-groups. In what follows, many of Ms. Daniels speeches are copied or adapted from Borko [1992]. We shall omit the references.

In the first Saturday plenary meeting, Ms. Daniels declared her interest in fractions and was suggested to join the existing sub-group of rational numbers coordinated by a Mathematics Education graduate student [Izzi, 1998]. However, she managed to convince some of the participants about the importance of dedicating one semester specifically to operations with fractions. The newly-formed subgroup found a tutor among the university teachers and graduate students. They established the time-schedule for their weekly meetings and had no trouble finding a school where they could carry out some experiments. In fact the cooperating teacher was very pleased: – "I can relax for a few weeks", she said, meaning that this was her only motivation. The following Saturday the group reported their plans to the plenary. In the first sub-group meeting Ms. Daniels conveyed confidence on her mathematical knowledge:

– I already know all about rational numbers; I have successfully completed over two years of course work as a mathematics major. I only need some techniques that will hold the students' attention, some ideas that will work.

The tutor wrote on the blackboard one over ½ and asked Ms. Daniels to complete it. She wrote "2" and asked surprised:

– What do you mean? Do you want me to describe how I would teach the topic to a sixth-grade class?

– No. I want you to tell me why *you* have done that. Why did *you* invert the bottom fraction? It is you, not your student who is on the spot here.

Ms. Daniels tried several explanations, but none stood up to the tutor's inquiry. The other elements of the subgroup were called to help her, but nobody succeeded. The group became united around this mathematical difficulty. Ms. Daniels finally confessed in a low voice: – "I don't know why you invert and multiply; I just know that's the rule" [Borko et al, 207]. Her faith on her knowledge was finally broken. This is

the moment when Lacan says that the hatch is opened. It is the only moment when the student is receptive to information that the tutor can pass through the opening before it closes again. The tutor conducted the dialogue through the following questions, eventually supported by diagrams and cubes:

– If you give one sausage to each half-dog, how many sausages does one dog eat? And if you give one sausage to each 5/8 of a dog, how many sausages will *five* dogs eat? And how many sausages per dog? As soon as Ms. Daniels produced the answer "eight sausages to five dogs make 8/5 of sausage per dog", the tutor remarked: – How come you said you did not know why you invert. You have produced the answer yourself...

The group was amazed. Other examples were tried. Some students started explaining to those who had not yet understood. The tutor intervened:

– No explanations, please! You may only ask questions until they get what you want them to understand.

Finally everybody got the idea. The session was over. The next Saturday they reported their intention to take the subject into the sixth-grade class as soon as possible. In the next sub-group meetings they planned how they would organize the classroom for group work, how to establish a *work contract* precisely indicating how grades would be assigned to participation in group-work[3]. They drew cartoons with figures of dogs whose bodies could be stretched by inserting cards[4] and discussed how they would move from this material to the conventional written algorithm. When all was ready, one of the plenary sessions was dedicated to testing the instructional material with all the community members. The group was urged to write a report about their classroom experience. They reported that the most disruptive students were the ones who got the idea first and acted as tutors to the other groups. They decided also to report on the detached and sometimes deleterious attitude of the cooperating teacher. Their diaries looked very much like the ones reported in Brown [1997, Ch. 7]. Their individual written reports were discussed in the sub-group meetings. The tutor's remarks about these reports *were also written* and subjected to the sub-group members for further discussion. Results of these discussions were regularly reported and debated in the Saturday plenary sessions. The paper finally produced was considered to be of joint authorship, like the papers stemming from other sub-groups: Souza et al [1995], Leal et al [1996], Baldino et al, [1997]. Here is a typical discussion of a plenary session.

Ms. Daniels. – I wonder why the mathematics methods instructor never mentioned this to us.

Participant. – He could not. He insisted on the measurement interpretation of division of fractions and "there is no direct or concrete way to demonstrate using manipulative, the derivation of this algorithm" [Borko et al, 1992:214].

---

[3] This is important, given the degree of deterioration of public teaching in the State of São Paulo

[4] This material was actually developed in Centro de Ciências, FAPERJ, Rio de Janeiro in 1983 and was named "Sispixa" ("Stretchy").

Ms. Daniels. – Why didn't he shift to the distribution representation like we did? Why did he insist on his representation knowing that it could not lead to an idea to use in the classroom?

Participant: He had no need for this shift. He was looking for "ways to represent mathematics concepts and procedures" [NCTM, 1991:151 in Borko et al, 1992]. He was not trying to build knowledge from a dialogue situation with you. He was merely trying to "explain that the derivation demonstrated that the algorithm produced a correct answer" [Borko et al, 1992:214]. Since he believes that knowledge has to be "represented", he naturally assumed the function of introducing this representation to a large audience. He talked, he explained, he demonstrated; students should have "followed" him. In the last PME Ron Tzur showed nicely how a teacher's epistemological conceptions determined the way he conducted his class [Tzur & Kinzel, 1998].

Ms. Daniels: Doesn't he realize that the theory he gives us is cut and dry and that most of us do not follow it?

Participant. For this he counts on the audience to which he is the *introducer of the representation* of knowledge. "(...) the bright ones who are good in math, will have a pretty good understanding of what's happening here. The rest of them I just have to take it on faith" [instructor's lesson in Borko et al, 1992:214]. What he was saying to you, Ms. Daniels, is that you are not included among the bright ones and that you will have to take it on faith. This is a very subtle way of blaming the victim. Apparently your instructor himself would not have been able to answer Elise's question better than you did. Your interviewers do not even believe that a concrete derivation of the inversion algorithm is possible. Yet you are charged because "you did not seem to feel that it was (your) responsibility to actively seek to improve (your) understanding of the mathematics (you) were teaching either by consulting resources or by engaging in hard thinking of (your) own" [Borko et al, 219]. What they have actually taught you is to set a good display of representations of knowledge and to charge those who do not follow you for not being bright enough. This is very different from the dialogue situation that we have here.

Ms. Daniels (exasperated): – This is a situation that I am certainly committed to change.

Participant (casually): Why? Why do you want to change it?

KAREN AND BENNY: DÉJÀ VU IN RESEARCH

Annette R Baturo, Tom J. Cooper, Campbell J McRobbie
Centre for Mathematics and Science Education
QUT, Brisbane, Australia

An integrated learning system (ILS) is a computer-based tutoring program that provides students with learning experiences in many disciplines across many years of school. This paper reports on the fraction knowledge of Karen, a Year 6 student using an ILS to remediate her fraction knowledge, and compares her resulting knowledge constructions with those of Benny (Erlwanger, 1973), a student using an Individually Prescribed Instructional (IPI) program in the 1970s. Karen was interviewed on tasks involving the common and decimal fractions and the results showed that she was able to progress on the ILS with an impoverished understanding of fractions, a phenomenon that echoes the earlier findings with respect to Benny. This paper discusses reasons for this phenomenon as well as the propensity of learning systems (computer or paper) to focus on syntactical and instrumental understanding (Skemp, 1978).

One of the by-products of the growth of information technology in education has been the computer-based integrated learning system (ILS) which includes extensive courseware plus management software. An ILS has three essential components, namely,*substantial course content*, *aggregated learner record system*, and a *management system* which tracks learners' task responses and progress, and provides performance feedback to the learner and teacher (Underwood, Cavendish, Dowling, Fogelman, & Lawson, 1996, p. 33). An ILS marginalises the teacher's role and virtually removes students' initiative and autonomy in the system's learning process (Bottino & Furinghetti, 1996).

This paper reports on diagnostic interviews undertaken with Karen, one of several Year 6 students who were using an ILS for remediation purposes. Karen was singled out because the ILS system revealed that she had made the most "gains" (about 18 months) in mathematics in a 5-month period. The interview probed her structural knowledge of fractions to determine the thinking strategies she employed when processing fraction concepts. The paper provides the results of Karen's interview and relates her responses to her performance on the ILS and to her beliefs about the ILS. These results are then compared with those of Benny (Erlwanger, 1973), a student working on an IPI program in the USA a quarter of a century ago.

Individual Learning Programs

The ILS used by the students was a comprehensive instructional system powerful enough to deliver complex courses. According to the manufacturer, its courses were designed to foster the development of foundation skills and concepts and to promote the use of higher-order thinking skills. It should be noted that the manufacturers endorse the system only as a tool for teachers to use to consolidate already introduced material and to diagnose student difficulties. They argue that it is the teachers' role

to introduce the material to be practised on the ILS, and to remediate the difficulties identified by the ILS. Thus, they contend that the effectiveness of the ILS depends on the quality of teacher input and that any evaluation of the ILS should take into account the role of the teacher in relation to the program.

The ILS in this study was a closed system, that is, the curriculum content and the learning sequences were not designed to be changed or added to by either the tutor or the learner (Underwood et al., 1996). Its major feature was its management system which, according to the manufacturer, has three main functions: (a) to deliver courses to each student according to the teacher's instruction; (b) to manage all student enrolment and performance data; and (c) to provide the means for teachers, laboratory managers, and administrators to organise the use of the courses, and to monitor student progress.

The ILS core numeracy course is divided into a range of *topics* (e.g., numeration, addition, multiplication, fractions, space) which are then sub-divided into collections of tasks that are sequenced in terms of performance at different *levels*. The difference between levels was constructed so that high mastery at one level (approximately 85%) is the same as mastery (above 60%) at the next level. The core numeracy course is based on USA syllabi but correlates reasonably well with Australian syllabus requirements; individual tasks were developed and placed in levels as a result of large-scale trials in the US. For their initial placement on the ILS, students are given a large number of tasks at different levels until the system finds the level at which they have reasonable mastery (about 65-75%). When students achieve high mastery at one level, the system automatically raises them to the next level. To maximise the chance that task performance correctly represents level, the tasks within a level are presented randomly. Any reduction of randomness affects the accuracy of placement and, therefore, the potential for students to achieve mastery. Without mastery, students may not experience the continual success, and therefore the motivation for achievement, that lies at the theoretical heart of the ILS.

The ILS tasks are in the form of electronic worksheets which are generally attractive in their presentation and sometimes creative in the way they probe understanding. They attempt to encourage the construction of knowledge by providing 2-D representations of appropriate teaching materials in mathematics (e.g., Multi-base Arithmetic Blocks, Place Value Charts, fraction and decimal diagrams). Built into the core numeracy course are online student resources that enable students to get special help during a session should the need arise. However, use of the Help and Tutorial icons automatically grades performance as incorrect. The Toolbox icon makes calculators, rulers, tape measures and protractors available for student use and also provides complex tools (e.g., graphing and drawing) for advanced levels.

For some topics and levels, there appears to be insufficient task variety to prevent repetition. Furthermore, some tasks have novel presentation formats which students find difficult to interpret (e.g., spring scales used to determine number size, not object mass). Other tasks require inflexible and/or novel solution formats which result in

students' correct answers being marked incorrect (e.g., failing to type the units digit first in operations) as are responses which differ syntactically from the expected responses even when they represent semantic understanding (e.g., the omission of zero in decimal numbers such as 0.63). There is a tendency for questions to be closed (i.e., "find the right number") and a tendency to base performance on speed (although the teacher can vary the time limits on answers). Time delays (e.g., while an algorithm is completed with pen and paper) can lead to the ILS's defaulting to incorrect. For each level and topic area, there are worksheets that can be printed thus providing students with extra practice and teachers with a guide to the types of activities that need consolidating.

The ILS is designed to work with individual students, a feature which appears to be contrary to modern teaching/learning principles which encourage group work that promote verbal and kinaesthetic interaction. However, students normally work on the ILS in mathematics for a maximum of 45 minutes per week over three sessions. Therefore, the amount of time working alone is small when compared against the total weekly time spent on mathematics (usually 200-225 minutes).

A computer search found only two evaluations of the ILS used by the students in this study. In a review of 32 studies, Becker (1992) concluded that only manufacturer-based studies reported significant gains for the ILS but that these studies, had "used the unusual procedure of eliminating cases from data analysis that showed sharp declines" (p. 30) while retaining cases that showed large gains. In a review of 9 studies, Underwood et al. (1996) found a substantial positive gain for mathematics performance in computation but not for fractions (which is of interest to this study). However, to compare mathematics knowledge gains, both reviewers used standardised tests which do not provide explicit information on students' mathematical knowledge structure and thinking strategies.

Integrated learning systems are reminiscent of the Individually Prescribed Instructional (IPI) packages that proliferated in the US in the 70s with the ILS activities presented in electronic, rather than paper, form. Both systems have a management system which marks students' responses, directs unsuccessful students to other similar activities until "learning" (familiarity?) takes place, and directs successful students to another higher level, and the process is repeated continuously. The only real difference between the two systems is that, in any ILS session, activities cover a variety of mathematical topics whereas in any IPI session, activities are presented in finely detailed sequences within the one topic. The pedagogical flaws in IPI systems were exposed by Erlwanger (1973) when he undertook a series of interviews with a variety of students in an attempt to understand what mathematical knowledge students acquired from individualised instruction and that knowledge was acquired.

One student, Benny, had been perceived by his teachers to be "very good" at mathematics, a perception that had been gained entirely from his rapid rise through the levels of instruction. The interview with Benny revealed that he had constructed several misconceptions that enabled him to accommodate the variety of answers that were demanded by the discourse of the package. The following protocol provides an

instance of Benny's misconception with respect to decimal fractions and his "incorrect generalizations about answers" (Erlwanger, 1973, p. 15). He had previously solved 2 + .8 = 1.0 (a revealed error pattern) and 2 + $^{8}/_{10} = 2^{8}/_{10}$ and was explaining (unsolicited) how IPI's answer key (the ILS's marking system) would mark him if he interchanged the answers to the particular problems.

Wait. I'll show you something. If I ever had this one (2 + .8) . . . *actually, if I put* $2^{8}/_{10}$, *I get it wrong. Now down here, if I had this example* (2 + $^{8}/_{10}$), *and I put 1.0, I get it wrong. But really they're the same, no matter what the key says. (p. 15)*

Method

Subject: Karen was one of 60 Year 6 students who had been using the ILS for approximately 3 months. She was selected for further interviewing because, according to the system, she had made the largest mathematical knowledge gains (about 18 months) but an initial interview had revealed that her understanding of elementary fraction concepts was impoverished. Furthermore, she liked using the ILS and believed that it was helping her learn.

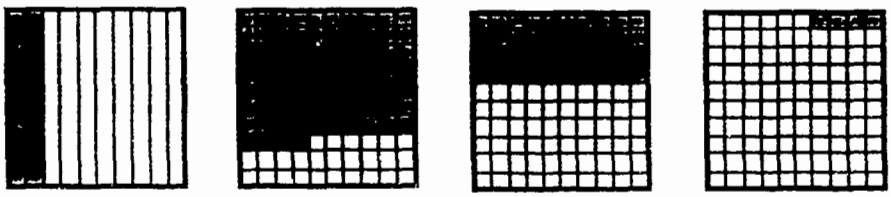
Instruments: Two diagnostic interviews were undertaken at the end of the study to probe Karen's structural knowledge of fractions. Interview 1 comprised tasks which involved: (a) probing understanding of the basic part/whole notion of fraction, that is, the relationship between fraction name, equal parts, and number of equal parts; (b) translating prototypic area representations (i.e., 10 × 10 grids) of tenths and hundredths to symbols (decimal fractions); and (c) translating tenths and hundredths, written in words to symbols, and vice versa. Interview 2 comprised tasks which involved comparing common and decimal fractions (see Figure 1). These tasks were based on a worksheet related to Level 4 (a level by which most concepts and processes related to fractions had been "taught" by the computer program), and which Karen had already completed successfully (according to the ILS).

In each set, circle the number that has the larger value.

A. $\frac{2}{5}$ $\frac{4}{5}$	D. $\frac{2}{3}$ $\frac{3}{4}$	G. 3.14 3.6	J. $\frac{9}{10}$ $\frac{99}{100}$
B. $\frac{1}{6}$ $\frac{1}{2}$	E. $2\frac{5}{6}$ $3\frac{1}{3}$	H. 3.84 3.7	K. $\frac{4}{10}$ $\frac{12}{100}$
C. $\frac{3}{5}$ $\frac{3}{8}$	F. 4.7 6.2	I. 2.08 2.8	

Figure 1. Comparison tasks used in Interview 2.

Procedure: For each interview, Karen was withdrawn from the classroom and the interviews audiotaped. In Interview 2, she was asked to read the given fractions before solving in order to address one of Erlwanger's (1973) major findings regarding students who were engaged in individually prescribed learning situations, namely, the lack of appropriate vocabulary required for discourse. Karen was asked



to provide an explanation for each selection she made to determine whether her comparisons were based on syntactic or semantic knowledge.

Analysis: The interview results were scored and Karen's responses and explanations were examined for error patterns. Inferences were thus drawn regarding Karen's structural knowledge of fractions.

Results

The pertinent results of Karen's first interview are provided to illustrate the impoverished fraction concepts and language that she brought to the second interview (and on which her progress through the ILS was based). Karen had a sound understanding of the need for equal parts when determining fractions but not of the relationship between the fraction name and the number of equal parts. For example, when asked why she had not selected the shape showing 3 equal parts (when identifying halves), Karen said she wasn't sure.

For the pictorial representations of tenths and hundredths, she wrote 2.10 for 2 parts out of 10 equal parts, 74.100, 40.50, and 4.100 (see Figure 2). With the exception of 40 hundredths, she was able to unitise the representations but was confused with decimal and common fraction recording forms. The representation of 40 hundredths seemed to invoke a part/part ratio notion instead of a part/whole fraction notion, indicating that she may have developed syntactic knowledge developed by overuse of prototypic representations.

2.10 74.100 40.50 4.100

Figure 2. Karen's responses in Interview 1.

Karen was able to read the given decimal numbers syntactically only (i.e., as "6 point three nine", for example, instead of "6 and 39 hundredths"). For the remaining task (writing numbers given in word form in digit form), Karen gave the following responses: *eight tenths* (08.10); *four and six hundredths* (4.600); *eight and nine thousandths* (8.9000); *five and thirty thousandths* (5.30 000); *47 thousandths* (47.000 000). Thus underlying Karen's 2nd interview (and her progress on the ILS) was incomplete or unconnected fraction knowledge of the notion of equal parts and number of parts, confusion between common and decimal fraction recording forms, and an inability to read or write decimal numbers.

Interview 2. Karen read the common fractions semantically (i.e., so the fraction name could be heard, for example, 2 fifths. 1 sixth) but read the decimal numbers syntactically as the following protocol shows for 4.7: *4 point 7* [4 and 7 what?] *4 and 7 um . . . I've forgotten.*

BEST COPY AVAILABLE

Karen misinterpreted Task A, reading it as *5, take away 4 minus 5, take away 2.* When focused on the task, she selected $^4/_5$ *because 4 is bigger than 2.* In Task B, she selected $^1/_6$ *because 6 is bigger than 2.* When asked to show how she could prove this, Karen drew the following shown in Figure 3 and said that *there's more of them* (sixths). Karen also drew similar representations for $^2/_3$ and $^3/_4$.

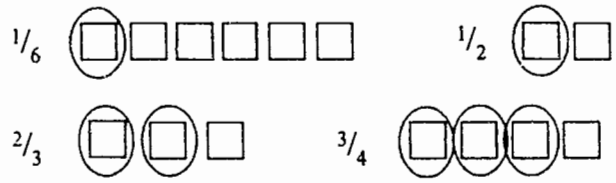


Figure 3. Karen's representations of fractions.

In Task C, Karen selected $^3/_5$ and then said she thought she'd marked the wrong one *because there's 8 on the bottom and 3 of them* ($^3/_8$) *and there's only 3 on the bottom here* ($^3/_5$) *and the same 3.*

Changing her mind turned out to be a common occurrence as shown by the following protocols. In Task D, she had correctly selected $^3/_4$, explaining that: *You've got 4 wholes and you've got a remainder 3* ($^3/_4$); *over here* ($^2/_3$), *you've only got 3 and a remainder of 2.* [So, how do you know one is bigger than the other in that case? Which part do you look at – that part (numerator) or that part (denominator) when you compare?] *That* (numerator) *but I also look down here* (denominator). *Um, I think it might be that one* ($^2/_3$) *now.* [Tell me why you think that.] *Well, there's 3* (drawing 3 small squares and circling 2 of them – see Figure 2) *and there's 4 and 3 of them* (drawing 4 small squares and circling 3 of them). [Well, there's the same amount left over (1 square). That makes it tricky doesn't it?] *Mm.* [So how do you decide if they've got the same amount left over?] (No response) [Are they the same value?] *They could be.* [You're not too sure about this one, are you?] *No.*

In Task E, Karen selected $2^5/_6$ as having a larger value than $3^1/_3$ because she said she just looked at the fraction parts. Similarly, in Task F, she initially selected 4.7 *because 7 is bigger than 2* (in 6.2). Unsolicited, she then went on to say *but then again, I was wondering about these two* (the whole-number parts). [So you can't make up your mind, then, whether you should look at these two (whole number parts) or these two (decimal-fraction parts). Is that what you're saying?] *Yeah, so I just chose one.*

For Task G (3.14; 3.6), she selected 3.14 but when asked why, she said, *Um, I think that one* (3.6) *should be the answer.* [Why?] *Because 3 point 6, um . . . I can't remember.* [You've done them before but you can't remember – is that it?] *Yes.*

Task H (3.85, 3.7) revealed the impact of prototypic tasks. Karen selected 3.7 *because that's* (3.7) *only got 1 number after it* (the 3), *and that's* (3.84) *got 2 numbers after it. I've had these on* – (ILS) *and there's usually only 1 number after.* This inappropriate strategy enabled her to make the correct selection in Task I (2.08, 2.8).

For Task J ($^{9}/_{10}$; $^{99}/_{100}$), Karen eventually selected $^{99}/_{100}$ *because there's only 1 more* (difference between numerator and denominator in each fraction)*so they're the same number. But this* (the denominator, 100) *is bigger than that* (the denominator, 10) *and this* (the numerator, 99) *is bigger than that* (the numerator, 9) so . . . [So you had a bit of a problem deciding then?] *Yep.* Karen used similar comparisons of numerators and denominators to make the correct selection in Task K ($^{4}/_{10}$,$^{12}/_{100}$). For future interviews involving comparison of fractions, a task such as comparing $^{8}/_{10}$ and $^{6}/_{100}$ will be included to challenge students who use a strategy similar to Karen's.

Conclusions and discussion

Karen, who had made the highest knowledge gains (according to the ILS) ot all the Year 6 students using the system at that school, revealed that she had an impoverished understanding of comparison of fractions, tasks which were based on those undertaken on the ILS. Karen had constructed "rules" and the rule she applied depended on the pair of fractions being compared. Amongst her repertoire of rules for comparing common fractions was a "whole number rule" that was invoked when the numerators were the same but the denominators were different (e.g., Task B– $^{1}/_{6}$, $^{1}/_{2}$; Task C – $^{3}/_{5}$, $^{3}/_{8}$). According to Karen's rule, $^{1}/_{6}$ is larger than $^{1}/_{2}$ because "6 is large that 2" and, similarly, $^{3}/_{8}$ is larger than $^{3}/_{5}$. However, she had a different rule when the common fractions being compared had different denominators and a difference of 1 between the numerator and denominator in each pair (e.g., Task D– $^{2}/_{3}$, $^{3}/_{4}$; Task J – $^{9}/_{10}$, $^{99}/_{100}$). For Task D, Karen couldn't make up her mind whether the fraction with the larger value was $^{3}/_{4}$ (because 4 is larger than 3) or whether the fraction were equal (because of the difference of 1). However, there was no such indecision with Task J where she applied the whole-number rue to both the numerator and the denominator (and thus selected the correct fraction but for an inappropriate reason). Inconsistencies such as these are indicative of superficial syntactic knowledge (Hiebert & Wearne, 1985; Resnick et al., 1989). The problem of applying rules without reason is that it can led to as many correct solutions as incorrect solutions, depending on the tasks provided, thus adding to the confusion and leading to the development of thinking that Benny exhibited (Erlwanger, 1973), namely,*but really they're the same, no matter what the key says (p. 15).*

Prototypic tasks also tend to promote incomplete structural knowledge as evidenced by Karen's performance in Tasks G (3.14, 3.6) and H (3.84, 3.7). Karen consistently applied the "fraction rule" (Resnick et al., 1989) where the number with the fewer number of decimal places is the larger in value because "tenths are larger than hundredths". The ILS tasks *(there's usually only 1 number after)* had promoted Karen's construction of the fraction rule although it is doubtful whether Karen considered the place values of the digits, focusing instead on the "length" of the decimal-fraction component of the number. It is also hypothesised that the ILS comparison of fraction tasks (common and decimal) focused on same whole-number parts so that she "learnt" to consider the fractional parts only (see her performance in Tasks E and F – $2^{5}/_{6}$, $3^{1}/_{3}$ and 4.7, 6.2 respectively).

An interview with Karen's teacher revealed that he was unable to provide specific instances where Karen's ILS gains had been transferred to improved mathematical performance in the classroom. However, Karen believed that it was helping her learn which raises two issues that need to be addressed in future research, namely, associating success with "getting things right" irrespective of the means to the correct response, and associating effort (i.e., time spent) with learning.

The anomaly between Karen's progress on the ILS and misconceptions revealed by the interviews raises the spectre of Erlwanger's (1973) report regarding IPI in which he claimed that IPI programs develop an attitude to learning that is answer-oriented, syntactically based and delivery-process driven. In this learning context, students tend to develop the skills required for a correct answer without developing mathematical knowledge that is transferable outside the closed system (Erlwanger, 1973; Fuglestad, 1996; Jones, 1998).

In the time ($15^1/_2$ hours) that Karen had spent on the ILS, a teacher trained in remediation should have been able to overcome the deficits in Karen's elementary fraction knowledge. However, for Karen, neither traditional teaching (including the years leading up to Year 6) nor the ILS had facilitated construction of appropriate fraction knowledge.

FRACTIONS, REUNITISATION AND THE NUMBER-LINE REPRESENTATION

Annette R Baturo and Tom J Cooper
Centre for Mathematics and Science Education, QUT, Brisbane, Australia

This paper reports on a study in which Years 6 and 10 students were individually interviewed to determine their ability to unitise and reunitise number lines used to represent mixed numbers and improper fractions. Only 16.7% of the students (all Year 6) were successful on all three tasks and, in general, Year 6 students outperformed Year 8 students. The interviews revealed that the remaining students had incomplete, fragmented or non-existent structural knowledge of mixed numbers and improper fractions, and were unable to unitise or reunitise number lines. The implication for teaching is that instruction should focus on providing students with a variety of fraction representations in order to develop rich and flexible schema for all fraction types (mixed numbers, and proper and improper fractions).

In summarising the literature, Behr, Harel, Post, & Lesh (1992) claimed that there are five subconstructs of rational number, namely, *part/whole, quotient, measure, ratio number*, and *operator*, and that comprehending rational numbers means having an understanding of each subconstruct as well as their interrelatedness.

Australian mathematics syllabi focus primarily on the *part/wole* subconstruct. Under this subconstruct, a *fraction* is a generic term used to denote a numerical amount that is a *part of a whole* (Kieren, 1983; Nik Pa, 1989; Payne, Towsley, & Huinker, 1990), where the whole is any continuous quantity (e.g., a region/area, a line or a volume) or discrete quantity (e.g., a set of objects). Thus, children's ability to interpret fractions is highly dependent on their notion of a unit (whole), their ability to partition the whole (Lamon, 1996; Pothier & Sawada, 1983), and to reconstruct units (Behr et al., 1992; Lamon, 1996; Nik Pa, 1989; Steffe, 1986). According to Steffe (1986), there are four different ways of thinking about a unit, namely, *counting (*or *singleton) units*, *composite units*, *unit-of-units* and *measure units*, with each type apparently representing an increasing level of abstraction There is a consensus in the literature (Behr, Harel, Post, & Lesh, 1992; Harel & Confrey, 1994; Hiebert & Behr, 1988; Lamon, 1996) that the cognitive complexity involved in connecting representations, symbols and operations can be attributed mainly to the changes in the nature of the unit. In particular, the complexity required to process unit-of-units and measure units has major implications for acquiring an understanding of rational numbers, particularly in relation to concrete and pictorial representations.

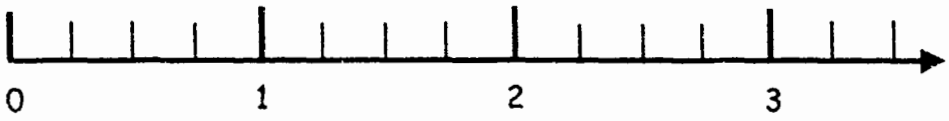
Whatever the representation of the whole, fundamental to the *part/whole* subconstruct is the notion of *partitioning* a whole into a number of *equal* parts and composing and recomposing (i.e., *unitising* and *reunitising*) the equal parts to the initial whole. According to Kieren (1983), partitioning experiences may be as important to the development of rational number concepts as counting experiences are to the

development of whole number concepts. Students, therefore, should be provided with several opportunities to partition a variety of fraction models in a variety of ways so that they come to understand that ½ (for example) always represents one of two equal pieces. *Partitioning, unitising* and *reunitising* are often the source of students' conceptual and perceptual difficulties in interpreting rational-number representations (Baturo, 1997; Behr et al, 1992; Kieren, 1983; Lamon, 1996; Pothier & Sawada, 1983). In particular, reunitising, the ability to change one's perception of the unit, requires a flexibility of thinking that may be beyond young children.

Australian syllabi advocate the use of the area model in developing the initial understanding of a fraction because of the conceptual and perceptual difficulties students have in interpreting the other models (Payne, 1976). For example, with the set model, students find it difficult to unitise a group of discrete objects (Behr et al., 1992; Nik Pa, 1989); with the linear model, children tend to see the marks as discrete points on a line instead of as parts of a whole unit and, again, the problem is related to unitising; with the volume model, the equal partitions are often not shown. Although the set, linear and volume models are not used in the initial development of the part/whole notion of fractions, they should not be avoided as full understanding of any notion requires an ability to abstract the salient features from a variety of materials (Dienes, 1969). In his study involving 220 college students, Silver (1983) reported on what he called *representational rigidity*, a limitation in the variety of mental models that was available to the students. This limitation appeared to be a major inhibitor of the students' ability to operate on fractions.

There has been a recent resurgence of interest in the number line representation, for place value (Bove, 1995), mental computation (Beishuizen, 1997), word problems (Okamoto, 1996), fractions (Maher, Martino, & Davis, 1994), percent problems (Dole, 1998; Parker & Leinhardt, 1995), and functions (Olsen, 1995). This would appear to be in conflict with the earlier literature (e.g., Payne, 1976; Payne et al., 1990) that stressed the conceptual difficulties students had in unitising and reunitising fractions represented by number lines. However, the number line appears to be an ideal representation to help students connect whole-number and fraction processes such as counting (e.g., 3 fifths, 4 fifths, 5 fifths, 6 fifths ... is isomorphic to counting whole numbers). A well, the partitions on a number line showing fractional parts can be recorded as improper fractions or as mixed numbers, thus strengthening the understanding that these two forms can be used interchangeably.

This paper reports on Years 6 and 8 students' responses to tasks involving placing a mixed number and improper fractions of a number line. The study's impetus was an interest in students' ability to use this representation, particularly with respect to unitising and reunitising, and the conflicting reports concerning number line success.



The study

Subjects. The subjects were 24 Year 6 students (12 girls, 12 boys) from 3 suburban and 2 regional primary schools and 10 Year 8 students (5 girls, 5 boys) from 2

regional secondary schools. The schools were generally in lower middle-class areas. The students were chosen by their teachers to represent a cross-section of abilities in their classes (not including extremes).

Instrument. There were three interview tasks (see Figure 1) which were designed to represent a sequence of cognitive difficulty (simplest to hardest).

Task 1: Show $2^1/_4$ on the number line below.

Tasks 2 and 3: Show $^6/_3$ and $^{11}/_6$ on the number line below.

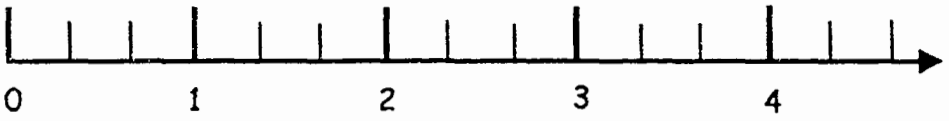


Figure 1. *Number-line tasks.*

Unitisation was required for all three tasks whereas reunitisation (in conjunction with physical or mental repartitioning) was required for Task 3. Task 1 was included to give all students the most chance of being correct in that it required unitisation only and the whole number provided a visual clue to the particular whole to be considered on the number line. Task 2 was considered to be more difficult that Task 1 because of the improper fraction recording of a whole number. It was thought that this would be a nonprototypic representation for most students. Task 3 was considered to be more difficult than Task 2 because, apart from the nonprototypic recording, it required reunitisation.

Procedure. The students were withdrawn from class and interviewed individually. They were asked to place the numbers and then to explain their responses. Before doing this, the tasks were read to the students to alleviate any difficulties that might arise from: (a) the use of the slash instead of the vinculum in the fraction recording, and (b) an inability to read fractions. The interviews were audiotaped.

Analysis. The students' responses and reasons were recorded and categorised into commonalities. Inferences were drawn with respect to the knowledge and strategies held by students giving certain responses.

Results

The results for each task were categorised in terms of correctness and closeness to correctness (see Table 1).

Task 1. When asked to explain their responses, students with correct placement tended to respond in terms of the existing parts on the number line and to

acknowledge that the 2 and the $^1/_4$ were separate [e.g., *because they're all quarters, and that's two* (the whole number) *and that's a quarter*].

Table 1
Number (%) of Task Response Categories for All Tasks by Year Level.

	Students	
Task response category	**Year 6 (*n*=24)**	**Year 8 (*n*=10)**
Task 1: $2^1/_4$		
Correct ($2^1/_4$)	54.2	60.0
Other quarters ($2^2/_4$, $2^3/_4$)	16.7	20.0
Eighths ($2^1/_8$, $2^5/_8$, $2^7/_8$)	20.8	20.0
Could not do	08.3	00.0
Task 2: $^6/_3$		
Correct ($^6/_3$)	25.0	10.0
Near ($1^5/_6$, $1^2/_3$, $2^1/_3$, $2^2/_3$)	20.8	20.0
High ($3^5/_6$, 4, $6^1/_3$, $6^2/_3$, $6^3/_4$)	29.2	10.0
Low ($^1/_6$, $^1/_2$, 1)	00.0	30.0
Could not do	25.0	30.0
Task 3: $^{11}/_6$		
Correct ($^{11}/_6$)	25.0	00.0
Near (2, $1^1/_3$, $1^2/_3$)	08.3	20.0
Mid ($3^1/_3$, $3^2/_3$, $3^5/_6$, 4)	20.8	30.0
High ($11^1/_3$, $11^1/_2$)	08.3	00.0
Low ($^1/_2$)	00.0	10.0
Could not do	37.5	40.0

The responses from the 6 students who marked incorrectly but focused on quarters (i.e., $2^2/_4$ or $2^3/_4$) were idiosyncratic. For example, of the 2 students who marked $2^2/_4$, one indicated prototypic thinking in that she seemed to associate the unit numerator with a half (*it has 1 here so it's in the middle*); the other student seemed to combine $2^1/_4$ with another quarter (*there's two up there and it goes up in quarters ... goes one quarter, two quarters, three quarters ... two quarters, so there).* Of the 4 students who marked $2^3/_4$, three seemed to associate the unit numerator with meaning 1 "space" less than the next whole number whilst the remaining student seemed to interpret $2^1/_4$ as having 2 wholes, 2 quarters, and then add on the ¼ [*cos there's two ... zero to two* (pointing at whole numbers) *... and you go up four* (pointing to quarters) *... go to two* (quarters) *and about there* ($^3/_4$)]. The responses from students who marked eighths generally appeared to ignore the relationship between the denominator and the number of partitions. They seemed to have developed a holistic view of mixed numbers so that $2^1/_4$ was *just a little past 2* (marking $2^1/_8$) or *just a bit before 3* (marking $2^7/_8$). The student who marked $2^5/_8$ indicated that he also associated the unit numerator with a half (*cos that's 2 and a quarter*) and then marked just past the ½.

The students who could not place the number were generally confused by the fourths. They counted the marks and, therefore, saw the intervals as thirds [e.g., *two* (pointing to the whole number) *and then it goes one, two, three instead of four* (pointing to the partitions)].

Task 2. Unlike Task 1, the Year 6 students' responses were more accurate than those of the Year 8 students. Students with correct placement tended to invoke the quotient (*2 threes are 6*) or operator (*6 thirds is 2*) subconstructs as well as the part/whole subconstruct (i.e., counting in thirds). Although correct, 2 of the latter students (part/whole) were unsure of their answers, for example, *I'm pretty confused about this but with thirds, there's 3 in each one of them* (the units) *but, if you count them like that, there's 6 there* (at 2). It seems as though this student had had little or no experience with renaming whole numbers (with the possible exception of 1) as fractions and that this was a nonprototypic task for her. The other student was confused between the 4 intervals (and therefore quarters) and the three partitions (and therefore thirds).

The explanations from students who marked "near" the correct response (e.g., $1^5/_6$, $1^2/_3$, $2^1/_3$, $2^2/_3$) showed that they tended to count thirds but either counted the partition lines starting at 0 ($1^2/_3$ or $1^5/_6 - 1^2/_3$ *with a little bit on*), counted an extra third (*I went 1, 2, 3, 4 5, 6 and then a third more* – $2^1/_3$), or thought that the partitions at the whole numbers could not be counted because they were not the same size as the internal partitions ($2^2/_3$). The responses from students who marked "high" (i.e., beyond 3) indicated that they thought the 6 in $^6/_3$ was a whole number. This belief was so strong that the students extended the number line to past the whole number 6 so that they could position the improper fraction [e.g., *six and a bit more* – marking $6^1/_3$; *you've got to put thirds* (between 6 and 7) *so you'd mark the 3rd one* – counting the partition at 6 as the first third and thus marking $6^2/_3$; *six, and three partitions for the third* – marking $6^3/_4$]. The responses from students who marked "low" (i.e., $^1/_6$, $^1/_2$, 1) showed very poor understanding of improper fractions and confusion between representations (e.g., *it's six threes ... six threes are eighteen ... so 18% of the whole* – marking $^1/_6$; *it's half* – interpreting the fraction as $^3/_6$; *I counted up six in a row and came back three* – marked 1).

Students who could not place the number tended to have the same misconception as those marking high (but without the initiative to extend the line), namely, equating the numerator with the whole number, 6 (e.g., *there's no six*; *not enough numbers*). One student couldn't interpret the improper fraction because it didn't have a whole number before it and therefore, there was no "range marker" [e.g., *there's 3 here* (counting the whole numbers) *but it didn't say a whole number to put it between, or, after or before*].

Task 3. As for Task 2, the Year 6 students were more accurate than the Year 8 (none of whom gave the correct response). Except in one instance, correct placement involved either overt physical repartitioning or mental repartitioning of thirds into

sixths (e.g., *well there's only thirds ... but if you count two of them, there'd kind of like be sixes - 1 sixth, 2 sixths*; *cut each third in halves*; *you'd have to draw them all ... put one in between*). The exception was the boy who invoked the quotient subconstruct (as he had for Task 2).

The "near" placements at $1^1/_3$ and $1^2/_3$ were based on idiosyncratic strategies, neither of which involved reunitising thirds as sixths [e.g., $^{11}/_6$ was interpreted as $1^1/_6$ and the partition after 1 was marked – $1^1/_3$; *2 sixes are 12 so take off 1* (third) – $1^2/_3$]. The "near" placement at 2 revealed erroneous thinking (e.g., $^1/_6 - {}^1/_3 + {}^1/_3$; $^1/_6 > {}^1/_3$). Generally, the "mid" errors were based on either counting the thirds as sixths and consequently marking $3^2/_3$ (if parts were counted correctly) or $3^1/_3$ or 4 (if partition lines, not intervals, were counted). "High" placement at $11^1/_3$ and $11^1/_2$ resulted from associating the numerator with whole numbers on the number line and then partitioning the unit from 11 to 12 into thirds. Again, this belief was so strong that the students extended the number line to past the whole number 11. The "low" placement at $^1/_2$ was a consequence of the same confusion between percent and fractions as for Task 2

The students who could not place the number appeared not to comprehend the fraction, the number line or how the two could go together (e.g., *you can't get it on there* and *but that's not sixths*). They exhibited no confidence and little interest in attempting the problem.

Discussion

The poor results for the simplest task (Task 1) suggests that there is an inherent cognitive difficulty involved in conceptualising the number line representation of fractions. The difficulty appears to be compounded when the given fraction is recorded in improper fraction form. These arguments are supported by the increased number of students who could not attempt to answer Tasks 2 and 3 (see Table 2).

Incorrect responses were idiosyncratic, that is, few error patterns were discerned, and same responses nearly always were the result of different (and inappropriate) thinking strategies. Those error patterns that were discerned were: (a) counting partition lines rather than intervals and therefore counting included 0; (b) associating the numerator (in improper fractions) with a whole-number marker and therefore counting whole numbers rather than parts; (c) failure to reunitise when required because of lack of awareness (and therefore a metacognitive shortcoming) or lack of knowledge (e.g., 1 sixth is composed by doubling a third, rather than halving a third).

Furthermore, maturation appears to have no effect on performance. In fact, performance in this study dropped with age (particularly for the improper fractions), a phenomenon we found difficult to understand, particularly as we had expected the Year 8 students to have been much more exposed to this form of fraction recording in view of the fact that they would have encountered addition and subtraction of unlike common fractions requiring decomposition, as well as being exposed to percent conversions to decimal and common fractions, and to prealgebra tasks. We

tentatively suggest that, if appropriate structural knowledge has not been constructed (i.e., semantic knowledge), then students are forced to create "rules", the number of which increase as more and more knowledge needs to be accommodated. The result of this would be to have no means of solving nonprototypic tasks or to invoke as many "rules" as one can think of. One student (Year 8) exemplifies this latter situation as his protocol shows. In Task 2, he had placed $^{6}/_{3}$ (which he read as 6 threes) at $^{1}/_{6}$ and, in Task 3, placed $^{11}/_{6}$ at $^{1}/_{2}$.

Task 2: *Six threes are 18 so 18% of the whole* (0 to 1) – *about there* ($^{1}/_{6}$).

Task 3: *I timesed 6 by 11 – 66% in a hundred so I took it to the nearest part, point five* ($^{1}/_{2}$).

Conclusions

This study found that students have conceptual difficulties in placing proper (e.g., $^{1}/_{4}$ in $2^{1}/_{4}$) and improper fractions on number lines may have been partitioned into the appropriate number of parts. Thus, the results tend to support Payne's (1976) findings that students have difficulties with unitising units on a number line. In particular, there appears to be confusion between whole and part [e.g., not counting the wholes ($^{6}/_{3}$ is placed at $2^{2}/_{3}$), counting markings not spaces ($^{6}/_{3}$ is placed at $1^{2}/_{3}$), and counting wholes as parts ($^{6}/_{3}$ is placed somewhere after 6)].

The study also found that the placement problems were exacerbated when the number of partitions did not match the given denominator, indicating a continuing difficulty with partitioning and unitising/reunitising on a number line (e.g., counting thirds instead of sixths so that $^{11}/_{6}$ is placed at $3^{2}/_{3}$; not knowing how to reunitise thirds as sixths). This finding reinforces the consensus in the literature on the fundamental importance of children's notion of the unit with respect to representations (e.g., Behr et al., 1992; Harel & Confrey, 1994; Kieren, 1983; Lamon, 1996; Pothier & Sawada, 1983).

The major implications of the findings are that: (a) unless teachers are aware of the inherent conceptual problems students have in processing number lines, their effective use as a teaching and problem solving aid will be limited; and (b) further research which focuses on analyses of students' comprehension of number line fraction representations is required in view of the current resurgence of interest in the area (Beishuizen, 1997; Bove, 1995; Okamoto, 1996; Dole, 1998; Olsen, 1995). An exhaustive review of the PME proceedings dating back to 1994 produced very few articles in this area, supporting the need for further research.

CLASSROOM COACHING: CREATING A COMMUNITY OF REFLECTIVE PRACTITIONERS*

Joanne Rossi Becker
Barbara J. Pence
San José State University, USA

Abstract

This paper reports on an observational study of 14 high school mathematics teachers who had been involved in one to five years of professional development, including intensive summer institutes, follow-up workshops, and purchase of resource materials and technology. The study was undertaken to determine the effects of the in-service programs on the actual classroom practices of the participants. Using a coaching model, the two authors observed over 200 classes of 17 sections. Seven categories of results were formed from observational data, interviews with teachers, informal interviews with students, and perusal of student work and other ancillary material. This paper reports on three of those categories and discusses critical dimensions of the model of coaching.

Perspective

The professional development programs upon which this research was based endeavored to adhere to promising practices identified by the California Post-secondary Education Commission in a study of projects it had supported from 1992 to 1996 (CPEC, 1996). These included the following aspects:

- *Successful projects found ways to create systemic change across entire school districts.* In the CPEC project we provided professional development to all high school mathematics teachers in two districts (about 150 teachers) over a three-year period. This project, coordinated with the national Equity 2000 project, aimed at helping teachers change their curriculum and instruction in algebra 1/course 1 as the districts implemented an "algebra for all" policy in ninth grade. In the NSF leadership project, we included teachers from several districts, but endeavored to incorporate at least two teachers from each school so that the teachers would have support as they went back to their sites and led curriculum reform.
- *While successful projects need a coherent and consistent set of goals and a reasonable theory of change, they also require strategies that allow participants the flexibility to meet their own personal needs.* The NSF project, in which some teachers participated for three summers four academic years, had the opportunity to incorporate this strategy by forming a small cadre of teachers to help plan subsequent workshops after the first year and by allowing teachers to work on projects of their choice.

* The research reported in this paper was partially supported by the Dwight D. Eisenhower Mathematics and Science State program administered by the California Postsecondary Education Commission (CPEC) grant #785-5. The professional development projects being evaluated were funded by CPEC (#785-5) and the National Science Foundation (NSF) Teacher Enhancement Program, grant # 9155282. The opinions expressed here are those of the authors only and do not represent the views of CPEC or NSF.

- *Successful grantees adopt their own system of internal assessment.* Such evaluation has been an ongoing aspect of both projects (Becker & Pence, 1998; Becker & Pence, 1996; Kitchen, Becker & Pence, 1997; Peluso, Becker & Pence, 1996).
- *Successful projects develop strategies that enable their teachers to achieve self-actualization.* Fundamental change in teacher behavior occurs when a teacher begins to think of her/himself as a professional and feels that authority is internal rather than conferred from an external authority. Without this orientation, Cooney has claimed (1994), teachers will be unable to exert control over their curriculum and even their pedagogy. Evidence of this level of professionalism was found in previous research (Becker & Pence, 1998).
- *Successful projects do much more than explain constructivism; they model it by involving their teacher-participants in well designed constructivist learning experiences.* As discussed in the next section, we modeled in the professional development a teaching approach that we advocated the participants use.
- *Successful projects know that time-on-task is an important determinant in teacher learning as well as student learning.* The projects utilized extensive summer institutes (three weeks or more) and at least 10 days of followup workshops during the academic year, repeated over several years.
- *Learning about new content or pedagogy is only a necessary condition for improving one's teaching; actually employing that knowledge in the classroom requires more.* The coaching model described in this paper was our approach to encourage teachers to use their new knowledge in the classroom.

The classroom coaching model we used had two main objectives as an extension of the professional development in which teachers had participated: to provide analytic and objective feedback to the teacher with regard to teacher-student behavior; and, to develop within the teacher the desire and ability to reflect upon her/his own behavior and evaluate the results of that behavior as a means of self-improvement. The coaching followed an adaptation of a clinical supervision model, providing teachers feedback that was descriptive rather than evaluative and always requested. The feedback was usually given immediately following the lesson observed, or as close to that as practical given the teacher's schedule.

Background

The professional development projects being studied in this research were based on the assumption that what a teacher believes and what a teacher knows both influence the teaching of mathematics (Fennema & Franke, 1992; Thompson, 1992). What a teacher knows is understood to include both content knowledge and pedagogical content knowledge (Cooney, 1994). Cooney (1994) has interpreted Shulman's (1986) original notion of pedagogical content knowledge in the discipline of mathematics. For Cooney, pedagogical content knowledge in mathematics involves integrating content and pedagogy, borrowing ideas from mathematics and from our knowledge about teaching and learning mathematics. he presents the example of the rational numbers, for which we have various interpreteations and a deep knowledge base about how children construct their

understanding of the rational numbers through these different interpretations. This integration of the mathematical and psychological domains defines pedagogical content knowledge.

As we structured the inservice education to enhance both content and pedagogical content knowledge, we were mindful that teachers themselves are constantly constructing knowledge, albeit knowledge about students' learning of mathematics, effective teaching of mathematics, as well as mathematical content. Therefore activities were structured to ensure that knowledge was actively developed by participant teachers, not passively received. Teachers were frequently involved in presentations, facilitation of small group activities, and even development of workshop foci as the inservice progressed. The professional development became a collaboration among university faculty, district curriculum coordinators, and participant teachers.

Methodology

A year-long observational study was undertaken to ascertain the impact of the two professional development projects on the classroom practice of participant teachers. A sample of teachers were invited to participate in this study. We selected the sample of 24 based upon the number of years of involvement in the inservice, which varied from one to five, and demographic factors such as gender, ethnicity, school district, and teaching experience. Fourteen teachers agreed to participate, and 17 different classes of the 14 teachers were observed by the authors for a combined total of 210 classroom observations over a six-month period. The authors alternated weekly visits of each teacher.

Courses observed varied from an algebra restart [for students who were unable to succeed in algebra the first semester] to algebra 2/integrated course 3. We observed one algebra restart, six algebra 1 classes, five geometry classes, one algebra 2, one integrated course 1, two integrated course 2, and one integrated course 3. The textbooks used varied from the traditional (3 classes) to "transitional" (10 classes), to integrated (four classes). The sample of teachers included five males and nine females from nine schools and four different school districts. Three teachers were Asian-American and the rest European-American. The participants varied in teaching experience from under five to thirty years, with inservice participation from one to five years.

In addition to the classroom visits, both informal and formal interviews were held periodically with each teacher. These interviews were based upon what had been observed in the teacher's class, probing such things as: goals for the lesson and the unit; planned assessment; use of technology; student understanding; plans for followup to the lesson observed; and curricular issues.

Description of Coaching

The classroom observations primarily used a clinical supervision model, in which the teacher and observer discussed before the lesson specific items on which

the observer would focus. The observer then endeavored to collect data to help inform the teacher about the teaching behavior(s) of interest to him/her. After the observation, the teacher and observer discussed the lesson; the observer shared information about the focus of the lesson with the teacher in a non-evaluative way. That is, the observer reported data on the behaviors of interest without assessing the merit of the teacher's classroom practices.

During each visit, the researcher acted as a participant-observer (McCall & Simmons, 1969), taking an active part in the class activities, helping students as they worked individually or in groups and asking questions of students to determine student understanding of new concepts. The observer acted as a true collaborator in the classroom. The debriefing sessions freqently included questioning and reflection on the part of the teacher, as we exchanged ideas for:

- further developing new mathematical concepts;
- reforming the curriculum;
- infusing technology into their teaching;
- ways to teach upcoming mathematical concepts;
- assessment techniques;
- equity issues in teacher-student interactions; and,
- ways to help recalcitrant or struggling students.

Results

In analyzing the data from observations and both informal and formal interviews, we formed seven categories on which we partitioned the classroom practices of the fourteen teachers. These categories included equity, multiple representations, and the use of technology, the foci of the observers. The additional four categories - student understandings, use of cooperative groups, alternative assessment, and reform curriculum - arose either from the observations or from questions raised by the teachers in debriefing sessions. Table 1 below delineates the partitioning formed, with "yes" indicating strong evidence of practices consistent with the emphasis of the professional development.

Due to space limitations, we will discuss three categories in this paper: equity, student understandings, and assessment. Each category is exemplified by instances from at least one teacher, instances which are representative of patterns discerned in that category.

Equity

Although more than half of the teacher sample showed evidence of inequitable treatment in the classroom, especially by gender, we want to highlight two teachers in particular. One male teacher, Damon, consistently called upon a small number of male students during questioning. In his geometry class, for example, in one observation Damon interacted with males on 16 occasions (seven of which were callouts), but only 3 with females (two of which were callouts). This class was only 37% female; however, the young women were only involved in 16% of the interactions with the teacher. This disproportionate pattern of

interactions was typical in this class. In his algebra 1 class, evenly split between young men and women, Damon usually interacted about twice as much with the young men as with the young women in the class. Damon learned about the observers' areas of interest because he asked and we answered honestly. Following this discussion, Damon asked one observer to share data relative to equity. He was most chagrined to learn about the inequities in his response opportunities, and was determined to monitor and change his own behavior.

A female teacher, Shana, was much more equitable in her teacher-student interactions, with most of these occurring during small group activities or as pairs worked on computers. However, she initiated discussions about this issue on her own. She had a student assistant tally her interaction patterns as a way of monitoring her behavior. And Shana, on her own initiative, devised a plan to ensure equitable interactions in her class. She planned to use the computer to randomly generate a new sequence of names for her to use each day as she called on students.

Student Understandings

Some concepts were difficult for teachers to teach for understanding. In an integrated course 1, Polly was introducing the concept of standard deviation, which she did rather traditionally, putting an extensive table on the board and having students calculate all the intermediate steps on a set of data. Then she showed the students how to find the standard deviation on a graphing calculator, and she allowed them to use this tool consistently thereafter. In this introduction, Polly did not attempt to provide an intuitive understanding of what the standard deviation measures. After the class, she remarked to the observer that although she thought students understood the steps in the algorithm, she did not feel they understood what the standard deviation meant from her instruction. This was confirmed by the observer in a later observation by questioning students as they worked in groups. Polly told the observer that she would think about how to provide meaning for this concept. In a later lesson, Polly presented a nice activity in which students collected data on the heights of students' navels from the floor and again while standing on identical chairs. Students then compared various measures of central tendency; they were not surprised that the mean changed by the height of the chair, but were very surprised that the standard deviation did not change at all. This activity seemed designed to help students begin to develop understanding of the standard deviation, and it seemed to meet its goal. Polly's concern about student understanding was, we felt, indicative of new knowledge Polly had gleaned from the inservice programs in which she participated. Although the text did not provide any guidance, Polly had the confidence and persistence to develop an instructional strategy that she felt would develop the understanding she valued.

Assessment

Shana had established a detailed scheme of assessment in her geometry class in which she included performance standards for homework, performance standards for projects, a rubric for computer work with a sample format, a culminating computer investigation for the semester's work, and a unit portfolio which was peer

reviewed. We should note that Shana had been working on this scheme over three years of her inservice involvement, revising it as experiences suggested needed changes. The coaching helped support Shana in this unusual assessment plan and assisted her in reflecting on its effects on student understandings and reporting to parents and her peer teachers.

Table 1: Observation Categories

Discussion

The intensive inservice program over three to five years impacted the teachers in a number of ways. The programs established a common base of content and pedagogical content knowledge (Cooney, 1994) and a common language between teachers and researchers which allowed for a challenge of traditional beliefs about the teaching and learning of mathematics. In addition, the teachers received a considerable amount of resource materials and technology, such as graphing calculators and computer software, essential for implementing new knowledge in the classroom setting. Perhaps most important to the teachers was the strong network of peers formed over the years. This network supported teachers as they attempted to implement change in their curriculum and instructional practices (Becker & Pence, 1996).

Past evaluations of the inservice documented these positive effects of the programs (Becker & Pence, 1996; Peluso, Becker & Pence, 1996; Peluso, Pence & Becker, 1994). In this work we used a variety of self-report measures to determine the effect of our inservice programs. However, we are well aware of the limitations of such data. Therefore, we initiated this observational study to ascertain the impact of the two professional development projects on actual classroom practices of participant teachers.

But, we were surprised that many of the 14 teachers reported that the **coaching itself** was a critical extension of the professional development program. The two-to-one contact over six months with each teacher served several purposes. First, it provided the opportunity for both observers to experience the development of full units of mathematical content. As the content developed, we were able to see how student work progressed and how student understandings grew. Weekly visits enabled the teachers to identify a conflict or concern, ask questions about student experiences and glean insight into their teaching from our feedback. Second, although we had a good working relationship with these teachers before

they assented to participate in the study, the coaching helped establish a stronger rapport and true collegial collaboration. We were not the authorities, but rather sounding boards with whom teachers could formulate instructional questions, extend those questions, and work out solutions for themselves.

Finally, our presence supported the teachers who were trying to make real change in their curriculum, instruction, and assessment. At some school sites, parents, other teachers, or administrators hindered reform efforts. Observer feedback and encouragement ameliorated such challenges. We acted as another voice, counteracting negativity these risk-takers sometimes faced (Peluso, Pence & Becker, 1994).

Summary

We should point out that the classroom coaching described in this paper requires a great deal of time and thus financial resources to effectuate. However, the results of this work indicate that such coaching may well be a critical component to consolidate changes in classroom practice as a result of professional development.

CONSTRUCTING AN UNDERSTANDING OF DATA GRAPHS

Dani Ben-Zvi
The Weizmann Institute of Science, Rehovot, Israel

I describe episodes of two 13-year-old students working on Exploratory Data Analysis (statistics) developed within an innovative curriculum. I analyze the microevolution of their incipient understandings of some features of graphs as data representations. The description includes the role of the instructional materials, the students' discussions and collaborative attempts to solve the tasks, and the teacher's intervention. Although her intervention seemed to be a miscommunication, it appears to have helped the students to make sense of their tasks.

BACKGROUND

The teaching of *Exploratory Data Analysis* (statistics) is mostly based on: (a) organization, description, representation and analysis of data, with a considerable use of visual displays (Shaughnessy et al., 1996); (b) a constructivist view of learning (Garfield, 1995); and (c) incorporation of technological tools for making sense of data and facilitating the use of various data representations (Biehler, 1993).

With these perspectives in mind, we developed a middle school statistics curriculum[1] (Ben-Zvi & Friedlander, 1997a), implemented it in schools and in teacher courses, and undertook research on learning (Ben-Zvi & Arcavi, 1997; Ben-Zvi & Friedlander, 1997b). The curriculum is characterized by: (a) a use of extended real (or realistic) problem situations; (b) collaboration and communication in the classroom; and (c) a view of the teacher as "a guide on the side" (Hawkins et al., 1992). The students pose, collect, analyze, interpret data, and communicate (Graham, 1987) using a spreadsheet. The classroom activities are semi-structured investigations, in which students, working in pairs, are encouraged to hypothesize about possible outcomes, choose tools and methods of inquiry, design or change representations, interpret results, and draw conclusions.

THE STUDY

A pair of 13-year-old students (*A* and *D*) was videotaped at different stages of their learning statistics (20 hours of tapes). I focus here on 15 minutes of their work with brief teacher interventions. The students were considered by their teacher to be both very able and very verbal. They were asked to talk aloud and explain their actions.

The purpose of the following analysis is to study how students construct their understanding of graphs as displays of real life data, and learn to design them to support certain claims. I used interpretive microanalysis (see, for example, Meira, 1991, pp. 62-3) to try to understand students' discussions, considerations, difficulties and solutions. In this analysis I consider socio-cognitive aspects, taking into account verbal, gestural, and symbolic actions, in the context in which they emerged --

[1] The project is part of *CompuMath*, an innovative and comprehensive curriculum (Hershkowitz & Schwarz, 1997).

comparing and contrasting the data with other pieces of data, written records, and conversations with the teacher.

The Problem Situation

The extended (four lesson) activity - *The same song, with a different tune* - occurs early in the curriculum. The context is the Olympic 100 meters race. The students were given, in a spreadsheet, the men's 100 meters record times, and the years in which they occurred (from 1896, the first modern Olympiad, to 1996). In the first part of the activity, the students were introduced to the context of the investigation and were asked to describe the data graphically and verbally. In the second part, the students were asked to manipulate data graphs, i.e., change scales, delete an outliar, and connect points by lines. In the third part, they were asked to design graph to support the following claim: *"Over the years, the times recorded in the Olympic 100 meters improved considerably".*

In the following, I present and analyze the students' work through the activity.

DEVELOPING UNDERSTANDING OF DATA GRAPHS: THE 'STORY' OF *A* AND *D*

In this section, I present three parts of the activity chronologically: (a) getting acquainted with the context, (b) acquiring tools, and (c) designing graphs.

(A) Getting Acquainted with the Context

In the first part of the activity, *A* and *D* analyzed the table of results, compared the records of consecutive Olympiads, considered the issue of extreme data, sorted the data, and created a graph with a spreadsheet (Figure 1). In their written summaries, they wrote that (a) the best record is 9.48 sec. and the worst is 12 sec., (b) the greatest improvement is from 10.25 to 9.48 sec., and (c) the differences between records are not constant. The first two conclusions are wrong: the best record is 9.84 sec., and the greatest improvement is from 12 to 10.8 sec. When requested to describe the data *patterns*, they did not seem to understand the meaning of the question. With the teacher's help, they concluded correctly that "the record times seem to improve, yet there was occasionally a lower (slower) result, than the one achieved in previous Olympiads".

Although *A* and *D* seemed to notice the general trend of improvement in the records, their view was mostly local and focused on discrete data points, or, at most, on two consecutive records. I claim (based on data not detailed here) that their difficulty to discern general data *patterns* was caused by: (a) the students' lack of experience with the notion of *pattern*; (b) the discrete nature of the graph; (c) the non-deterministic and disorganized nature of statistical data, which is very different from the deterministic formulae, they had met in algebra.

(B) Acquiring Tools

In the second part of the activity, the students became acquainted with three strategies for manipulating graphs (changing scales, deleting an outliar, and connecting points), and considered the effect of these changes on the shape of the graphs. The objective was to prepare for the *design* task (Part C below).

Changing Scales

The following transcript describes the students' comments on the effect of changing the vertical scales of the original graph from 0-12 to 0-40 (Figures 1& 2):

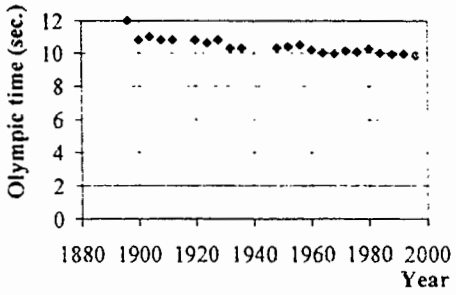

Figure 1: Given graph

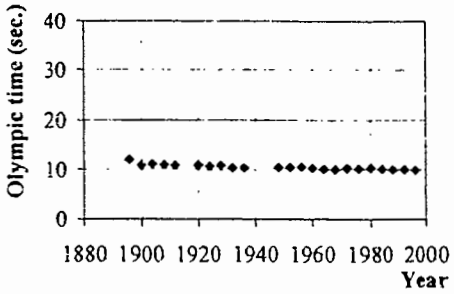

Figure 2: Manipulated graph

A. *Now, the change is that... that the whole graph stayed the same in shape, but it went down...*

D. *The same in shape, but much, much lower, because the column* [the y-axis] *went up higher. Did you understand that?* [*D* uses both hands to signal the down and up movements of the graph and the y-axis respectively.]

A. *Because now the 12, which is the worst record, is lower. It used to be once the highest. Therefore the graph started from very high. But now, it* [the graph] *is already very low.*

The students' perception of the change is restricted to the overall relative position of the graph; they considered the shape itself as remaining "the same". Their description includes: global features of the graph ("The whole graph ... went down"), an interchange of background and foreground (the graph went down and/or the y-axis went up), and local features (12 as a "starting point" of the graph). These descriptions are linked and complement each other. *A* wrote the following synthesis in his notebook: "The graph remained the same in its shape, but moved downward, because before, 12 - the worst record - was the highest number on the y-axis, but now it is lower".

Deleting an Outliar

In this task, the students were asked to delete an outlying point (the record of 12 sec. in the first Olympiad, 1896) from the graph (Figure 2), and describe the effect on its shape. First, *D* justified why 12 can be considered an outliar:

D. *It* [the record of 12 sec.] *is pretty exceptional, because we have here* [in the rest of the data] *a set of differences of a few hundredths, and here* [the difference is] *a whole full second.*

Figure 3: Outliar deletion

Then, they struggled to interpret the effect of the deletion on the graph (Figure 3):

D. *The change is not really drastic ... Now,*

BEST COPY AVAILABLE

however, the graph looks much more tidy and organized.

A. One point simply disappeared. The graph... its general shape didn't change.

They wrote in their notebooks different descriptions of the change: "The graph became straighter" (*D*); "One point in the graph disappeared" (*A*). Thus, the students struggled between different views of the effect: global and significant change (the graph is tidy and organized), no change at all (the general shape didn't change); or just a mere description (one point disappeared).

Although the dispute about the outliar was not resolved, it served another purpose: it drew *A*'s attention to a mistake in their conclusions in the first part of the activity, and corrected it: "the greatest improvement is from 12 to 10.8 seconds".

Connecting Points

In the third task, they were asked to connect the points to obtain a continuous graph. The new graph (Figure 4) elicited many comments from the students, who tried to make sense of what they saw. They were particularly intrigued by the fact that the connected graph included both the original points, and the connecting line.

D. OK. You see that the points are connected by lines. Now, what's the idea? The graph did not transform to one line. It transformed to a line, in which the points are still there. It means that the line itself is not regarded as important.

A. This line is OK. We previously thought that if we connect the points with a line, they might disappear. But now, there is a graph, and there are also the points, which are the important part.

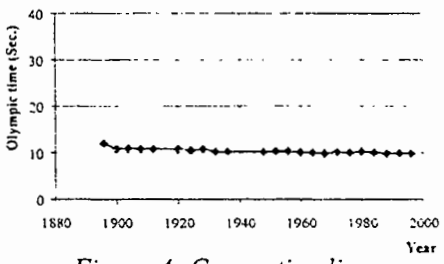

Figure 4: Connecting line

In their view, the connecting line (as provided by the spreadsheet) not only did not add any new meaning, but also contradicted the context, as *D* observed: "Olympiads occur only once in every four years" (namely, there is no data between the points). The students did not see the line as an aid to detect or highlight patterns in the data, and this is consistent with their previous difficulties in recognizing data patterns.

So far *A* and *D* were practicing manipulations (changing scales, deleting an outliar, and connecting points), and discussing their effect on the graph's shape. The intention was to provide students with the means to design a graph, in order to support a particular claim. In the following section, I discuss in what sense this preparation helped them achieve this purpose.

(C) Designing Graphs

I present here a fragment of the students' work on the third part of the activity. The students were asked to design a graph to support the statement: "*Over the years, the times recorded in the Olympic 100 meters improved considerably*". I bring first a teacher intervention, which eventually helped the students understand the task. Then, I focus on five attempts (*Stages 1-5* below) to obtain a satisfactory form of the graph.

The Teacher Intervention

A and *D* did not understand the task and requested the teacher's (*T*) help:

T. [Referring to the 0-40 graph displayed on the computer screen -- see Figure 4.] *How did you flatten the graph?*

A. [Surprised] *How did we flatten it?*

T. *Yes, you certainly notice that you have flattened it, don't you?*

D. *No. The graph was like that before. It was only higher up* [on the screen].

The teacher and the students are at "loggerheads". The teacher assumes that the students (a) had made sense of the task, but just did not know how to perform it, (b) had acquired the necessary tools, and understood their global effect on the graph's shape to be used to support the claim. Thus, her hint consisted of reminding them of what they had already done (scale change). However, the students did not regard what they had done, as changing the graph's shape. Although this intervention seemed to be a case of miscommunication, it apparently had a catalytic effect, as reflected in the dialogue, which took place immediately afterwards:

T. *How would you show that there were very very big improvements?*

A. [Referring to the 0-40 graph -- see Figure 4.] *We need to decrease it* [the maximum value of the y-axis]. *The opposite...*[of what we have previously done].

D. *No. To increase it* [to raise the highest graph point, i.e. 12 sec.].

A. *The graph will go further down.*

D. *No. It will go further up.*

A. *No. It will go further down.*

D. *What you mean by increasing it, I mean - decreasing.*

A. *Ahhh... Well, to decrease it... OK, That's what I meant. Good, I understand.*

Even though their use of language is not completely clear, their previous perception that the graph shape remains the same was not mentioned at this stage. Moreover, *D* expressed what appears to be a new understanding:

D. *As a matter of fact, we make the graph shape look different, although it is actually the same graph. It will look as if it supports a specific claim.*

At this point, *D* seems to discern that a change of scales may change the perceptual impressions one may get from the graph. Thus, they seemed to understand the purpose of the activity, and started to focus on its goal. In the following, the students' five attempts to design corresponding graphs are presented.

Stage 1 (The scales are changed to x: 1880-2000; y: 0-5)

D suggested (Figure 4) changing the scale on the y-axis to 0-11. It seems that he chose 11, since he had previously deleted the outliar, making 11 the maximum data point. They didn't implement this change, because he immediately proposed another scale change: 0-5. This suggestion seems to be based on his assumption that

the smaller the range the larger the decline in the record time would look *(Idea I)*. However, when they implemented this change, the graph disappeared.

A. We don't see the graph at all, since there is no graph in 5.

Stage 2 (x: 1880-2000, y: 0-12)

Having failed to present a new graph, they returned to the 0-12 range (see Figure 1):

A. The graph looks more curved, because the difference between records is much bigger, since we increased the... now the "Olympic time in seconds" [y-axis] *is from 0 to 12, and every record– as much as it descends – it is bigger than the record... the line is more...* [*D.* interrupts] *Wait a second, the line is bigger than it used to be from 0 to 40.*

The effect of changing scales on the graph's global features (straight, curved), which were not noticed initially, and started to be considered after the teacher's intervention, were now being fully considered. Still, the students struggle to verbalize and explain what they do, or want to do.

Stage 3 (x: 1896-1996, y: 0-12)

At this stage, it seemed that *A* and *D* had exhausted the changes on the y-axis. So they turned to the x-axis. *D* suggested changing the upper limit of x from 2000 to 1000 (*Idea I* above). They realized, however, that this would cause the graph to disappear again (the year's range is 1896-1996). Thus, *D* proposed using 1996 (instead of 2000) as the upper limit of x. Although the effect[2] was marginal, *D* commented:

D. One can really see, as if there are bigger differences in the graph... Very interesting!

Although they had presumably understood how changing scales effects the graph's shape, *D*'s wrong impression of this horizontal change, seems to originate from his ambiguous distinction between vertical or horizontal "differences" and/or distances. However, having focused their attention on the x-axis, they realized that it does not start at zero, which triggered the following idea *(Idea II)*.

Stage 4 (x: 1896-1996, y: 8-12)

A transferred attention from the x-axis to the y-axis, and suggested changing the lower limit for y from 0 to 8 (to get a scale of 8-12). Observing the resulting sharp visual effect, he reacted immediately:

A. It looks much bigger.

Stage 5 (x: 1896-1996, y: 9.48-12)

D suggested applying *Idea II* to the x-axis, but withdrew, when *A* indicated that it already started at a non-zero value. Instead, *A* suggested using the minimum

[2] The lower limit for y changed automatically to 1896, resulting in a final range of 1896-1996, instead of 1880-2000, which were the default values provided by the software.

record time (9.48 sec.) as the lower limit of y *(Idea III)*. The resulting graph (Figure 5) satisfied them, and they made the following final comments:

D. This way we actually achieved a result [graph] *that appears as if there are enormous differences.*

A. To tell you the truth, this booklet is lovely.

D. Right, it is nice!

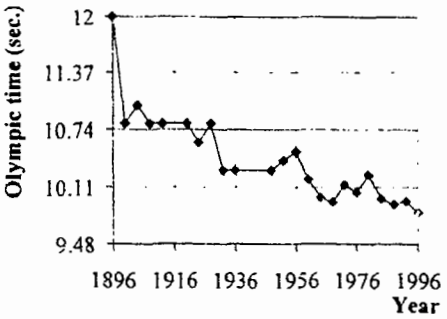

Figure 5: Final design

DISCUSSION

This 'story' of *A* and *D* traces the microevolution of incipient understanding of some features of graphs as displays of real life data (see also Bright & Friel, 1997). It describes the students' perceptual development from a stage in which they did not understand the requirements of the task and the notion of data *pattern*, to the final successful completion of the *design* task. The following elements seem to have contributed to the construction of students' understanding of certain characteristics of data graphs.

Careful instructional engineering. The students worked with semi-structured guidance to solve open-ended questions. First, they acquired tools to modify graphs and then, they employed these tools in the design of graphs, to support a certain claim.

Close collaboration between the pair of students. The students:

a) verbalized almost every idea that crossed their minds. At times this spontaneous verbalization produced mere descriptions, but later served as stepping stones towards a new understanding, and at times, it served as self-explanation (Chi et al., 1989) to reinforce ideas;

b) complemented and extended each other's comments and ideas, which seems to have "replaced" some of the teacher's role in guiding their evolution;

c) decided to request the teacher's help when faced with a difficulty, which could not be resolved among themselves; and

d) transferred and elaborated, in iterative steps, ideas of changing scales, from one axis to the other.

The teacher's main intervention. At a first glance, the teacher's intervention to help the students make sense of the task, can be considered unfortunate. She did not grasp the nature of their question, misjudged their position, and tried to help by reminding them of their previous actions. The students, however, did remember the acquired tools, but perceived them differently.

Nevertheless, this miscommunication itself contributed to their progress. At first, *A* and *D* were surprised by her use of the notion of *flattening the graph* as a description of what they had done. Then, they started to direct their attention to the

shape of the graph, rather than to its relative position on the screen. Although puzzled by the teacher's language, the students appropriated (Moschkovich, 1989) her point of view on what to look at. Their previous work and their "struggle" with language seems to have prepared them for the reinterpretation of what they had done, triggered by their teacher's comments.

In sum, the microevolution of the students' understanding of data graphs was influenced by the instructional engineering, the students' ways of making sense (descriptions, self-explanations, questions to a colleague and the teacher, transfer of ideas, etc.), and the teacher's intervention and the use students made of it.

Acknowledgment. I thank Abraham Arcavi and Alex Friedlander for their helpful comments and suggestions.

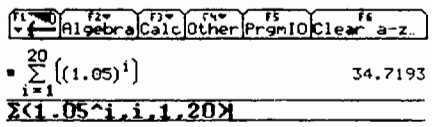
ROUTINE QUESTIONS AND EXAMINATION PERFORMANCE

John Berry & Wendy Maull — University of Plymouth, UK
Peter Johnson & John Monaghan — University of Leeds, UK



Abstract *This study concerns student performance in pre-university examination questions. In particular whether lower attaining students in mathematics examinations generally gain their marks on routine parts of questions? This is an important issue because routine questions could be awarded fewer marks if algebraic calculators are allowed in examinations. Students' scripts in a recent mathematics examination were examined in an attempt to evaluate this question. The results are not conclusive but indicate that a problem of this type does exist, though the nature and location of the problem is not as straightforward as expected.*

Introduction

Our starting point is the question: do A-level Mathematics[1] students who attain lower pass grades (D and E) generally obtain these grades by answering 'routine' parts of A-level Mathematics questions? Routine questions may be viewed as those for which students may be expected to execute a rehearsed procedure consisting of a limited number of steps. Problems in characterizing routine questions are considered later. The next three paragraphs explain the rationale for and import of the study.

During the period 1994-1996 the then Schools Curriculum and Assessment Authority (SCAA) set up a number of working groups investigating possible consequences of student use of a new generation of algebraic calculators on A-level Mathematics questions and papers. One important debate was whether such use would accentuate the difference between higher and lower attaining students, e.g. between those attaining A-level grades A & B and those attaining grades D & E. An example should clarify matters.

A typical question on geometric series may start by a request to evaluate $\sum_{i=i}^{20} 1.05^i$ and then proceed to a question on compound interest, e.g. "If I invest £550 at a rate of 5% per annum, how many years must I wait until I have more than £1000 in this account?" It should be noted that the new generation of algebraic calculators can perform the first part of this question, e.g. the TI-92 screendump below. In the ensuing discussion everyone initially assumed, as a generality with exceptions, that students

[1] Advanced level (A-level) Mathematics is the most common senior public examination for students in the UK. It covers considerable algebra and calculus of a single variable. There are five pass grades, A to E. Examinations are set and marked by independent institutions called Examination Boards. Examination sheets are called papers.

attaining lower A-level grades learnt how to do the first routine part but would have difficulty with the second non-routine part. At the next meeting, however, the discussion continued with several people saying they were not sure that this really was the case. There appears to be no literature of direct relevance in this area.

Now if lower attaining students generally obtain the majority of their marks on routine questions and if, as seems likely, such questions are allocated a relatively smaller share of the total mark scheme when algebraic calculators are permitted in examinations (see Monaghan (to appear) for a discussion of this issue), then these students will find it more difficult to pass these examinations. Mathematics is already considered a difficult subject at senior school level (see Fitz-Gibbon & Vincent (1994, p.23) for UK data) and we would be extremely concerned if mathematics examinations became more difficult to pass.

Methodology

To address the question we analysed the performance of students with different A-level grades (A, B, C, D & E) in questions which have routine and non-routine parts. An A-level Examination Board provided us with the scripts from a recently marked Pure Mathematics paper. A Pure Mathematics paper was chosen, rather than a Mechanics, Statistics or Discrete Mathematics paper, since Pure Mathematics is the core for all mathematics options and because it is the area most likely to be affected by algebraic calculators (see Monaghan (to appear) for a discussion of this). Over 300 scripts from an almost equal number of male and female students who obtained scores at the boundaries of the A, B, C, D and E grades were provided.

Each question part was coded as routine or non-routine (further details below) and the marks for the question parts were adjusted in accordance with our expectations of what future marks, where routine questions were allocated a relatively smaller share of the total mark scheme, would be like. Students' scripts were then remarked.

The A-level paper and mark scheme(s)

The paper used was the first of six papers. It was one of three papers that all students following a popular modular A-level scheme had to take. There were four questions each worth 15 marks. Questions 1, 2 and 4 had four parts. Question 3 had five parts. We reproduce question 2 below as an example of the kind of question asked. The original marks are given in square brackets.

The gradient of a curve is given by $\frac{dy}{dx} = 3x^2 - 8x + 5$. The curve passes through the point (0, 3).		
(i)	Find the equation of the curve.	[4]
(ii)	Find the coordinates of the two stationary points on the curve. State, with a reason, the nature of each stationary point.	[6]
(iii)	State the range of values of k for which the curve has three distinct intersections with the line $y=k$.	[2]
(iv)	State the range of values of x for which the curve has a negative gradient. Find the x-coordinate of the point within this range where the curve is steepest.	[3]

The other questions concerned: Q1, trigonometry in context; Q3, coordinate geometry (lines, circles and ellipses); Q4, integration in context (comparison of exact and numeric methods). We classified each question part as routine (R) or non-routine (N) and obtained: Q1 (R, N, N, N); Q2 (R, R, N, N); Q3 (R, R, N, N, N); Q4 (R, R, R, N). The division of marks for routine and non-routine parts was 30 marks each. Various alternative mark schemes were developed, all adjusting the mark ratio so that routine parts of questions scored fewer marks. The agreed version left each question with 15 marks, left the mark allocation of Q1 unchanged but adjusted the others so that routine parts totalled 23 marks and non-routine parts totalled 37 marks. The parts of Q2, for example, were allocated 3, 4, 4 and 4 marks respectively.

The grade boundaries for this paper were: A, 40; B, 33; C, 27; D, 21; and E, 15. In keeping with A-level conventions A, B and E grade boundaries were determined by examiners' judgement while C and D boundaries were fixed at equal intervals between B and E grade boundaries.

Results

311 scripts (63, 63, 62, 62 and 61 at grades A, B, C, D and E respectively) were remarked to the new mark scheme. The use of statistics in this study must be carefully examined for much of the data is far from independent (consider, for example, the relationship between the total on the original mark scheme and the total on the revised mark scheme). The statistics which follow are intended to give the reader a feel for the general patterns in the data. Three aspects are examined here: the overall scores; the proportion of marks to routine and non-routine parts of questions; and factor analytic results suggesting that students follow through whole questions.

The scatter diagram, figure 1, of old and new totals illustrates the general pattern. The ranges overlap but the ranges from the original grades retain their hierarchical structure. The new totals are generally lower than the original totals. In fact of the 311 student scripts examined 297 obtained lower scores from the new mark scheme, 11 scores remained the same (3, 3, 2 and 3 from A, C, D and E grade students respectively) and three obtained higher marks (a B and a D grade student obtaining one more mark and a C grade student gaining three more marks). This indicates that increased emphasis on non-routine questions leads to a general lowering of the overall marks obtained.

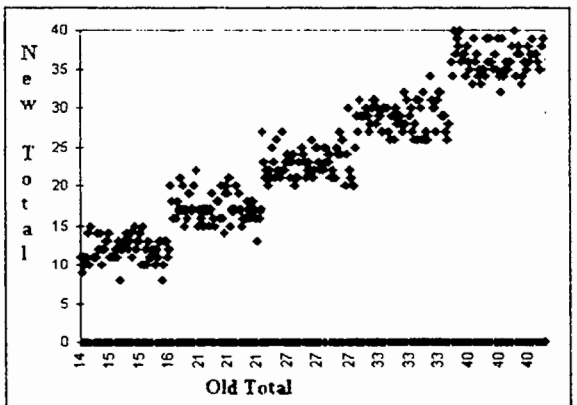


Figure 1, scatter diagram showing total scores under both mark schemes

Figure 2 displays the mean marks obtained by the groups of students at each grade level for:

- Old routine (O-R) parts (out of 30)
- Old non-routine (O-N) parts(out of 30)
- New (revised) routine (N-R) parts (out of 23)
- New non-routine (N-N) parts (out of 37)

	O-R	O-N	N-R	N-N
A	26.3	13.7	19.9	16.4
B	23.2	9.3	17.4	11.2
C	19.9	7.1	14.8	8.1
D	15.8	5.2	11.1	6.2
E	11.8	3.2	8.3	3.6

Figure 2, mean marks over grades

Note that each column decreases with decreasing grades (hardly surprising) and that mean marks obtained for routine parts of questions are consistently greater than mean marks obtained for non-routine parts of questions even though there were more marks for non-routine parts of questions in the revised mark scheme. This may be interpreted as evidence that students attaining at all pass grade gain more marks on routine parts of questions An examination of the ratios O-R:O-N and N-R:N-N is interesting. For grades A-E we get, respectively: 1.9, 2.5, 2.8, 3.0, 3.7 and 1.2, 1.6, 1.8, 1.8, 2.3. The decrease in the second list, relative to the first list, clearly mirrors the higher weighting given to non-routine parts of questions in the revised mark scheme. The increase in both lists, however, may be interpreted as evidence that higher (respectively lower) attaining students gain proportionally (to their overall mark) more (respectively less) marks on non-routine parts of questions.

Principal component analysis of both the old and the new scores yielded 6 factors with eigenvalues greater than one. In both old and new scores the question parts which loaded significantly on the factors were as follows: all parts of Q2; all parts of Q4; Q1 parts i, ii, and iii; Q3 parts i, ii, iii, and iv; Q3 parts ii, iv and v; Q1iv, Question 1i (negatively) and Q2i. The first five factors suggest an interpretation that the correlations of the scores of the parts within a question dominate the analysis, i.e. if you do well on one part of Q2, you tend to do well on all of it.

Grades and routine questions

So, do lower attaining students gain a substantial proportion of their marks on routine parts of questions, compared to higher attaining students? The results are not conclusive but they are not without interest. Before considering them we address an aspect of their surface validity. The results arise from at least two semi-arbitrary decisions: the categorization of parts of questions as routine or not (and the dichotomy implicit in this categorization); the weightings given in the revised mark scheme. These are important factors to bear in mind but it should be noted that both decisions were made after considerable debate by a group of people with considerable experience of the type of examination paper in question.

The overall lower scores obtained from the revised mark scheme and the distribution of mean marks over routine and non-routine question in both mark schemes clearly indicate that all students score substantially more marks on what we have designated routine parts of questions. The increasing ratios of routine to non-routine mean

marks over grades in both mark schemes, however, does provide evidence that lower attaining students do obtain proportionally more of their marks on routine parts of questions. Looking at the scatter diagram in figure 1, however, it would not appear that this would make a substantial difference to the overall grades (if they were still determined by the same judgement/equal interval rubric) given the small 'new total' overlap over old grades. Indeed, several experiments at reallocating grades under the revised mark scheme were conducted and none of these resulted in more than a 10% reallocation of grades. The outcomes are not recorded in this paper for fear of introducing another semi-arbitrary element.

The principal component analysis results alerted us to a possibility we had not, but should have, anticipated: that many students, at all levels of attainment, exhibit a propensity to follow a question through. This may have many bi-causal connections with other influences, including a familiarity with a specific content area – indeed a dialectic may exist between attainment and familiarity with a range of content areas. Again we must view these results with caution, due to regularity conditions implicit in the analysis and a lack of prior hypotheses, but five out of six located factors indicating such a propensity in students certainly deserves consideration.

What this and other results lead to is the need for further investigations. Two such investigations are a refinement of what is meant by the term 'routine question' and a more realistic interpretation of curriculum development vis a vis assessment development. We turn to a considerations of these now.

Problems in characterizing routine questions

A problem with this study is that it implies that routineness is located in a question rather than being a psychological construct of the relation between an individual, or group, and a question. The latter appears more valid. Indeed, the psychological relation is likely to be a socio-psychological relation. Routineness as located in a question is, however, one way to approach this study. This study's origins grew from a SCAA working party examining examination questions and we had the opportunity to explore this issue by examining completed A-level scripts without exploring classroom situations. Rather than viewing our approach as flawed we choose to view it as exploring one avenue of routineness.

There are very few readily available references to routine questions in the mathematics education literature. An important paper, which addresses a similar level/type of mathematics to this study, is Seldon, Mason & Seldon (1989). They make a distinction between problems and exercises and view, in a similar way to the above socio-psychological relation, a problem having two components: task and solver(s). They view 'cognitively non-trivial' problems as those where "the solver does not begin knowing a method of solution". and note that traditional calculus courses contain few cognitively nontrivial problems. They note that 'tasks' require skills and are divided into parts, algorithms, sample solutions and examples and that many problems are made routine in this way. This accords with our own experiences

of UK A-level mathematics classes. Seldon et al, however, do not define what they mean by 'routine'.

Boaler (1997) explored a range of issues from two schools with strikingly contrasting ethoses and teaching methods. We focus here on her analyses of pre-A-level students' performance on conceptual/procedural questions, which may be viewed as a form of the non-routine/routine division. She defines procedural questions as "those questions that could be answered by a simplistic rehearsal of a rule, method or formula." Conceptual questions were viewed, in contraposition, as questions which require "the use of some thought and rules or methods committed to memory in lessons would not be of great help". Boaler claims that conceptual questions are more difficult, for students, than procedural questions, and descriptive statistics support this view. Notwithstanding the fact that cursory summaries do not do justice to Boaler's work it can be said that performance on conceptual and procedural questions shows that similar overall results in examination performance may be obtained in different ways (ratios of success in the two types of questions) under different school ethoses and subject teaching methods.

Boaler's work raises the obvious question of the relationship between routineness and teaching methods. Nagy et al (1991) examine the relationship between test content and instructional content at the level of High School calculus. It would be in injustice to characterize their study as purely quantitative as their foci are intent of instruction, nature of materials and operations. However, their analysis of assessment activities on a six-category system, ranging from skills to situational problems, showed wide variation in teachers' emphasis, especially at the skill level. This calls attention to the importance of further studies on instruction which our study cannot contribute to.

A parallel question to the 'routine/non-routine' distinction is "What makes one exam question more difficult than another?" (Fisher-Hock et al. (1997)). This is the starting point of the Question Difficulty Project which examined UK mathematics and other subject examinations taken by 16 year old students. The project examined a model of question answering based on reading, application and communication through protocol analysis. The study notes the difficulty of both social and mathematical language, to the presentation of answers and the concomitant recording of steps (the latter two being particularly important for future work with algebraic calculators). Trials of variations in mathematics questions revealed 22 sources of difficulty, from command words to irrelevant information. The import of this for our study is the sheer number of factors impinging on what might make a question difficult (routine) or not.

This study and the work of Boaler alert us to the issue of context. Context is a term in mathematics education that is particularly difficult to define. Indeed, we believe that no definitive definition can be produced. It was the original intention of our study to examine contextual/non-contextual questions as well as routine/non-routine questions but the problems of finding real context questions and the problems of

characterizing context questions forced us to focus on the more manageable routine/non-routine distinction. We leave the question of context to further research.

Three further thoughts on routineness:

The relation between experience and the examination question is metonymic, at the level of syntax rather than meaning[2], i.e. the form of words used in a question, evokes a particular response. Arguably the most routine question at this level in the UK is, *find the equation of the tangent to __ at the point __*.

Students opinions of what are routine and non-routine questions are important, though it must not be assumed that students share a collective meaning of the term. We asked 100 students who had studied the paper we examined, in the course of their revision, to categorize the question parts, see figure 3. These responses generally show: only partial agreement with our categoization; several parts are neither generally perceived of as either routine or non-routine; greater apparent accord on routineness than on non-routineness.

	1i	1ii	1iii	1iv	2i	2ii	2iii	2iv	3i	3ii	3iii	3iv	3v	4i	4ii	4iii	4iv
total 'routine'	**98**	**81**	**47**	**4**	**99**	**97**	**32**	**40**	**95**	**87**	**71**	**47**	**49**	**93**	**69**	**87**	**70**
total 'non-routine'	**2**	**19**	**52**	**94**	**1**	**3**	**68**	**59**	**5**	**13**	**29**	**53**	**51**	**7**	**31**	**13**	**30**
Our categorization	**R**	**N**	**N**	**N**	**R**	**R**	**N**	**N**	**R**	**R**	**N**	**N**	**N**	**R**	**R**	**R**	**N**

Figure 3, student classification of routine and non-routine parts of questions

Finally we discussed routineness with the relevant mathematics officer of the Examination Board whose paper we used. They had a policy for question design: "In a standard question of four parts, the first two parts require an application of a standard algorithm, the next two parts require insight." This may be construed as a form of the routine/non-routine division and accords quite closely with our categorization in the paper considered.

Curriculum development and assessment development

This study is located in what may be termed 'traditional' examinations. Common themes of contemporary research in assessment are the purpose and validity of assessment and alternatives to traditional forms of assessment (see Niss, 1993). We applaud this but traditional forms will continue to persist in many countries and investigations into how students perform in them are important. This will be the case with the UK A-level examination (see http://www.qca.org.uk/aframe.htm and go to A/AS subject core consultation, then to Mathematics).

In the medium and long term scenarios, when algebraic calculators become commonplace in developed countries' classrooms, it is possible that the curriculum will develop to incorporate the potential offered by these calculators (see Browne & Ellis, 1997). Ideally examination questions, if not the form of examinations, will change in line with curriculum developments. In this projected setting the current

[2] Suggested by T Rowland in personal correspondence on the nature of routine questions.

study is partially misplaced as an attempt to second guess the future without taking account of parallel curriculum and assessment development. It is difficult, however, to envisage how a realistic 'future' experiment might be conducted for traditional examinations.

In regions that permit less rigid senior school examinations the potential problems exhibited by UK examinations are not necessarily present. Where teacher-generated examinations are allowed there is scope for simultaneous curriculum and assessment development. In some schools in Austria, for example, where regular use of algebraic calculators is made teacher-generated 'parallel' calculator and non-calculator examinations take place (Browne & Ellis, 1997).

Conclusion

There are many issues in this study which require further investigation: the effect of teaching and learning styles and of instructional content on students' performance in questions and question parts; an analysis of what makes an A-level question difficult regardless of apriori categorizations such as routineness; an exploration of the factors involved when students follow a question, of several parts, through.

Regardless of further research there is a need, in countries with traditional senior school examinations, to take the indicators in this study seriously lest, when algebraic calculators are allowed in examinations, that the examinations become more difficult to pass for a class of students. Although this study in not conclusive the indicators are such that we cannot ignore the equity issue present.

PUPILS' IMAGES OF TEACHERS' REPRESENTATIONS

Chris Bills and Eddie Gray
Mathematics Education Research Centre, University of Warwick
COVENTRY CV4 7AL, UK.
email: chris.bills@warwick.ac.uk and serah@warwick.ac.uk

This paper suggests that learner's procedural and conceptual knowledge of mathematics is constructed, in part, from their mental representations of teachers' external representations. These mental representations reproduce the learner's perceptual experiences and are thus referred to as images. In the first instance individual images may be quasi-sensory or language-like in format. Some pupils form a general image of the structure inherent in the external representations whilst others have specific images which embody the surface characteristics of those representations teachers use to communicate the mathematics. For such pupils the medium becomes the message.

INTRODUCTION

Teachers use a variety of representations, involving verbal, written, pictorial and concrete material presentations, to communicate their mathematics to pupils. Pupils are asked to replicate the mathematical activity through the use of these 'external' representations. Their talk, writing, drawing or actions indicate the nature of their knowledge construction. This paper considers the mental representations pupils form from these varied stimuli and seeks to answer the question "What kinds of mental representations do pupils form from the representations given and how do they make use of them?" A preliminary study in an English school for 5 to 11 year olds suggests that pupil's internal representations are initially 'image-like' in that they reproduce, in part, their previous perceptual experiences. These images may not be visual or tactile, yet, when they are evoked for mental calculation, pupils use language associated with spatial or motor aspects of the external representation. The study also suggests that the pupils' construction of mathematical meaning appears to be based on their internal representations of the teacher's external representations. It is conjectured that the way in which these internal representations 'stand-in' for the original experiences varies between pupils of different abilities. It is also conjectured that individuals' mathematical knowledge construction may be transformed from a quasi-sensory mental representation (visual, auditory, tactile) to a more general, language-like, representation over different time periods.

The paper provides a brief review of some of the literature on representations and images which has influenced and informed the study and gives some detail of the Phenomenographic methodology. The focus for the initial classroom observations and semi-structured pupil interviews has been whole number place value and addition and subtraction of two digit numbers. The implications of these findings and recent research at the University of Warwick are considered and the conclusion is drawn that a longitudinal study of teachers' and pupils' representations is needed to investigate the influence of the one upon the other.

REPRESENTATIONS AND IMAGES

Lesh, Post, & Behr (1987) suggest that five types of representation are available to mathematics teachers: world contexts, manipulatable models, pictures and diagrams, spoken language and written symbols. Such representations are not *the mathematics* but transformations of the mathematics into communicable form, a process that Kang & Kilpatrick (1992) have termed 'didactic transposition'.

The way in which pupils form mental representations from their mathematical experiences is open to debate. The Piagetian view is that mental representations are constructed by the individual. This is, in a sense, a compromise between theorists such as Fodor, who assumes an *innate* representational language of thought, and others, such as Vygotsky, who insist on the priority of public external representations that are *copied* to become the internal representations (For a fuller discussion see Olson & Campbell, 1993).

The study reported in this paper starts with the same premise as Lesh & Kelly (1997), that the learner's internal conceptual structures cannot simply be received from others but are developed from, and expressed using, external systems of representation. The assumption is also made that aspects of the internal representation can be inferred from the children's use of external representations, in this case through their language and the physical movements that they use (see also Thomas, Mulligan, & Goldin, 1996). However, no precise claims can be made about the nature of these internal representations (Kaput, 1992).

The pupil's encounter with a teacher's representations is a multi-sensory experience and the first interest of this study is the image formed from the child's perception of this experience. An image "reproduces in part some previous perceptual experience in the absence of the original sensations" (Russell, 1956) or, more generally, it is a quasi-sensory experience that is a "concrete re-presentation of sensory, perceptual, affective or other experiential states" (Richardson, 1969). In this sense an 'image' of Dienes Blocks might be the almost tangible sense of feeling them or moving them, a recalled vision of them on a desk, the recall of a teacher talking about them, a memory of thinking how to add tens and ones, or remembered pleasure in piling them higher than anyone else.

In the field of visual imagery Kosslyn (1980, 1996) has demonstrated that images can have depictive, picture-like, qualities that could not be explained by purely propositional, language-like, mental representations. His model suggests that images are short-term memory representations generated from long-term memory representations that may have a depictive or propositional form. He also proposes a 'Representational-Development hypothesis' which has strong parallels with the development from procedural to proceptual thinking in some individuals (see for example Gray & Tall, 1994). Kosslyn suggests that the type of internal representation that is predominantly used changes with age and that later types of internal representation, being more powerful, supplement and eventually overshadow older ones.

Kosslyn further suggests that visual imagery will necessarily be used in response to a question about a concrete object where the information has not been stored as part of a propositional representation or can not be deduced from propositional representations. As propositional knowledge increases and deduction becomes easier then visual imagery may be used less. Indeed, he suggests that with the increasing use of facts the image is more likely to take on a propositional format. If the child has few representations in other formats he has little choice but to use his visual image. Imagery generation may be preferred because it is quicker than propositional reasoning which requires more or different processing resources. A similar point is made by Intons-Peterson & McDaniel (1991) that the less familiar we are with a task the closer is our imagery to the original perception.

Paivio (1986) refers to 'proto-typical' mental representations of conceptual categories that are either the best example or a composite of typical features of that category. Kosslyn (1996) suggests that proto-typical images tend to be stronger because they have been accessed more often but that a particular exemplar may be stronger if it has been refreshed frequently. In the context of this paper children may form proto-typical images from the variety of teacher's representations, for example a sense that 62 is 6 tens and 2 ones without reference to columns or blocks. Others may have an image based on the most frequently used exemplar (for example 'counting-on' for addition) or most recently used exemplar (for example Dienes Blocks for addition).

METHOD

The assumption made in this exploratory study is that the images formed by pupils can not be studied in isolation from the context of the classroom or the interaction between the pupils and teachers. It is therefore regarded as essential to observe the common experiences of the learners as a basis for the analysis of their different conceptualisations. The focus is on what the teachers and pupils say and do in the lessons and how the pupils make reference to their experiences when questioned in interviews.

The research approach adopted is a naturalistic qualitative one which can be termed 'Phenomenographic' in that it is an investigation of people's understanding of phenomena and it seeks to categorise and explain the qualitatively different ways in which people think about the phenomena. The initial discovery of previously unspecified categories of thinking may be peculiar to the researcher and context but the test of their validity is in their applicability for other researchers and as a source of explanation of differences in learning outcomes (Marton,1988).

The study was conducted in a school for 5 to 11 year olds in a large middle-income village near Birmingham, UK in the period October 1997 to July 1998. One lesson per week was observed with follow-up interviews with individual children. Audio transcriptions of children's interviews were supported by detailed field notes. The teacher observed is an experienced male and his 33 pupils were those judged by their previous teachers to be the most able of the 80 Y2 pupils (6 to 7 years old) in the school. Samples of these pupils were interviewed in October, March and July.

RESULTS

The discussion of the results will draw upon the several representations used by the class teacher (Mr. K.) to demonstrate 2-digit addition. These included a Number Track, ranging from 1 to 105, a Hundred Square, Dienes Base Ten Blocks, Numeral Cards, printed with single digits, and the written algorithm. The pupils practised a representation-specific procedure with each of the materials. Though each representation is structure-oriented, in the sense used by Resnick & Ford (1981), the 'transparency' of the correspondence between the material and the structure is variable (Meira, 1998). The validity of using such a variety of representations of the same mathematics has been questioned (Dufour-Janvier, Bednarz, & Belanger, 1987) but the intention of this study was to observe the effect of the variety not to criticise it. To trace the relationship between teacher's representation and pupils' internal representations over the 9-month period two themes are examined:

- The common experience of the pupils and their individual conceptualisations from the experience.
- The medium term proto-typical representations that are formed by the pupils.

Conceptualising from Experience

A typical lesson prior to the October interviews shows one of the teacher's representations involving Dienes Blocks used in demonstration mode:

> The teacher gave Mandy two tens (In response to the question "Another way of putting it?" Mandy said "twenty") and 4 ones. When asked "How many altogether?" Mandy said "Twenty-four". A similar demonstration was used with Nina. She was given 1 ten and 2 ones and responded correctly to similar questions. The teacher requested Mandy and Nina to "Now put them together in my hands". In response the two children put the *tens in one hand* and the *ones in the other*. The teacher then requested "How many altogether?" adding "Look how easy it is to add them instead of all individual cubes".
>
> Pupils were then directed to work on two-digit addition questions presented in the textbook as pictures of Dienes Blocks with written numerals

One week later, after some further practise with the representations, 11 pupils were asked to work out one question, 24 + 53 (presented on paper), in their heads . They were then asked how they had worked it out. Though none of the pupils spontaneously mentioned visualising Dienes Blocks, Elspeth's response has a clear trace of the teacher's representation:

> Elspeth: Well you add the tens together then you add the units because its like *in one hand* you have the tens and *in the other* you have the units

Elspeth was one of only 2 pupils who gave the correct answer to this problem. The other pupil counted on from 53 using fingers to help.

Though the above example lesson involves the teacher's use of Dienes Blocks a dominant representation, previously presented to the children, had been the Hundred Square used for two-digit addition. When the children were prompted to think about either a Hundred Square or Dienes Blocks (their choice), none could mentally

manipulate them without considerable assistance. Max's responses, however, suggest that he had formed an image related to the Hundred Square:

Max If it was 24 add 11 it would be 35 ... Because it was diagonal like that. (moves head to the right and down)

Asked what 24 add 10 was he replied "34" and explained

Max because you just go down and it would just go back under there .. 'cos that would go in tens and then that would stay in the same place and the tens would just go back under there.

In each instance it sounds as if he is describing a visual image yet when requested to move down 5 squares from 24 he could not do so. A possible explanation is that he has a 'global' image (Kosslyn, 1996) of a Hundred Square that lacks the visual resolution for him to scan very far over it.

Another instance where the internal representation is a consequence of what has been attended to and extracted (see Kosslyn, 1980) is given by Neal

Neal You get 24 in your head then add on the 5 and the 3. .. 32

Here he has attended to the separate adding of tens and ones.

A second indication of a relationship between the teacher's representation and the child's conceptualisation is provided from an example obtained in March. During a lesson that focused upon adding one to a three digit number a temporary teacher summarised previous teaching in the following way:

"You have been throwing dice and all sorts of things. You also looked at rolls of raffle tickets like this... [186] (Drawn on board) What comes next? Why wasn't the 1 or the 8 changed?" A pupil replies "Because you are not adding tens or hundreds."

The teacher next wrote 199 in the middle position and again asked "What comes before? What comes after?" Going on to comment: "But that means I'm altering the tens and hundreds. That's because I can't have more than 9 in any column."

The teacher continued to talk to the group of pupils who had experienced difficulty. To illustrate "*going to*" the next number she held up 3 Numeral Cards and then *changed* the units digit card for a different one. She indicated that only the units digit changed except when the 9 is changed for a 0 and then the tens are changed as well. The children were invited to use similar cards to help them with additional exercises concerning raffle tickets. In the exercise which followed half of them made mistakes by altering the wrong digit.

The usual class teacher also makes use of these Numeral Cards to illustrate changing digits to increase a number by one, ten or a hundred. Interviews conducted during March included a question focusing upon children's conceptualisation of adding one. Fifteen children were asked: "What comes next after three hundred and seventy nine?" and then "How did you decide that?"

The results of these interviews suggested that three quarters of the children were influenced by these experiences. The separate digit reasoning of the pupils has traces

of the single-digit representation involving changing individual digits of a number. Two thirds of this 'influenced' group (9 children) obtained the correct solution:

Hazel Because um three hundred and seventy nine we have to *change* the um ten, we have to change the 7 to an 8 and we take 9 to an oh.

Elspeth Well when you add, you said that it was seventy nine, and add one on and it equals to seven, so, eighty because when you add one on to 9 it has a nought at the end.

Brian Well you just um well um you don't think about the first number, well, you don't *change* the first number but you um you have to change the second two numbers because it's *gone on to* a nine and it's like *going on* to a ten

However, one third of those who made use of separate-digit reasoning attempted to add one to the wrong digits:

John ... 389 ... I *changed* the ten to the next

Ann 4 hundred . 480 'cause if you just keep it on 3 it wouldn't be right

Christine ... 4, ... 5 hundred, and, ... fifty. Well I was thinking about, I added one more on to, the units makes ten and then I, added it on so it was 4 made 5, the hundreds, and 7 would ... uh... becomes 5 little dots

The use of words such as 'change', 'changed' and 'gone on to' suggests that these particular pupils' representations are image-like in that there are spatial allusions to the teacher's representation and an echo of the teacher's words. It is conjectured that these representation-specific words are not those that the children would use if their mental representation were simply based on counting.

A final group of children, approximately one quarter of the number interviewed, reflected a more powerful form of knowledge construction based upon a deeper conceptualisation of numeracy.

Jack(1/4) 'cause you know 79, eighty , just add a hundred to it, 380.

Clara(20/4) 'cause um I know, I know the hundred well what comes after 79 is 80

Steph(20/4) ... 380 I added one on ..... I added another one on.

Representational Consistency

The pupils were interviewed again in early July. In the period between the two interviews the children had many lessons in which adding tens by increasing the tens digit was demonstrated and practised with Dienes Blocks and Numeral Cards. Nine pupils were given verbally-presented questions requiring addition of ten in both interviews. There are striking similarities in the language they used in response. For example

	March interview: 81 add on 10	July Interview: 38 add 10
Cora	*ninety* one. You just add one, I know nine comes after 8.	I just add one onto the tens
Jack	*ninety one*. If you just go 8, 9 then you just make it into a ten and you put the 1 on, *ninety one*	... forty-eight. I know my ten times table and then I just put the eight on
Christine	well I, ... sort of ignore the units for a minute and just added like a ten on.	I would leave the un... units and just add on ten

Mandy	well cause in Mr K's we did adding on ten and I remembered cause 81 add on 10 is 91	Well we did it in Maths and he just said you add on ten so it would be the same
Brian	well I just change the tens and I just leave the units.	Well 'cause all you have to do is add the ten. You leave the units

In July questions on 2-digit addition and subtraction showed that half of the pupils used the same form of words for each, indicating reference to similar images or perhaps a single image of 2-digit manipulation. Some children's representations were very close to the teacher's written algorithm which he based on Dienes Blocks. There is evidence here of a proto-typical image being recalled and described to explain their calculation

DISCUSSION

Gray and Pitta (1996, 1997) indicate that there are qualitative differences in the images formed and used by pupils of different abilities. They suggest that some children continue to mentally reconstruct the numerical procedure rather than encapsulate it. Lower achievers tend to use pictorial and iconic representations and attempt to mentally manipulate images of these. High achievers more often have symbolic images that appear to act as thought generators and memory aids. The divide between high and low achievers is also apparent in the images they project of concrete nouns (ball, car) and abstract nouns (five, fraction). Pitta goes on to conjecture that children may have a disposition toward different kinds of mental representations which transcends arithmetical and non-arithmetical boundaries (Pitta, 1998).

In this paper it is assumed that initially the image a learner uses when thinking about a piece of mathematics is an amalgam of verbal and non-verbal information derived directly from perceptual experience of the teacher's representation. Paivio (1986) notes that such a representation of past episodic experience has been refered to as a 'memory trace'. The 'image' is subsequently augmented, however, by the learner's experiences of using both external and internal representations. Furthermore an image may no longer be evoked when automatic recall of a known fact replaces it. It would appear that some pupils seem more capable than others of constructing an efficient proto-typical image that embodies the structure inherent in the representations whilst disregarding surface characteristics. Some pupils mentally manipulate digits to decide 380 follows 379, for others it has become a known fact. Some continue to count-on for 2-digit addition, others use a mental analogue of the written algorithm and yet others count on in tens and ones.

The preliminary study in this paper provides evidence of the relationship between the teacher's representations and the pupils' images. It also suggests that the images can remain unchanged over a short time scale. Knowledge construction in arithmetic and algebra requires a cognitive shift to encapsulate active aspects of arithmetic into numerical concepts. The abstraction, which is the essence of this shift, requires that the surface characteristics of, and actions on, representations that are didactic transformations of the mathematics be eventually overshadowed. It remains to be

seen whether or not Kosslyn's representational-development hypothesis is applicable to images used for mental calculation and place value and whether mental representations formed in mathematical and non-mathematical contexts follow similar development in individuals. A longitudinal study may resolve these issues.

Problem solving processes in geometry.
Teacher students' co-operation in small groups: A dialogical approach

Raymond Bjuland, University of Bergen, Norway

This project investigates how students' mathematical understanding develops in a social context and when using mathematical language in small group dialogues. The empirical material has been collected by means of an ethnographical research method, while the analysis of group discussions and the reconstruction of the students' problem solving processes are based on a dialogical approach. The theory is presented in two categories: problem solving and cooperative learning. The participants were first term teacher trainees at a Norwegian college of education in the autumn of 1996. In this paper two episodes which illustrate some aspects of the dialogues are presented. The students have created an open atmosphere in the groups. Their reflections during the solution process and their social skills play an important role in order to develop their mathematical understanding.

1. Introduction

In this paper I will give a brief overview of my ongoing research. I am working on a doctoral thesis and the preliminary title is: *'Problem solving processes in geometry. Teacher students' co-operation in small groups: A dialogical approach'*. I focus on two perspectives.

The first perspective is to identify the students' mathematical thinking and understanding, their social skills and different affective characteristics. My research questions concerning the first perspective are: What mathematical thinking and which social skills can be identified? Which affective characteristics, like joy, frustration, willingness and endurance to work on the problems are prominent in the small group dialogue?

The second perspective is to analyse how students in three small groups develop their mathematical concepts through social interaction and to analyse how the students reflect on the solution process. Here I investigate similarities and differences in the three groups of students as far as the following research questions are concerned: How do the students reflect on the solution process? How do the students develop their understanding of mathematical concepts through the social interaction?

The empirical material is based on a group project on problem solving in geometry. The project was carried out on teacher trainees in their first term at a college of education in the autumn of 1996. One hundred and five students attended the course, and they were divided into groups of five.

The material consists of fieldnotes from observation in three randomly chosen groups of students with 8 lessons in each group, tape recordings from the same lessons and the reports of all the groups. So far, I have started a qualitative study of three groups of students where the students' dialogue in the groups and the reconstruction of the solution process for the mathematical problems are analysed.

In this paper two episodes which illustrate some aspects of the dialogues based on my first perspective are presented.

2. Theoretical Background

The theoretical material consists of five categories: problem solving, cooperative learning, affective aspects, classroom research, and social and cultural aspects. In this paper I focus on two of the categories: problem solving and cooperative learning. These areas play an important role when it comes to pupils' work on problems in a social context. The research literature is quite comprehensive for each of these areas and different traditions of research have different approaches. I therefore limit my presentation to some important studies related to my work.

2.1 Problem solving

Much attention has been paid to the concept of problem solving in the American literature from 1970 and onwards (Silver 1987; Schoenfeld 1985, 1992). In the literature the concept has been used with multiple meanings that range from 'working rote exercises' to 'doing mathematics as a professional' (Schoenfeld, 1992, p. 334). Schoenfeld defines a mathematical problem in the following way:

> 'For any student, a mathematical problem is a task (a) in which the student is interested and engaged and for which he wishes to obtain the resolution, and (b) for which the student does not have a readily accessible mathematical means by which to achieve that resolution.' (Schoenfeld, 1993 p. 71)

Schoenfeld (1993) also emphasises that it depends on the pupils' prior knowledge if a task is a real problem. He claims that most exercises in textbooks are not real problems since they often can be solved by means of a well-known algorithm. He points out that a problem must confront a student as a difficulty. It is this understanding of a mathematical problem that forms the basis of my work.

Metacognition is another concept which has played an important role in the American literature during the 80s and the 90s (Silver 1987; Schoenfeld, 1985, 1992). This concept, which is related to problem solving, also has different definitions in the literature. According to Barkatsas & Hunting (1996) there is however one definition which is generally accepted, having incorporated two important aspects of metacognition: to monitor and regulate ones own cognitive processes. The students' monitoring and reflections on the solution process are an important starting point of my analysis.

Two models are of vital importance as far as the mathematical solution process is concerned (Polya, 1945, Borgersen, 1994). The models show different stages in the problem solving process. The stages are not linear, but they must be seen as dynamic and cyclic.

Schoenfeld (1992) is concerned with developing a theoretical framework in order to analyse complex problem solving behaviour. He raises two important questions: What does it mean to think mathematically? How can we help pupils to think mathematically? His framework consists of five categories (the knowledge base, problem solving strategies, monitoring and control, system of beliefs and socialization). These categories form the basis of my analysis of the students' mathematical thinking.

Lester (1994) gives an overview of the problem solving research during the 70s, 80s and into the 90s. He is worried about the decline of research within this field in the USA. He emphasises that there is still a need for more research on problem solving instruction. Lester suggests that research should focus on the role of the teacher, the interaction between teacher-student and student-student and on groups and whole classes rather than individuals.

2.2 Cooperative Learning

The social psychologist, Kurt Lewin was concerned with cooperation in groups in the 30s and 40s. Morton Deutsch (1949) continued to work within this field. The tradition from Lewin and Deutsch went on in the 60s, 70s and 80s in the direction of more practical, methodological implications of teaching on all school levels. A method called 'Learning Together' which is developed by David and Roger Johnson at the University of Minnesota, has inspired Norwegian researchers to develop cooperative learning in Norwegian schools (Haugaløkken, 1987; Digre & Solerød, 1993).

Johnson & Johnson (1990) give some advice how cooperative learning can be used in mathematics. They suggest some basic elements in cooperative learning. These elements (positive interdependence, promotive interaction, individual accountability, interpersonal and small group skills, and group processing) have formed the basis of my analyses when it comes to the identification of the students' social skills.

In recent years, researchers of different theoretical traditions have focused on the activity of the classroom where the social interaction between teacher-student and student-student plays an important role. Cestari (1998) has used a dialogical approach in order to explore communication in the classroom. The aim of her research was to identify how mathematical concepts develop through language, in a dialogue between teacher and student (see Cestari, 1997a, 1997b). Such a dialogical approach has been the basis of my analysis of the communication in the small groups.

3. Method

Three groups of students were observed, and 8 lessons were tape-recorded in each group. I was a non-participating observer. The empirical material consists of these observations, fieldnotes and group reports. A dialogical approach has been used to interpret and analyse the conversation of the students. A dialogue is characterised by

> 'an interaction, in temporal and spatial immediacy, between two or more participants who face each other and who are intentionally conscious of, and orientated towards each other in an act of communication' (Markova & Foppa, 1990, p. 6).

This definition is the basis of my analysis of the dialogue between the students in their learning processes. I analyse each utterance by examining the turns both before and after the utterance. In this way, every single utterance is analysed and put into a wider context. An utterance is maybe caused by an earlier idea or a statement in the dialogue, and we get an idea of how the utterance is related in the context. By using this dialogical approach, I try to identify what kind of social interaction is established by the members of a group and how they verbalise their mathematical reasoning in this social context.

The transcription of the dialogue of each group session has been divided into episodes which are related to the research questions on the two perspectives. A new episode starts when there is a natural change in the conversation, maybe a pause or a new idea, a statement or a question that generates new thinking processes between the students.

Every single episode will be analysed on three levels. The first level analysis describes what the students say. The second level analysis is my interpretation of each utterance. On the third level I discuss my description and interpretation and link it to related literature. The levels are not separated, but together they will form a unit for each episode.

4. The context of the study

A new, private college of education was founded in the autumn of 1996 in Norway. The first year 105 students attended the school, and they all participated in the problem solving project on geometry in small groups. The students attended the course in their first term at the college. The students were divided into project groups of five by the administration (21 groups), and three groups were randomly selected for observation. In the project period all groups got their own room.

5. Presentation of data

In Bjuland (1998) I introduced four episodes from the dialogue of group A, which show some important aspects of my study. In this paper I present two episodes. The first episode from group A identifies some of the student reflections during the solution process, while the second episode from group B is concerned with the interaction of mathematical understanding and social skills. Both episodes are selected from the first group meeting of the groups, and the students are in the process of solving the following problem:

Choose a point P in the plane. Construct an equilateral triangle in such a way that P is an inner point and the distances from P to the sides of the triangle are 3, 5 and 7 cm respectively.

5.1 Student reflections as part of the solution process

The students of group A have only been working on the problem for some minutes. They have drawn a model, and they have constructed three circles with radius of 3, 5 and 7 cm respectively, with P as centre. This episode focuses on the students' first reflections on the solution process.

134. Unn.	So, we have to construct the tangents...
135 Roy:	Eeh...yes
136 Unn.	Haven't we done this in an earlier problem?...
137. Liv:	What?
138. Unn:	Constructed the tangents? . (6 sec) ..
	Roy and Liv study the figure of the triangle that Roy has drawn
143 Unn.	We are able to construct those tangents...aren't we?...(9 sec)..
144. Roy:	An equilateral triangle where P is an inner point and the distances from P to the sides
145.	are three, five and seven centimetre respectively...
146. Liv:	So, it is an equilateral...
147. Roy:	Yes, that's true...you have a point there...
148. Unn:	We have to read the problem...(Liv is laughing)...
149 Roy	Wait a moment...is it when all sides are equal?...
150. Liv.	Yes...
151 Roy	Yes isosceles is two sides...this isn't correct then...(Liv is laughing)...then we have to
152	give up what we have done so far .
153. Liv:	I think I write it on the blackboard (READ THE PROBLEM)
154. Roy:	But...eeh...since it is an equilateral.. then all angles must be sixty degrees...

Unn starts the episode by focusing on the construction of the tangents (134). She defines in a way the next step in the solution process. Roy has just drawn a model, and perhaps his brief response (135) suggests that he is busy studying it. The next question from Unn (136) shows that she tries to invite the other students to take part in the discussion on how to construct the tangents. It seems like the students have solved a similar problem before, and Unn is now reflecting upon whether the other problem could be helpful in the solution process. By looking back on an analogue problem, Unn tries to put the problem into a familiar context. According to the research literature (Polya, 1945; Schoenfeld, 1985; Borgersen, 1994), such a reflection could be an important problem solving strategy in order to succeed in solving a problem. The brief question from Liv (137) invites Unn to repeat the idea of constructing the tangents (138). The pause (138) could suggest that Unn has to wait for a response to her last utterance (138). Roy and Liv are still studying the figure of the triangle.

The dialogue shows that Unn repeats the idea of constructing the tangents (143). She has now repeated this idea three times (134), (138), (143). When her utterance is ended by a question (143), she is inviting a response. On the other hand, it seems as if Unn is patient and gives the other students some time (143) to reflect on her idea. Leder (1987) refers to some studies where teachers after introducing a question, only allowed students to think for one second before giving an answer.

Instead of responding to Unn's question (143), Roy breaks the silence by reading the problem once more (144), (145). We see that the students' solution process is not linear and straighforward, but it is dynamic and cyclic. When they look back and study the problem, Liv recognises that it has to be an equilateral triangle (146). The section (144) - (148) shows that the students have discovered that they missed important information the first time they read the problem. Roy reads the problem (144), Liv discovers the missed information (145), while Unn emphasises how important it is to read the problem carefully (148). We see how all the students contribute in the mathematical discussion.

Roy's question (149) may show that he is not certain of the differences between an equilateral and an isosceles triangle, but on the other hand, he does perhaps invite the group members to be aware of the characteristics of these triangles (149) - (151). Roy recognises that they have to give up what they have done so far (152), and Liv's writing on the blackboard suggests that she really wants to stress how useful it is to read a problem carefully before starting the implementation (153). It seems that the students have made a useful experience. Roy's statement (154) suggests that the group members have got a better understanding of these special triangles.

We see how the students' reflections could help them to put the problem into a familiar context. When they look back and read the problem once more, they also experience how important it is to study a problem carefully before starting work on it. The reflections may help the students to develop their understanding of an equilateral and an isosceles triangle. We also see that the students' solution process is not linear and straightforward, but dynamic and cyclic.

5.2 The interaction of mathematical understanding and social skills

In group B the students have read the problem, and they have constructed three circles with radius of 3, 5 and 7 cm respectively, with P as centre. The mathematical discussion shows that the students intend to construct tangents to the circles by constructing angles of 60 degrees and displace parallels to each of the circles. The students are not sure how to do it. Jon and Maj discuss how to continue the construction, while Eli helps Siv to construct an angle of 60 degrees.

263. Jon: Are we ready to work together again?..(inaudible talk) ..
264 Eli: If you just try without the circle once. .you just take a line ..
265. Siv: Yes...
266 Eli Then you put a dot on that line.

267. Siv: Mmm...(5 sec.). .
268. Eli: Then...
269. Siv: Yes
270. Jon: Yes, that's nice
271. Eli: Then you put the compasses...
272. Siv: We have some basic learning...
273. Jon: Yes, that's nice

Jon's question (263) suggests that he and Maj may have got an idea of how to go on with the construction, and now he is concerned with introducing the idea to the other students. On the other hand, Jon's question could also be an invitation to the rest of the group to participate in the same discussion. It seems as if Jon is aware of how important it is to work together on the problem.

Jon does not get any response to his question. Eli goes on helping Siv with the 60-degree construction (264). It is important to notice that Eli does not want Siv to focus on the circle, but just to focus on the angle. Eli has perhaps seen that doing this construction could be a difficult exercise for Siv. It seems as if Eli tries to simplify the situation for Siv by suggesting that Siv should not think of the circles but 'just take a line' (264). The brief response of Siv (265) shows that she has understood what to do, and Eli then continues the explanation (266). The dialogue shows how Eli gives help to Siv step by step, by 'just take a line' (264), then 'put a dot' (266), and Siv makes brief responses (265), (267). The pause (267) could suggest that Siv gets time to think and reflect on each step.

It is interesting to emphasise that when Eli breaks the silence (268), she does not continue the step by step instruction (271) until Siv has confirmed that she is ready (269). The social interaction between the two girls shows an open atmosphere where Eli, who operates in the role of a teacher, is really concerned with helping Siv with the angle construction. Jon (270) indicates that he has been listening to the instruction and is aware of what the two girls are doing. Instead of being impatient to continue the construction, Jon praises the work of Siv and Eli. This also suggests how the group members try to establish an open learning environment. Siv informs the other students of the 'basic learning' (272) Eli gives her. It is possible that Siv feels her lack of knowledge is an obstacle for the progress of the solution process, but the response of Jon (273) shows that she has nothing to fear. He still appreciates what the two girls do.

The dialogue shows how one student is concerned with helping another student to understand a basic construction. We see that the group members are determined to have a common starting point in the solution process so they are able to participate in the mathematical discussion. We see the students helping, listening to, respecting, and encouraging each other. This suggests that the students have developed their interpersonal and small group skills, which according to Johnson & Johnson (1990), are basic elements in cooperative learning.

6. Summary

In this paper I have given a brief overview of my research on problem solving processes in geometry as teacher students cooperate in small groups. Two episodes are presented to illustrate some aspects of the group dialogues. The episodes suggest that the students really want to participate in the mathematical discussion, and it seems as if they already at the first group meeting have created an open learning environment in the groups. The students' solution process is not linear and straightforward, but dynamic and cyclic. The dialogues show that the students' reflections on the solution process and their social skills play an important role in order to develop mathematical understanding.

CHALLENGING THE ESOTERIC: LEARNING TRANSFER AND THE CLASSROOM COMMUNITY.

Jo Boaler, Stanford University, California.

In this paper I use the perspective of situated cognition to analyse the results of paired interviews with 76 students from six schools. The students' perceptions about the individual, abstract or 'esoteric' nature of school mathematics environments are used to challenge traditional models of teaching, on the grounds that they problematise movement from the communities of practice of the classroom to those of the socially constituted World.

The Oxford Dictionary defines the esoteric as that which is accessible only to 'the initiated, not generally intelligible, private (and/or) confidential'. I intend in this paper to show that a range of features of the traditional mathematics classroom (Boaler, 1997a; 1998), contribute to the esotericism of the classroom environment and, in so doing, limit the usefulness of the mathematics that students learn. I shall draw upon data from an ongoing research project that is studying the mathematical learning of students in six schools in England (Boaler, Wiliam & Brown, 1998). The aim of the project is to monitor the impact of teaching method and ability grouping and the interaction between the two, upon students' understanding of mathematics. In a series of paired interviews with 76 students from the six schools, a range of factors emerged that the students cited as limiting their understanding. The relationship between these factors and the peculiar or esoteric nature of the mathematics classroom will be the focus of this paper.

Situated perspectives on learning (Lave, 1988; Wenger, 1998) move the focus of research away from individuals and their construction of knowledge (Lerman, 1996) towards the broader communities of practice in which people operate and the relations formed between people and systems of their environments. Lave has challenged traditional notions of 'learning transfer' as they suggest that knowledge exists, independently of the World, and may be taken from one place to another, impervious to context, situation or process of travel. But whilst the 'transfer' term may be inadequate because it suggests a view of cognition that is distinct and separate from the social world in which it is constituted, it is clear that people function in the World through a process of using, applying and adapting learned knowledge. One of the main purposes of school is to prepare students to use the knowledge they learn in the classroom, in the rest of their lives. Mathematics education appears to be particularly problematic in this regard, as a range of research projects have shown that students are unlikely to use the mathematics they learn in school in any other places (Masingala, 1993; Nunes *et al*, 1993), resorting instead to their own invented methods. I will suggest in this paper that this problem arises, in part, from the fact that mathematics teaching is often based upon narrow models of the mind and learning transfer.

Research Methods

The six schools in the study are located in five local education authorities in England. Some of the school populations are mainly White, others mainly Asian, while others include students from a wide range of ethnic and cultural backgrounds. Approximately 1000 students are being monitored as they move from year 8 to year 11. Research methods have included approximately 120 hours of lesson observations during years 8 and 9 (ages 12-13) and 38, in-depth, interviews with single-sex pairs of year 9 students. This has included 4 students each from a high, middle and low 'ability' group in the 4 schools that use ability grouping and students from a comparable range of attainment in the 2 schools that teach mathematics to mixed ability groups.

In interviews with the 76 students, students were asked, amongst other things, to describe what they liked and disliked about mathematics lessons, they were asked to describe particularly good and bad lessons, and they were asked to contrast their current experiences of mathematics lessons with experiences in previous years. In most cases the same questions were asked of students, but as interviews were open, allowing the interviewer to respond to issues that the students raised as important, some questions were not asked of all students. The conversations with students were coded, using a process of open coding (Glaser & Strauss, 1967). A number of issues emerged from the interviews that the students cited as significant to their learning of mathematics; four of the themes related to the unusual, particular or esoteric nature of mathematics classrooms in a particularly significant way and these themes will be the subject of this paper.

Research Results

Monotony

In the UK, mathematics teaching is characterised by a strict adherence to a particular scheme, with a scheme usually comprising a series of mathematics textbooks or workcards. In the six schools that are being studied, two use the SMP 11-16 scheme; one uses Oxford mathematics textbooks; one uses the SMILE workcard scheme, one uses 'Task Mathematics' textbooks, another uses NMP textbooks. All six of the schools rely upon their particular scheme to a large extent, with 90% or more of lessons requiring students to work through books or cards. In approximately 120 hours of observations, researchers observed students working through books or cards, with no practical, investigational or group work; although students did report that they were given occasional investigations or open-ended tasks each term.

At the beginning of the interviews all of the pairs of students were asked to describe their mathematics lessons. Fifty-two of the 76 students immediately communicated the lack of variety they experienced, with words like 'just' and 'every' being used in almost all of the student descriptions, for example "we just work through books every lesson". Sixty of the students were also asked if they could describe a lesson that was

particularly good, a lesson that stood out for them as being enjoyable. Twenty-two of the students simply answered that they could not. Two students laughed at the suggestion that a mathematics lesson could be *particularly* good, one said that she would have to "have a really long, hard think" and most explained that they could not think of such a lesson because mathematics lessons were "all the same". Twenty of the 22 students who said that there were no particularly good lessons were girls. Nine of the 19 students who could think of a good lesson, chose one in which they had abandoned their normal work and completed a project or investigation. Three students chose lessons when they 'didn't do any work', four students chose lessons by the same teacher who was popular, mainly because he used a variety of approaches. Only three students chose lessons involving the books or workcards that they used in the vast majority of their lessons. For example:

P: Every day we was copying off the board and just doing the next page or the next page or the next page and it gets really boring. (Paula, School A).

I: The lessons can be a bit tedious, the same thing every lesson.
J: Just the same thing for weeks on end. (Isaak & Jake, School F).

When students were asked to describe subjects that they particularly liked or that contrasted with mathematics, many of their descriptions centred upon variety:

I: For instance in English you're doing different topics, like once we did Shakespeare, now we are doing a magazine and stuff like that. (Ishak, School F)

The monotonous nature of school mathematics lessons was an important, distinguishing feature of mathematics for the students.

The Individual Learner

Grouping decisions are commonly made in UK schools, with individuals being moved into teaching groups according to perceptions of 'ability' or some other factor, with the assumption that groups are made up of separate individuals and that relationships between students have minimal impact upon their learning. Yet many of the students interviewed, cited their relations with other members of the group as the most important factor influencing their predilection towards mathematics. Four of the six schools in our study had recently changed the grouping of students from mixed ability, to 'setted' ability grouping, with students regarded to be of similar ability placed into the same groups for mathematics and taught work at particular levels. This meant a change in teacher and teaching method, as well as level of work, for the majority of students. Seventy of the students were asked whether they preferred working in mixed ability or setted groups. Fifty-one (73%) chose mixed ability groups, 19 (27%) chose setted (11 of these students came from intermediate groups, neither high nor low groups were popular with students – see also Boaler, 1997b). What was particularly significant for this analysis was that 31 of the students cited the relationships they had formed within groups as the main reason for their preference:

N: Some people, they don't like see what set they are in, they see what people are in their class. (Nigel, School R).

The impact of students' relationships with classmates, upon their attitudes towards and learning of mathematics, was a totally unexpected outcome of the research:

A: I prefer being with my class because you know everyone and you get on with more people. In this class you don't know everyone and it's difficult. (Aisha, School W).

P: I think it makes us better when we are as a form, because when we are as a form, that is you learn. Like, if you know that's like your group of people you don't feel shy to do anything in front of them or anything. (Paula, School A)

The importance of the relationships formed between students also emerged when students were asked about the way they moved forward in mathematics when they encountered a difficult problem. Forty-five out of 50 of the students asked, said that they found it more helpful to ask other students for help than the teacher. This suggests that the relations formed between students were formative at an important point in their learning, when they needed to learn something new and possibly experience cognitive conflict. Another indication of the importance of student relationships was revealed when students were asked to describe their favourite lessons. Many of the students' descriptions centred upon the rare opportunities they received to work with others:

R: I like the ones when we do experiments, when we are in a group, again. So you can work in a group, so if anybody is stuck on anything you can help people and if you are stuck you can ask people for help." (Ruby, School C)

C: Frogs (investigation) was good because everyone was involved.
A: It was fun because everyone like joined in with it and everything. We all had a go with it didn't we? (Carla & Ann, School R)

The significance students placed upon their relationships with other students is perhaps unsurprising, given that most adults would probably cite relationships with colleagues as important factors impacting upon job success and satisfaction. The formation of student relationships is however, a factor that is rarely considered by schools and absent from many analyses of learning. This seems to be particularly significant for mathematics education as the majority of mathematics classrooms in the UK place a premium upon individual work. In the six schools in our study students were allowed to talk to each other as they worked, but none of the teachers encouraged discussion as a form of mathematical thinking or learning, except for during occasional lessons. It seems significant that the social relations formed between students and the discussions they held with each other, were cited by many students as the most important feature of their learning, yet this social dimension was largely downplayed or ignored in the schools, by virtue of the mathematics approaches

employed. The students located their learning of mathematics within a broad, social domain, which is entirely consistent with situated perspectives on learning, whilst the schools regarded the students as individual learners.

Lack of Meaning

Many students regard the purpose of mathematics lessons to be the memorisation of procedures (Boaler, 1997; Schoenfeld, 1985). Teachers of mathematics introduce methods and procedures to students in the hope that students will learn and understand the procedures, as well as link the different procedures to the broader mathematical domain. But, as Mason points out, this does not always happen: 'To the teacher they are examples of some good idea, technique, principle or theorem. To students they simply are. They are not examples until they reach examplehood.' (Mason, 1989 p29). The distinction between the teachers' intention to demonstrate examples of a broader phenomenon, and the students' inclination to view the examples as facts to be learned, is revealed by the fact that teachers rarely regard mathematics as a subject which involves a lot of memorisation, whereas students often do:

F: It's because maths is different from other subjects. You have to know the facts and remember them, (...) remember the rules and stuff, remember which way goes that way and there's just a lot to remember. (Fiona, School W)

In the six schools in our study, many of the students appeared to regard mathematics as a vast collection of rules and equations that held little meaning for them:

A: It's because there are so many equations and stuff.
L: It's hard and it's boring.
JB: It's different to other subjects then?
A&L: Yeah.
L: Some of the questions are so hard and so weird. (Aisha & Lena, School W)

C: I look at it right, and it looks like Greek on the page, sometimes and it's like what? (Cheryl, School C)

Conversely, when students talked about subjects they liked, they often related their preferences to the meaning the subjects held, and their relationship with the World:

H: (In science) you learn about normal things in life, that you don't really know, like energy. Energy and stuff and acids and all that, stuff in your own homes." (Harnack, School W)

P: (In geography) you learn about people and places and you get to research and stuff – researching places, statistics from countries and things. (Peter, School H)

C: History is like learning what happened in the past and how its affected us now. (Charlie, School W)

The students talked about working hard in other subjects because they were genuinely interested in the content of the subject. Those students who were motivated in mathematics seemed only to be inspired by the prospect of gaining correct answers. None of the students' descriptions of mathematics gave any indication that the students were encouraged to appreciate the beauty of the subject, the creativity possible in the exploration of problems, or the links between mathematics and life:

DW: Do you ever work hard on something just because you are interested in it?
C: Yeah, but not in maths. (Colin, School R)

The distance between the World of school mathematics and anything that was meaningful or real for the students carries obvious implications for students' enjoyment of mathematics, but the students' perceptions also convey the esotericism of the school mathematics community within which they were required to operate. This may carry a significance that extends beyond enjoyment. Being good at mathematics in such a community, appeared to some students to involve being less than human:

M: Like we are robots. All we want to do is work like. But in the other classes it's different. (Mitch, School A)

The students' perceptions of the unrealistic nature of school mathematics may account for the fact that 30 of the 42 students asked, said that they could see no links between the mathematics of the classroom and the rest of their lives, for example:

S: It's got no connection. It's just something to make you think. (Suthida, School C)

M: I just think I am never going to see this again – you look at some things and you think – I am never going to see this again, so what is the point? (Moynur, School H)

A: You learn stuff that you think, oh God, what am I going to do with this? Why am I learning this? (Amy, School C)

Discussion and Conclusion

Situated theories posit learning as an 'aspect of changing participation in changing "communities of practice" everywhere' (Lave, 1996, p150). Students do not just learn cognitive structures and forms in mathematics classrooms, they learn to '*be*' school mathematics learners, becoming inducted into specialized and institutionalised forms of knowledge (Dowling, 1996). My concern for the students in the 6 schools in this study, as well as students in other specialised, esoteric mathematics environments, is that the students regarded the mathematics classroom as sufficiently strange and other-worldly that learning to '*be*' a mathematics learner, involved adopting the identity (Wenger, 1998) of an 'alien' (Mitch, school A) or, at the very least, someone who could abandon natural human desires to attain meaning and interact, socially, with others. In a previous in-depth study of students learning mathematics in two

schools (Boaler, 1997a; 1998; *forthcoming*), I found that students who learned mathematics in a traditional environment found it difficult using their school mathematics in non-classroom settings. They related this difficulty to the fundamental differences they perceived between the environments of school and the 'real world'. Such environmental differences impacted upon the students' use of mathematics. The results of these two studies both suggest that even when students learn a mathematical procedure in the classroom, if the community in which they learned mathematics is abstract, individualistic and generally esoteric, they will find it difficult adapting their participation in that community to any other.

In the late seventies and early eighties many schools and textbook publishers responded to the awareness that students face difficulties using school learned mathematics in their jobs and everyday lives, by placing mathematical examples 'in context'. But the use of pseudo-realistic contexts (Boaler, 1993) appears to have done little to enhance students' mathematical competencies in the 'real world'. More recently researchers have advocated the use of meaningful problems that provide the kinds of realistic constraints and affordances (Masingila, Davidenko and Prus-Wisniowska, 1996) that students are likely to meet in their lives. This is an important development, but I would like to suggest that our focus as mathematics educators should extend beyond the mathematics problems given to students, to the communities of the mathematics classrooms and the identities students develop in relation to these. In addition to providing students with the opportunity to use mathematics, and to choose, adapt and apply methods, we must recognise that students' learning is socially constituted and that students need to interact with the people and systems of their environment (Greeno & MMAP, 1998), in the mathematics classroom as they do elsewhere.

The suggestion that mathematics teaching approaches should offer varied, realistic constraints and engage students in discussion and negotiation is far from new. But the situated perspective adds another dimension to such proposals. For if learning mathematics entails more than the construction of cognitive forms, but of changing participation in a range of communities, then a classroom community that lacks the human and worldy qualities of social interaction and meaningful engagement, may 'bound' (Siskin, 1994) students' knowledge. Thus it is not the form of knowledge that is in question, but its accessibility. Classrooms that appear 'alien', esoteric or other-worldy to students may simply condemn their mathematical knowledge to nether reaches of their minds, producing learning identities that lack compatability with any other places.

ABOUT THE GENERATION OF CONDITIONALITY OF STATEMENTS AND ITS LINKS WITH PROVING

Paolo Boero
Dip. Mat. Univ. Genova

Rossella Garuti
Scuola Media "Focherini" Carpi
and IMA CNR Genova

Enrica Lemut
IMA CNR Genova

Abstract : *Conditionality of statements (i.e. the fact that statements of theorems are implicitly or explicitly shaped according to the* "if A then B" *clause) has been a peculiarity of theorems throughout the history of mathematics and of various related fields. The aim of the research partially reported in this paper is to detect and describe a set of processes of generation of conditionality in statements (PGC) that is wide enough to cover the majority of PGCs that occur in different fields of mathematics. In this paper we will describe four kinds of PGCs, along with some productive links between these PGCs and the processes of construction of proof.*

1. Introduction

In our previous investigations we considered the conditionality of statements (i.e. the fact that statements of theorems are implicitly or explicitly shaped according to the *"if A then B"* clause) as a peculiarity of theorems throughout the history of mathematics and various related fields. (see Boero and Garuti, 1994). We also considered two possible ways of generating conditionality in the geometry field, and posed the problem of finding other ways (see Boero et al, 1996). In one case (that of generation of conditionality by a "time section" in the exploration of the problem situation), a strong link was detected in students' protocols between the process of generation of conditionality (PGC) and the process of construction of proof (see Garuti et al, 1996).

The aim of the research reported in this paper is mainly to detect a sufficiently wide set of PGCs and describe them in order to cover the majority of PGCs that occur in different fields of mathematics. We will describe four kinds of PGCs; we may add that no other PGC was detected in the examined protocols (see 4.1). In addition, as part of our continuing research on the cognitive unity of theorems (see Garuti et al, 1998), we will here describe some productive links between the PGCs and the processes of construction of proof (see 4.3.).

This research may have important implications for mathematics education: it seems to be possible (through suitable tasks) to let students experience different kinds of PGCs that are important in mathematical activities concerning theorems (see 5.).

2. Background Research

Psychology has always devoted much attention, in a developmental perspective, to reasonings concerning conditionality (a landmark contribution in this direction is the early scientific production of Piaget: (see Piaget, 1924, Chapter 2). More recently, psycholinguistic research has explored in depth the acquisition of the *"if... then..."* clause, analysing its context-dependence and its links with other aspects of mental development, in particular those related to mastery of causality (see French, 1985 for a survey).

On the mathematicians' side, processes related to producing conjectures and proving theorems have for decades been a fundamental point of attention: we may quote Hadamard (1949), Polya (1962) and, recently, Thurston (1994).

Progressively, this attention has shifted from descriptions of personal experiences or very general statements to more precise hypotheses.

Recently, research in the fields of logic, foundations of mathematics and artificial intelligence have converged on the need for understanding of how humans actually produce conjectures, prove theorems and exploit the knowledge thus acquired: *"We do not yet see how humans are able to discover proofs, we cannot yet explain how they affect the human mind"* (Robinson, 1998).

Educational research too has focused on the topic of analyzing processes of production of conjecture and construction of proof, in order to create suitable learning environments and tasks to enhance them. Recent contributions in this direction are the theoretical constructs of *"transformational reasoning"* by Simon (1996) and *"transformational proof scheme"* by Harel (1998).According to Simon,

"Transformational reasoning is the physical or mental enactement of an operation or set of operations on an object or set of objects that allows one to envision the transformations that these objects undergo and the set of results of these operations. Central to transformational reasoning is the ability to consider, not a static state, but a dynamic process by which a new state or a continuum of states are generated" [...] "[...] transformational reasoning is a natural inclination of the human learner who seeks to understand and to validate mathematical ideas. The inclination, like many other inclinations [...] must be nurtured and developed [...]."

"It seems that transformational reasoning can serve several cognitive functions including, theorem generation, making of connections among mathematical ideas and validation of mathematical ideas".

In our research about historical-epistemological, cognitive and educational aspects of conjecturing and proving (see Boero & Garuti, 1994; Boero et al., 1995; Boero et al, 1996; Garuti et al, 1996; Garuti et al, 1998) conditionality of statements was a point of major concern.

Conditionality has been a crucial peculiarity of theorems throughout the history of mathematics and of all related fields. Heath (1956) points out how conditionality is always present in Euclid's "Elements" theorems, whether in explicit terms or in implicit terms. In the latter case, the statement can be reformulated in order to make the *"if A, then B"* clause explicit (for instance in the case of Pythagoras' well known theorem, the usual statement *"in a rectangular triangle, the square built up on the hypotenuse... etc"* can be reformulated as follows: *"If a triangle is rectangular, then..."*). We may remark that, today, statements of theorems do not differ from Euclid's as concerns conditionality. After Hilbert's revolution the epistemological perspective has changed considerably as concerns the nature of truth expressed by the statement of a theorem, the nature of postulates, the requirements of proof. However, the formulation of a statement in (explicitly or implicitly) conditional terms remains a peculiarity of theorems. Moreover, when we consider the conditionality of statements we do not limit ourselves to the textual property of statements. Its substantial importance in mathematical activities concerning theorems lies in the fact that the proving process keeps the *"if A then B"* clause as a crucial orienting reference for validating the statement. The difficulty is to match this evidence about the importance of the conditionality of statements from the epistemological point of view with a cognitive analysis of how it is generated during mathematical activity of conjecturing and how it is linked to the proving process.

Our research work on some PGCs detected in students' protocols (see Boero et al, 1996) pointed out some peculiarities of those processes, related to management

of virtual time and space variables in students' "inner visual space" (Vygotskij, 1978, Chap. I). In particular, we described in the following way a particular kind of PGC detected in students' protocols:

"the conditionality of the statement can be the product of a dynamic exploration of the problem situation during which the identification of a special regularity leads to a temporal section of the exploration process that will be subsequently detached from it and then "crystallize" from a logic point of view ("if..., then...)".

We also found some links with the proving process(see Garuti et al, 1996).

Our next research work was aimed at finding other PGCs and determining more precise links between PGCs and proving processes. In this paper we will describe some kinds of *"transformational reasonings"* (Simon, 1996) that intervene in producing and proving conjectures (see 4.1.).

3. Method

Following occasional hints, a systematic investigation was performed on students' protocols concerning conjecturing and proving. We considered:

- beginners' written protocols (grades from V to VIII), in order to explore some basic PGCs not yet influenced by known patterns and complex analytic techniques; these protocols were used as sources of ideas about possible generative processes;
- undergraduate mathematics students' protocols, in order to validate the definitions deriving from preceding analyses and make them more precise and content-independent. Most were written protocols but some recorded dialogues with the teacher were also considered. Students were attending mathematics education courses on problem solving in the last four years.

A common production condition for all protocols was that in all cases the educational setting should stimulate students to write or orally express their thinking processes. In most cases this was done as real-time wording of their intuitions and endeavors, in others as on the spot reports about their reasoning. In the case of undergraduate students, this was done by systematically exploiting their written (or possibly recorded oral) solutions as anonymous texts to be discussed by their fellows, without any evaluation about correctness. In this way students recognized exhaustive wording of processes as a necessity in order to get interesting material for discussion. In the case of beginners, writing down reasoning was a part of the didactical contract in the classes engaged in Genoa Group Projects for primary and junior high school.

The fields of mathematics involved were:

- elementary plane and space geometry, arithmetic (properties of natural numbers) and elementary algebra for VII-VIII graders: five tasks with more than 20 protocols for each task;
- mathematical analysis, euclidean geometry, algebra and theory of numbers for undergraduate mathematics: nine tasks, more than ten protocols for each task.

The analysis of students' protocols was performed following these steps:

- first, detecting and trying to describe PGCs and their links with proving processes as they arose in single, clear protocols (see later for some examples);
- then, challenging the description through the comparison with other protocols (possibly by different students and in different fields of mathematics) that presented similarities as concerns PGCs and their links with proving; and

subsequently improving the description in order to make it content-independent;

- finally, trying to establish a common style of description among the different PGCs that had been detected, trying to get an overall vision of them and show any possible relationships, symmetries, etc. among them.

The reported results represent a final summary of what emerged during these analyses. They are quite complete as concerns the four detected PGCs, they are far from being exhaustive as concerns links with the proving processes.

4. Some Results

4.1. Processes of generation of conditionality

In order to make the presentation easier to understand, examples will precede definitions. The examples will be given related to different fields of mathematics so that "invariant" elements are highlighted. The following kinds of PGCs were detected in the students' protocols, covering the different fields of mathematics.

PGC1.

For some examples concerning VIII graders, see Boero et al, 1996. Here are some others.

EX.1.1.: geometry field, undergraduate students. Task: *"In the euclidean environment, formulate and demonstrate, a conjecture concerning the possible existence of a minimum area among the areas of all triangles obtained by closing an angle with straight lines passing through a point on the bisecting line of the angle itself".*

One student draws the configuration angle/bisecting line/point on the bisecting line and then draws several straight lines passing through that point. Initially, these are sharply very inclined with respect to the bisecting line, and on the same side; then come other lines close to the perpendicular line and finally lines on the other side that strongly diverge from the perpendicular line. Afterwards, the student states: *"It seems to me that the areas of the triangles decrease as they approach the position ... the perpendicular line ... I see triangles growing and growing on one side without any balance on the other side." (She shades in one large triangle emerging from the isosceles triangle and the corresponding smaller incoming triangle. Perhaps the conjecture is: if the passing through line is perpendicular to the bisecting line, the area gets its minimum".*

EX.1.2.: algebra, undergraduate students. Task: *"Let ax+by be an expression where a and b are positive integers, x and y integers; find out under what conditions on a and b the expression ax+by can assume its minimum positive integer value.".*

A student writes: *"Let me try: a=4 and b=6: 4*1+6*1=10; 4*2+6*1=14; 4*2+6*2=20. The results are increasing; but...I can also use negative values for x and y: for instance, 4*2+6(-1)=2; 4*2+6(-2)=-4; 4*3 + 6(-2)=0; 4(-4)+6*3=2. It seems to me that the results can not go lower than 2. I try with 3 and 5: 3*1+5(-1)=-2; 3*2+5(-1)=1. I reached 1, which is the minimum positive integer value. It is easy now, perhaps because 3 and 5 do not have any common divisor (but 1).*

The conjecture: if a and b do not have any common divisor (but 1), the minimum value is 1."

Generally speaking, a PGC1 can be described as a time section in a *dynamic exploration* of the problem situation: during the exploration one identifies a configuration inside which B happens, then the analysis of that configuration suggests the condition A, hence *"if A, then B".*

PGC2.

EX. 2.1.: the study reported in Boero & Garuti (1994) concerned VII-graders who had to express in general geometric terms "Thales' discovery" (i.e. the anecdote concerning the determination of the height of a pyramid by exploiting the proportionality between the heights of objects and the lengths of the shadows they cast).

BEST COPY AVAILABLE

The following kind of reasoning was identified in 3 out of the 34 students: *"The length of the shadows is proportional to the height of the sticks*; sunrays *are parallel. But straight lines might not be parallel. If the straight lines are parallel, the lengths of the segments cut by another two lines will be proportional"*

EX. 2.2.: undergraduate students. Task: *"Can we always represent f(x)=sin(Ax+B) by finite linear combinations of products of integer powers of sinx and cosx?"*

"It seems so, by applying the trigonometric formulas. For instance, if A=2 and B=3, I can write: sin(2x+3)= sin2x.cos3+cos2x.sin3= 2sinxcosx.cos3 +(cos^{2}x-sin^{2}x).sin3.

But A might be π also: we cannot write sinπx in that way. And also A=1/2 does not work: we would need roots. On he contrary, if A is an integer, it works".

Generally speaking, a PGC2 can be described as: noticing a regularity B in a given situation, then identifying, by exploration performed through a *transformation* of the situation, a condition A, present in the original situation, such that B may fail to happen if A is not satisfied.

PGC3.

EX. 3.1.: algebra, undergraduate students. Task: *"Generalize the following property: the sum of two consecutive odd numbers is divisible by 4". Demonstrate the property found".*

"Let me consider 3 consecutive odd numbers, e.g. 3+5+7=15 or 5+7+9=21. It seems to me that only divisibility by 3, which is the number of addenda, emerges. I shall try with 4 consecutive odd numbers: 3+5+7+9=24; 5+7+9+11=32; 1+3+5+7=16. What do 24, 32,16 have in common? They are divisible by 8. I shall try with 6 consecutive odd numbers: 1+3+5+7+9+11=36; 3+5+7+9+11+13=48. Both sums 36 and 48 are divisible by 12.

If there are 4, the sum is divisible by 8. If there are 6, sum divisible by 12. If there are 2, we have seen that the sum is divisible by 4. It seems to me that what is emerging is that the sum of an even number of consecutive (odd) numbers is divisible by its double, by the double of the numbers of addends I am adding.

EX. 3.2.: V-graders (cf. Bartolini Bussi et al., to appear). Task: *"Ascertain what happens when the number of cog-wheels, engaged and arranged in a ring configuration, increases, having already found that three can not turn all together, while four do".*

"(One pupil draws 5 wheels and indicates the rotation direction with arrows) *"5 wheels can not turn*; (draws 6 wheels) *6 can turn* (draws 7 wheels). *It could turn with 4 but with 3 it could not. So, if the numbers of cog-wheels is even, they can turn. If it is odd, they can not".*

Generally speaking, a PGC3 can be described as a 'synthesis and generalisation' process starting with an *exploration* of a meaningful sample of conveniently *generated* examples.

PGC4.

EX. 4. 1.: (undergraduate students) In the task presented in EX. 3.1., a student begins considering 8 consecutive odd numbers and finds out that the sum is divisible by 16. He writes: *"It may be that the double of how many numbers I am adding is influential in someway, but it might depend on the fact that 8 is a power of 2".* He considers ten consecutive odd numbers, and finds out that their sum is divisible by 20. *He concludes conjecturing that: "If n is even, the sum of n consecutive odd numbers is divisible by 2n".*

EX.4.2.: (V graders) In the task presented in EX.3.2. a student acts as follows: He draws 6 engaged cog-wheels, and marks each of them with a clockwise or counter-clockwise arrow alternatively. *"With 6 wheels, it all turns well, but if I put one more* (he draws a small wheel between one pair of wheels and draws two arrows beside it (one clockwise and the other counter-clockwise) very close to the two wheels it is contacting; *this wheel prevents the others from turning. It is an odd number. It is like with 5 wheels with respect to 4. If they are odd, they can not turn."*

Generally speaking, a PGC4 consists in a reasoning which can be described as follows: the regularity found in a particular *generated* case can put into action "expansive" research of a "general rule" whose particular starting case was an

example; during research, new cases can be generated (cf. Pierce's "abduction" ; see Arzarello et al. 1998)

4.2. Some Comments

We may observe that PGC1 and PGC2 are, to some extent, dual processes. Indeed, in the first case mental exploration (centered on B) leads to detection of A as an arrival point, while in the second case the starting point is the regularity, and then dynamic exploration starts (by transforming the situation where the regularity occurs). We may wonder whether there is a common underlying cognitive background. N. Douek (personal communication) suggests that in PGC1, exploration leads to the "cause" that originates B, while in PGC2, exploration reveals the "cause", whose lack may make B fail to occur. In this way links emerge with the hypothesis of "causality" as one of the possible backgrounds of conditionality (cf French, 1985).

PGC3 and PGC4 too are, to some extent, dual processes: in PGC3 extensive exploration leads to intensive insight; in PGC4 intensive exploration leads to a local insight, which in turn gives rise to extensive exploration that may confirm it and make it more exhaustive. N. Douek (personal communication) suggests that PGC3 implies the passage from the analytical description of several cases to an expression able to synthetize (some of) them while PGC4 involves the passage from a more or less synthetising expression of a particular case to a more general one suitable for wider application. In both cases, the passage from one representation to another seems to play a major role.

Bearing in mind preceding descriptions of PGCs and comments, we may expect that apriori analysis of the task (formulation and content) could to some extent predict the PGCs that will be produced by students. In particular, in a task aimed at discovering a singularity, we may expect that most PGCs will be of the PGC1 and PGC2 type, while in a "generalization" task most PGCs should be of the PGC3 and PGC4 types. The examined protocols confirm this prediction. For instance, in the case of the "generalizing and proving" task of EX. 3.1 and EX.4.1. only PGC3 and PGC4 were detected in the 43 protocols examined (with the exception of one student who produced his conjecture through a PGC2-type exploration).

In the examples considered, students produce only one PGC; in general, we observed that in many cases the same student tries and abandons different PGCs before getting a conjecture he/she finds satisfactory. But in the case of the undergraduate students we also noticed quite frequently that a generation of conditionality can be reached through a sequence of coordinated steps, each of which bears a peculiar PGC (possibly different from those found in the other steps).

4.3. Some links between PGCs and construction of proof

We have detected an important link between the PGCs described in the preceding subsection and students' proving processes under the same task: *frequently the same mental exploration which leads to the conjecture is re-started by the student with entirely different functions during their proving process.*

For example, as concerns PGC1, exploration can move from a support to the selection and the specification of the conjecture (in the conjecturing phase), to a support for the implementation of a logical connection (in the proving phase): some

examples are reported in Garuti et al (1996). Here is reported the beginning of the proof produced by the student of EX. 1.1.:

"I draw again the situation in a careful way. (she draws angle, bisecting line and the perpedicular passing by the chosen point, then another straight line passing through this point. She shadows the outcoming and incoming triangles) *I see that the outcoming triangle is much bigger that the incoming triangle. But why is it bigger? Let us see. The area is base multiplied by height* (she draws the heigths coming out from the vertex lying on the bisecting line). *Yes, the heigths are equal and the bases are very different (etc.) "* (underlying puts into evidence the point where the resumed exploration of the situation becomes explicitly functional to proving).

As concerns PGC4: during the proving process, some students re-start from the particular case in which the regularity was detected, and then extend to other cases in order to find appropriate links between the hypotheses and the thesis; the function of the exploration changes from *"what regularity this is a case of "* to *"what link this is a case of"*. An example is the proof by the student of EX. 4.1.:

"We start again from 8 consecutive odd numbers; we try to write in that case the formula;: 2K+1+2K+3+2K+5+...+2K+15=(2K).8 + 1+3+5+...+15. I see that I obtain the sum of 8 consecutive odd numbers; also this sum must be divisible by 16; but this fact remind me that in the sum of 15 numbers there is the factor 16... No, here we do not have 15 numbers; but we have all the odd numbers from 1 to 15. I have to find the formula that fits this case. I am remembering perhaps that it is n^2 *. Let us check. With 2 odds it is 4. With 4 odds it is 1+3+5+7=16. It is OK. The square of 4. But how can the square of 8 be divisible by 16? Yes, it is. 64=16x4. Let us check if it is true in general . n is even. Hence* $n^2=(2m)^2$ *is divisible by 2n".*

(underlining puts into evidence "abduction" phases during the proving process).

Some students who had produced conditionality through a PGC3 also revealed this kind of behaviour in the same task; and (on the contrary) some students who had produced conditionality through a PGC4 realized, during the proving process, an exploration similar to that exemplified in EX. 3.2. This seems to confirm the existence of deep links between PGC3 and PGC4 (as dual processes).

5. Possible research developments and educational implications

The content of the preceding subsection raises interesting research problems about the links between the conjecturing process and the proving process in the perspective of the cognitive unity of theorems (see Garuti et al, 1998). In general, the exploration underlying a PGC and the exploration performed during the proving process are very similar in "nature" but differ in "function". What is the precise meaning of these two words? Another interesting research development concerns modeling of the possible links between PGCs and proof construction processes, especially when the task *"Demonstrate that.."* requires the appropriation of a conjecture produced by others and then the production of new lemmas through PGCs, with related demonstrations (a typical situation in advanced mathematics).

And, naturally, the problem of identifying possible PGCs that differ from the four described in this paper still remains open.

Some connections with results produced by other researchers emerge from our analyses. We would particularly point out the need for in depth comparison of PGC2 and PGC4, and Balacheff's "crucial experiment" and "generic example", although the two criteria of analysis, ("cognitive" in our case, and "epistemological" in the case of Balacheff) are different. Emerging connections bear deep, potential points of contact between epistemological and cognitive analyses.

As to the educational implications of this study, preceding analyses can be exploited to find appropriate tasks for students in different grades, so as to allow

them to experience processes which seem to be relevant in mathematical activities concerning theorems. Indeed, we have remarked that the formulation and content of the task may influence students' PGCs (see 4.2.). Naturally, the interest lying in these considerations is related to an hypothesis of "educability" of the capacity to produce PGCs by experiencing them (cf. Simon, quotation in Section 2.).

Working with pupils' meanings: changing practices among teachers enrolled on an in-service course in South Africa

Karin Brodie
Department of Education, Wits University

This paper reports on the second-phase of a research project which investigates the changing practices of teachers on an in-service course at Wits University in South Africa. The paper looks at the teachers' mediational strategies, in particular how teachers elicit and work with pupils' mathematical meanings. It focuses in detail on the teachers' use of groupwork, their responses to pupils' ideas, and their use of questioning, highlighting some of the difficulties they experience. It reflects on the role of the courses in facilitating teachers changing practices.

Introduction

In this paper, I will present some interim results from an ongoing research study which focuses on the changing practices of mathematics teachers who are studying on an in-service course, the Further Diploma in Education Programme (FDE), at Wits University. The main aim of the study is to investigate the influence of the FDE programme on teachers' practices. This paper will focus on some of the teachers' mediational strategies, in particular those that might be seen to be aspects of a learner-centred approach, and will reflect on the ways in which the FDE programme influences teachers' development of more learner-centred practices.

The FDE Programme

The FDE Programme is a two-year, mixed mode (distance and residential), in-service programme for mathematics, science and English teachers, and school managers. Students enter the programme with a 3-year, post-matric, teaching qualification. Successful completion of this course gives equivalence to a 4-year qualification. An aim of the course is to enable teachers to improve their qualifications through undertaking studies which are of direct relevance to their teaching. The programme's goals are to contribute towards improving teaching and learning in South Africa through: extending teachers' educational, subject and subject teaching knowledge; developing teachers as competent, reflective professionals; and enabling teachers to work with curriculum innovations (among others). The programme started in 1996, and about 130-150 teachers register each year.

Mathematics teachers on the FDE programme take five courses over a period of two years. Three of these are mathematics courses, two of which focus on mathematical content and one on teaching approaches The other two courses are general Education courses, which all FDE students take as core courses.

In the next section, I will give an overview of two of the courses. "*Theory and Practice of Mathematics Teaching*" (Dikgomo et al, 1996) was developed and is taught by a team of mathematics educators. Its focus is on the teaching and learning of mathematics from theoretical and practical perspectives. "*Curriculum and Classrooms*" (Brodie and Purdon, 1996) is a core education course which was developed by two members of the Wits Education Department and is taught by a team of education tutors, led by myself. It focuses on generic issues (across subjects) relating to curriculum, curriculum innovation, and teaching and learning.

The FDE courses

A broad overview of the course materials for these two courses shows that both take a broadly social-constructivist view of learning. They attempt to counter behaviourist approaches to learning and present some of the ideas of Piaget and Vygotsky (to different extents) as alternate ways of understanding learning.

"Theory and Practice of Mathematics Teaching" deals explicitly with classroom management, and with groupwork under the title of "co-operative learning". The section on classroom management attempts to develop a sense of a classroom culture where the learners are disciplined and take responsibility for their own learning, and where mathematical thinking is developed. It includes a section on classroom questioning, pointing out the benefits of open questions and giving examples of them. Much practical advice is given to teachers on how to develop a culture of mathematical thinking and learning in the classroom. The section on co-operative learning provides a short justification for co-operative learning based on social-constructivist theories, and then gives different ways in which teachers might use and develop groupwork and co-operative learning in the classroom. Other issues dealt with in the course are the use of resources (blackboard, OHP, textbooks, "manipulatives", calculators, computer software); problem-solving and investigations; and professionalism.

"Curriculum and Classrooms" deals with the notion of learner-centred teaching as teachers eliciting, listening to and attempting to understand pupils' meanings and building on these to develop pupils' knowledge. This notion is developed out of Piagetian and Vygotskian theories, and examples of teachers engaging and not engaging with pupils' meanings are discussed. Bruner's notion of scaffolding is developed in detail, whereby teachers listen to and work with pupils' ideas and provide guidance and support to help pupils develop their ideas. Questions are seen as part of scaffolding and the kinds of questions and responses that might be useful are discussed. Many examples are given and teachers are asked to identify examples of good and poor scaffolding in their own lessons. Both courses emphasise the role of the teacher in learner-centred classrooms The teacher is seen as mediator of knowledge and as crucial to the development of mathematical meaning on the part of pupils. Both courses also work substantially from transcripts and case studies, and students have reported that these are very helpful as models for their own teaching (Adler, Lelliott and Reed et al, 1998, pg 156-157).

The FDE teaching staff attempt, very consciously, to model teaching approaches that we think are useful. During the residential session, students work in groups for much of the time, particularly where there are classes with large numbers of students. However, lectures are also given, even in classes of up to 200 students. We structure tasks carefully, ask open-ended questions and attempt to give time for students' interests, difficulties and concerns to be taken up in tutorial sessions. Mathematics content is taught in investigative and problem-solving ways, in disciplined and relaxed environments.

The research

The research project is a three-year study of a sample of mathematics, science and English teachers who enrolled on the FDE programme in 1996, the first year in which we ran the programme. Data was collected by a team of researchers. We visited the teachers in their classrooms in August 1996, 1997 and 1998. The 1996 visit provided for baseline data (Adler, Lelliott and Slonimsky et al 1997) and the 1997 visit focussed on changes and continuities in

teachers' practices, in the context of their schools (Adler, Lelliott and Reed et al, 1998). This paper focuses on data from the 1997 analysis.

The school contexts in which the teachers work vary considerably, both materially and in relation to the culture and atmosphere established for teaching and learning. Some schools, predominantly those in urban areas, are relatively well-off, with electricity, laboratories, and functional classrooms, where there is usually enough space for the number of pupils. Most rural schools do not have electricity nor running water, and many classrooms are without windows, floors or ceilings. In many cases there is not enough space to accommodate the number of pupils. Some schools function well, with clear time-tables and procedures. At others, pupils and teachers are not always in class, with much late-coming and absenteeism. During the data-collection week at least two days of teaching were lost in some schools, due to cultural events, teacher- and civil-service strikes.

There are ten mathematics teachers in the sample[1], five primary and five secondary teachers Observations of 3 lessons of each teacher were made according to a structured observation schedule, and narratives of each lesson were written. A video was taken of each teacher teaching one lesson. Each teacher was interviewed at length about her/his teaching and about conditions in the school. Principals in each school were also interviewed. Pupils' books were examined in order to get a sense of coverage throughout the year, and to see whether written work differed from oral work in any way. Tests and/or exams were also looked at in order to investigate formal assessment strategies.

The data for each teacher was analysed qualitatively by different members of the research team according to a set of categories developed by the team. An overview was then written looking across the teachers[2]. This paper will report on part of the overview, looking across the teachers through the category of mediation, with subcategories: groupwork, working with pupil responses and questioning.

A shift to groupwork

Perhaps most significant among the mathematics teachers in 1997 was a shift to groupwork. In 1996 only one teacher included organised group activities in her lessons, and three others had pupils seated in rows but working in pairs[3]. In 1997, seven teachers explicitly organised groupwork and nine teachers, in at least one of the observed lessons, had learners either seated in groups and working together, or seated in rows but working in pairs. Only one teacher was coded as having pupils work individually in all three lessons. All teachers expressed positive attitudes towards groupwork, though they varied in whether and how groupwork is implementable in their classrooms.

Ways in which groupwork is structured and mediated varied across levels and teachers The

[1] See Adler, Lelliott and Slonimsky (1997) et al for details about how the sample was chosen

[2] The mathematics data was analysed by myself, Mamokgethi Setati, Phillip Dikgomo and Jill Adler An overview analysis was then written by myself and Jill Adler

[3] Interestingly, the one teacher who used groupwork last year, did not do so this year. She had lost a lot of school time, and was working to try to catch up with her Grade 11 and 12 classes

576

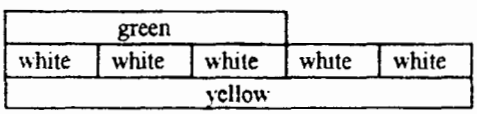
secondary teachers who used groupwork did so with standard textbook tasks. In one case these were written up on the board, and in the second a worksheet was distributed, one to each group. The groups were relatively small, with four to six pupils in a group. In most cases, the pupils interacted substantially with each other in the groups, there was a "buzz" in the classroom, and most pupils seemed to be on task. The two teachers circulated and interacted with the groups, clarifying instructions and helping with difficulties. One of these teachers had 68 Grade 10 pupils in a classroom built for 40. She was able to organise the class very quickly into groups of four, indicating that pupils were used to groupwork. Her pupils involved themselves in the task set, she circulated among them (not easy with so little space), and in so-doing demonstrated that successful organisation of group work is not necessarily a function of class size. In the smaller class, pupils from each group wrote their solutions on the board, these were compared and discussed, and mistakes corrected.

Groupwork in the primary school was very different from the secondary school. Groups were more explicitly organised and structured, pupils generally sat in their groups most of the time, and there were usually at least 6 pupils in a group, sometimes more, depending on the size of the class. The primary teachers' ways of working with groups also differed from the secondary teachers, and were worrying in some ways.

In one lesson, a Grade 3 teacher called one group up at a time to her desk to demonstrate measuring the table. While she worked with each group, the rest of the class sat unoccupied. She only managed to work with two groups during the lesson. So, although she explicitly organised the class into groups, her method of working with the groups ensured that there was very little pupil participation or pupil-pupil interaction in the lesson, and that very few pupils actually spent time on the task. In this teacher's second lesson, each group worked on a different pen and paper task (standard algorithmic tasks such as long subtraction, fractions etc). There was absolute silence while only one pupil in each group worked on the task. The children who were not working watched the child who was. This means that the benefits of interaction were not achieved, while the benefits of individual work, ie each child getting a chance to work on a task were diminished. Report backs from these groups involved a pupil from each group writing up the solutions on the board. Some were repeated by the teacher and mistakes were corrected. No comparisons were possible because the task done by each group was different. Moreover, each group's work was rubbed off before the next one began. So most pupils had no record of the work in their own group nor the work of the other groups.

A second primary teacher (Grade 7) also had pupils sitting in groups with very little working together and interaction. At times pupils interacted with each other covertly, by whispering, which suggests that pupil-pupil interaction is frowned on in this class. The pupils had cuisenaire rods, and there were enough for each pupil, but many did not do anything with them. Thus again, many pupils were not on task.

The other three primary teachers who used groupwork enabled more interaction between pupils in the groups. Resources were shared between pupils, and they worked together. However, even in these classes, it is not clear that all pupils benefitted. In one grade 7 class, where about 40 pupils were divided into 6 groups, it was clear to the observer that at most half of each group was on task and contributing at any time. The teacher knew this, but her only way of mediating in the classroom was to tell everyone to contribute and listen to each other (advice which comes from the FDE courses) This advice was not very helpful for pupils who did not know how to contribute or how to allow others to contribute



In looking across primary and secondary teachers, the following features of groupwork are evident. Primary teachers have clearly organised groups who sit together. They tend to give less standard tasks, using resources brought in from outside the classroom (measuring tape, cuisenaire rods etc...). None of the primary teachers intervened to deal with the mathematics while the pupils were working. They preferred to wait for report-back sessions to do this, ie they are concerned with maintaining a particular form of organisation of groupwork, rather than with the substance of what happens in the groups. In the following section, I will show that they struggled to deal with unexpected responses from pupils which makes it difficult to mediate effectively in groups. The secondary teachers on the other hand, mediate the work in the groups more actively. They seem more able to deal with pupils' productions, probably because they have not attempted to vary the tasks substantially, and because they are more confident mathematically. However, even in secondary classrooms, there are questions about actual pupil-participation in groups. In the case of one of the secondary teachers (Grade 12), the observer noted that the teacher did not know how to enable girls to participate, even though she was aware of less participation from girls.

The above analysis suggests that although most of the teachers are taking up the use of groupwork from the courses, they may be doing so without attention to the details of how to work with groups, particularly how to intervene mathematically. Moreover, none of the teachers spoke explicitly to pupils about how to work in groups during the observations, and it is not evident that they had done so previous to our visits. None of the techniques for co-operative learning discussed in *"Theory and Practice of Mathematics Teaching"* (eg jigsaw, think-pair-share or pairs-check) were evident in any of these lessons. This suggests that teacher education programmes need to think carefully about how to work with teachers so that they don't only "do groupwork", but use it well. We need to identify difficulties and concerns that teachers have, such as those described above, and deal with them explicitly in our courses.

Working with pupils' meanings

In the above section we have seen teachers who did not attempt to work with the pupils' constructions, for example the Grade 3 teacher in the report-back session. Other teachers however, did attempt at times to mediate and work with pupils' ideas during report-backs or in whole class discussions. Here too, they experienced difficulties as the following example will show.

The teacher is working in Grade 7 with cuisenaire rods. She has structured the activity by getting the pupils to make up a bigger rod with a number of smaller rods. After one has been made the pupils chant: "two yellow rods make one orange rod". The teacher then asks what fraction the yellow rod is of the orange rod and the answer "half" is given. Then, working in their groups, the pupils make up other combinations of rods and the teacher asks some pupils to show the class Here is an example which was discussed in the whole class:

The pupil who constructed these rods said. "one green and two whites makes one yellow", and "the green is a "third" because "it takes three whites". This pupil demonstrated a particular understanding of the task, ie put any combinations of smaller rods together to make a bigger rod, they do not necessarily have to be equal. He also displayed some confusion relating to naming

fractions, ie he called the green rod a "third", rather than the white. The teacher reinforced his contribution with "very good" and asked the other pupils what he had said. Here she got: "The green rod is a third because three white rods are equal to the green rod", which emphasises the conceptual confusion. At this point the teacher tried to work with the pupils' meanings, by saying that the "green rod is now the whole" and the "three whites stands for the parts". In fact she reversed their meaning in order to bring them in line with her understanding. Then she concluded with "one whole and three parts, therefore this is a third" (and it is not publicly clear what 'this' is - but given the prior articulations, pupils could think that "this" refers to the green).

In this lesson, the use of concrete apparatus in the groups did not enable the development of mathematical concepts because the teacher's way of talking about the part-whole relationships obscures the fraction concept. Moreover, she did not explain the prior conceptual link: between the number of small rods that make a big rod, and the name of one of the small parts. Given some of the pupils' mistakes, this link was not understood by the pupils. Even more worrying is that the mathematics that is spoken about is incorrect. The teacher and some pupils might well understand that it is the whites that are the thirds of the green and not the other way round, but this is not explicitly dealt with. An incorrect way of naming mathematical relationships in English remains in the public domain, and was moreover confirmed by the teacher.

Although this teacher manages to achieve some pupil participation in the class, she does not know how to deal with offerings that she does not expect, for example the fact that one green and two whites make a yellow. She does not take this opportunity to work with the notion of fractions as equal parts of a whole. This teacher cannot utilise pupils' offerings to deal with aspects of the concept that they are struggling with. The teacher confirmed in her interview that she was aware of a problem with this example, and had tried to turn or shift the expression around, but nowhere was there any clear rearticulation of appropriate and relative wholes and parts.

Similar examples were observed in at least three other classrooms, two primary and one secondary (Adler, Lelliott and Reed et al, 1998). In all cases, the teacher struggled to know what to do with pupils' ideas and meanings. The *"Curriculum and Classrooms"* course explicitly deals with engaging pupils meanings in the section on learner-centred teaching. The students often use the examples presented there to illustrate points about learner-centred teaching in assignments and exams. However, when they are confronted with similar situations in their classrooms they struggle to manage them. An important question for the study is why this is the case. Is what teachers do and don't recognise and admit into classroom discussion related to their own mathematical knowledge? Or are they still working with conceptions of teaching which suggest that they must give the pupils the knowledge? If the latter is the case, then they will be working with two contradictory notions simultaneously, that of the courses which says they should elicit and hear pupils meanings, and another, more transmission-oriented view which does not facilitate their making use of pupils meanings. Perhaps the courses do not focus enough on <u>how</u> to work with pupils' ideas, focussing rather on the fact <u>that</u> this is important.

"Opening up" and "closing down"

In the Grade 7 example above, we have seen a teacher who attempts to allow meaningful participation in her class, but struggles to deal with the responses that pupils give. "Opening up" the classroom to pupils' meanings does not ensure that the discussion will remain open Teachers can easily "close down" what started as open-ended discussion.

Our findings overall regarding questioning were that most teachers' questions remained narrow and required one word answers, factual recall or procedural explanations. Two of the primary teachers and three of the secondary teachers did ask questions that required elaboration or explanation, but these were generally answered procedurally by pupils. Four teachers (three primary and one secondary) did ask more open-ended questions or set open-ended tasks. However, even in these cases, only the secondary teacher was really able to probe the pupils' understandings through these kinds of questions. Even in this case, the pupils' explanations were often about definitions or were procedural, so deep conceptual thinking was not probed.

The following example of "closing down" occurred in one of the primary lessons. The teacher was trying to make links between tessellations and tiles in pupils' houses, and asked pupils where they see shapes outside of school. One pupil answered "tins", meaning that he saw circular shapes in coldrink tins. This was so different from what the teacher wanted to hear, that she thought he was struggling to express himself and asked him to explain in his main language, TshiVenda. Eventually, after much prompting by the other pupils, she acknowledged his answer and gave her answer, "tiles". So her open question had a closed answer, a perfectly acceptable response from a pupil could not be heard by the teacher because she was expecting something different.

In one of the secondary classrooms, the pupils were working on a problem on the board and obtained the solution -0. This happened twice and the pupils were interested in finding out about it. However, the teacher ignored their questions and continued to explain how to cancel algebraic fractions. In this case a possibility for interesting discussion was closed.

In contrast to this are two other secondary teachers. One teachers' questions are not oper. ded, however she uses them effectively to scaffold pupils' knowledge. She does work with pupils' meanings, although these are more likely to be what she expects, because her questions are less open. Another teacher encourages pupil questions and therefore enables pupils to set the agenda for discussion. This teacher listens to pupil questions and answers them, which may qualify as "closing down", but since it is in response to pupils' own questions, he is working with pupils' meanings.

The teachers' use of open and closed questions suggests that the situation requires more complex analysis and practice than a mere shift from closed to open questions suggests. Two teachers use closed questions effectively and teachers who try to use open questions encounter difficulties. Wood (1992) argues that research (in the Northern hemisphere) has shown that teachers struggle to raise the level of cognitive demand of questions. This research confirms this finding in a different context, and suggests that a more nuanced view of what questions actually do and don't achieve and the range of purposes for asking them, may help teachers to use them more effectively

Discussion and Implications

For the FDE Programme there is much to reflect on The most commonly used 'new' approach is groupwork, which is used with varying success. Secondary teachers seem to use it more effectively, perhaps because they keep the tasks standard Primary teachers, and some secondary teachers, struggle to deal with pupils' meanings. Important questions for the programme are: why does this happen and are the courses able to deal with it. Can we anticipate teachers' difficulties in our courses or can we only provide a basis from which teachers can embrace the difficulties they experience along the way as a natural part of changing? On the basis of my analysis here it

seems clear that some "fine-tuning" of ideas, introducing nuances and texture are important.

This paper provides evidence that teachers who have been involved in almost two years of an INSET programme which attempts to help them to develop their practice, experience difficulties in doing so. They certainly do manage to try out some new ideas. In relation to learner-centred practices, some elements are easily taken up, for example organising pupils into groups, while others are more difficult to deal with, such as asking open questions and dealing with pupils' meanings without closing down the discussion. The difficulties that these teachers experience suggest that teachers with less time to think about change or less input as to what it might mean would struggle even more. This adds to my argument (Brodie, 1998a) that it is not helpful to exhort teachers to change to learner-centred practices without clarifying what these might be More work has to be done, with teachers, based on research into their teaching, on what new concepts and practices might mean in a South African context, and what happens as teachers begin to try them out in their classrooms.

All of the teachers in our research study showed strengths and weaknesses in their uptake of the ideas in the various courses and in their practice. Some of the differences across teachers can be explained by the levels at which they teach, what other aspects of change they are trying to manage simultaneously, their own personal preferences for which courses are the most useful (for example some teachers found mathematics content courses empowering while others found the education courses more useful), and by their contexts, some contexts are clearly more enabling of change and development than others (see Adler, Lelliott and Reed et al, 1998). How they have managed to work with certain ideas in their classrooms will come from an interaction between the individual teacher, her context, what she has learned from the courses, and what she has learned from other sources, including the prominent new Curriculum 2005 discourse. It is not possible to untangle the effects of all the disparate influences on a teacher, to be able to attribute particular changes to a particular programme or course. Nor is it desirable to do so, because the teacher-in-context is always part of and contributing to a range of influences on her practice. However, research into teacher practices can be formative for the development of courses, identifying what can be assumed and what needs to be further developed in more sophisticated ways.

NEEDING TO USE ALGEBRA - A CASE STUDY

Laurinda Brown, University of Bristol, Graduate School of Education

Alf Coles, Kingsfield School, South Gloucestershire, UK

In the UK there has been a move away from teaching algebra to pupils aged 11. Kieran (quoted in Sutherland, 1997) has suggested three components of algebraic activity: generational, transformational and global meta-level. A comparison of the work of two high achieving 15 year olds with two high achieving 18 year olds gave evidence for Kieran's model as a useful way of describing algebraic activity and prompted the question: would it be possible to work meaningfully with 11 year olds on all three components of algebra? We link this question with Sutherland's (1991) call 'Can we develop a school algebra culture in which pupils find a need for algebraic symbolism to express and explore their mathematical ideas?' This paper analyses, as part of a project funded by the UK Teacher Training Agency (TTA), the work of one 11 year old pupil who has needed to use algebra.

Background

Issues relating to algebra have formed conclusions to two recent reports (Winter et al. 1997, Sutherland, 1997) into mathematics teaching and learning at secondary schools in the UK. Winter et al (1997) is a national report in which algebra is identified as a key component in facilitating a smooth transition for pupils between school and higher education in mathematics. Pupils' algebraic skills were often found to be in need of attention by teachers at the start of higher education courses. The Sutherland (1997) report was the outcome of a Royal Society (RS) and Joint Mathematical Council (JMC) working group, set up in 1995 *to make recommendations about the teaching of algebra* (p. ii), partly in response to *the apparent lack of articulation between mathematics taught at school and that required by higher education* (p.ii).

In the RS/JMC report a key conclusion is that: *the National Curriculum is currently too unspecific and lacks substance in relation to algebra. The algebra component needs to be expanded and elucidated - indeed rethought* (p.iii). A further conclusion is: *that more research is needed to understand the relationship between what algebra is taught and what is learned* (p.iii).

Both these conclusions sparked our interest in looking at algebra in secondary schools. In particular, we wanted to explore Sutherland's (1991) challenge:

Can we develop a school algebra culture in which pupils find a need for algebraic symbolism to express and explore their mathematical ideas? (p.46).

What is algebra?

In asking ourselves the question: *what is algebra?* we wanted to find a definition with which we could work to try to understand what pupils actually did which could be described as algebraic activity when they were engaged in doing mathematics. In reviewing current research on algebra strands emerged to do with context, meaning-making, complexity and control which we found useful in our thinking. Introducing and using algebra in a context is talked about from a view which we support that:

Traditionally, algebra in schools has been dealt with at a syntactical level; the students have no 'meta-control'; they know that they are allowed to do some things and not others, and obviously they sometimes make mistakes ... to improve the situation one can call to mind an algebra which is always linked to a context; not necessarily to the (often unreal) 'real world problems', but to the properties of numbers, or to the manipulation of functions, in all cases where it is necessary to interpret the result (Menghini 1994, p.13).

We see the important task as making symbol representation meaningful rather than as a submission to the Cockcroft report (1982) expressed that: *Mathematics lessons are very often not about anything. You collect like terms, or learn the laws of indices, with no perception of why anyone needs to do such things* (para 462).

... it was the lack of this (linking symbols to the situations they represent) that led to failures in the past teaching of algebra: the children who failed thought of x and y as meaningless marks that had to be played with by peculiar rules (Sawyer, quoted in Anderson 1978, p.20).

One argument is that this meaning might be achieved through working with pupils on thinking mathematically, where algebra is one component:

One major part of the effort to reform secondary school mathematics is the project of changing the goal of studying school algebra from mastery of symbolic manipulations to the ability to reason mathematically (Yerushalmy 1997, p.431).

Pupils need some fluency in symbolic manipulation, however:

The manipulation of symbols is only a small part of what algebra is really about, the traces that are left behind after mathematical thinking has taken place (Mason 1992, p.5).

One implication of this is that:

symbolic manipulation should be taught in rich contexts which provide opportunities to learn when and how to use those manipulations (Arcavi 1994, p.32).

In other words algebra should arise from complex situations:

Algebraic symbolism should be introduced from the very beginning in situations in which students can appreciate how empowering symbols can be in expressing generalities and justifications of arithmetical phenomena ... in tasks of this nature, manipulations are at the service of structure and meanings (Arcavi 1994, p.33).

There is never an end-point in this conception of learning mathematics. If I am learning to reason mathematically to structure my thinking about problems, then what I learn is in an ongoing state of complexification and enrichment.

Here we had our link to the challenge (Sutherland, 1991) of creating a school algebra culture in which pupils find a need for algebraic symbolism. The need we envisage here is for expression of awarenesses within complex situations. This clearly places onus on us as teachers to create a classroom culture in which there is the possibility for

pupils to work at and attempt to express what they are aware of. What we are prepared to notice and able to perceive is to a large extent dependent on the culture around us, and the language available to us.

We view the developing culture and ethos of our classroom as a community of practice (Lave and Wenger, 1991), where the practice is mathematical inquiry (Schoenfeld, 1996). The learning of algebraic thinking is part of learning mathematics and is situated in the classroom interactions.

A unifying strand through all these quotes is the sense of algebra as an evolving language that can emerge from situations and contexts that are already laden with meaning. Algebra can be used to express and offer insights into those situations. It is in this emergent expression and consequent empowerment that pupils can discover the need for algebra.

We have taken the following defintion of algebraic activity from the Sutherland (1997) report:

(i) Generational activities which involve: generalizing from arithmetic, generalizing from patterns and sequences, generating symbolic expressions and equations which represent quantitative situations, generating expressions of the rules governing numerical relationships.

(ii) Transformational activities whch involve: manipulating and simplifying algebraic expressions to include collecting like terms, factorizing, working with inverse operations, solving equations and inequalities with an emphasis on the notion of equations as independent 'objects' which could themselves be manipulated, working with the unknown, shifting between different representations of, function, including tabular, graphical and symbolic.

(iii) Global, meta-level activities which involve: awareness of mathematical structure, awareness of constraints of the problem situation, anticipation and working backwards, problem-solving, explaining and justifying (Kieran, quoted in Sutherland, 1997, p.12).

Within the discussions of the working group set up to write the report (Sutherland, 1997) this definition was the one which covered every member's interpretation of what algebra is. Such a broad definition allows us, as teachers, to work on our recognition of what algebra is in what the pupils do.

Methodology and methods

The definition of algebraic activity that we have chosen supports our need for a way of looking at what pupils do which will in turn transform our perspectives of how to work with the pupils in the culture of the classroom. We work within what Bruner (1990) called a 'culturally sensitive psychology':

(which) is and must be based not only upon what people actually do but what they say they do and what they say caused them to do what they did. It is also concerned

with what people say others did and why ... how curious that there are so few studies that (ask): how does what one does reveal what one thinks and believes (p.16-17).

We are interested in focusing on what we and the pupils in our classroom do and, consequently, we use an enactivist methodology (Reid, 1996, Brown and Coles, 1997, Hannula, 1998) the two key features of which are firstly: *the importance of working from and with multiple perspectives, and the creation of models and theories which are good-enough* for, *not definitively* of (Reid, 1996, p207).

theories and models ... are not models of. *That is to say they do not purport to be representations* of *an exisiting reality. Rather they are theories* for; *they have a purpose, clarifying our understanding of the learning of mathematics for example, and it is their usefulness in terms of that purpose which determines their value* (Reid, 1996, p208).

The second key feature of enactivist methodology is that we take multiple views of a wide range of data:

The aim here is not to come to some sort of "average" interpretation that somehow captures the common essence of disparate situations, but rather to see the sense in a range of occurrences, and the sphere of possibilities involved (Reid, 1996, p207).

We see our *research about learning as a form of learning* (Reid, 1996, p208) where our learning is gaining a more and more complex set of awarenesses about our teaching of mathematics.

In a pilot project two pairs of high achieving pupils, one pair of 15 year olds and one pair of 18 year olds were interviewed as they worked on a problem set by Alf. This problem could be tackled algebraically. The major difference between the two pairs of pupils was the control with which the older ones first explored the problem numerically, until they had some sense of what was going on, and then moved effectively to an algebraic representation and solution showing evidence of all three of the components of algebraic activity. The 15 year olds, on the other hand, reached for the symbolism quickly but became bogged down in the transformational work.

This experience led to our asking the question: would it be possible to create a classroom culture of 'being a mathematician' with 11 year old pupils so that when they themselves were aged 15 they would be operating as the 18 year olds did? We started work in September, 1998 on a project, funded by the TTA, to investigate this question with one mixed ability class taught by Alf. In order to gain evidence of the pupils' developing algebraic awarenesses we have stressed their need to write about their ideas and conjectures when doing mathematics and periodically we have asked them to write about 'what I have learnt?' both in terms of mathematical content and 'being a mathematician'. We have been surprised at the sophistication with which this class has developed and extended the culture of 'being mathematicians' but that is part of a larger project and not our concern here. In this paper we focus on the evidence of developing algebraic competence within one child as mathematician.

The case of Alex: needing to use algebra

This case study, told in three stages, illustrates one eleven year old pupil's developing use of the three components of algebraic thinking (Kieran, quoted in Sutherland, 1997) over the first term in secondary school, specifically leading to an example of the pupil (Alex) finding their own need for algebra. The interviews with Alex at the beginning and end of term, his exercise book, his writing on *what I have learnt?*, a half-term review, base-line entry test data and notes from observations of class lessons form the data set from which the following three incidents have been selected.

The first activity the class tackled was a rich numerical problem that lasted for seven lessons. In that time the teacher was using strategies to allow pupils to raise many questions within the group although everyone also had a lot of practice with the processes of basic addition and subtraction.

Stage 1: Algebra introduced by teacher but not used by pupil

Some of the questions pupils raised involved wanting to know why 9s fell in particular places in the calculations. The teacher recognised that one way of answering these questions was to use an algebraic demonstration, since no pupil was using algebra. Alex had not used algebra before. On being interviewed after the seven lessons he remarked that *basically all of it in my primary school was sums* and further that ideas of proof were not used at primary school. After the demonstration 11 out of the 27 pupils could recreate the manipulations and 8 were able to extend the techniques to show other similar results within the problem. We did not, however, expect pupils to be able to reach for algebraic technique in a different context (the situatedness of learning, Lave and Wenger, 1991) nor were we concerned that the majority of pupils might not be able to reproduce the original demonstration at this time. The possibility of using algebra to know why things work as they do was now within the community of practice (Lave and Wenger, 1991) and from another viewpoint the zone of proximal development (Vygotsky, 1978) of the pupils and this was our main purpose in introducing the algebra. At this stage Alex thought of thinking like a mathematician as *you've just got to ask yourself why is it doing this?*

In the first interview Alex was invited (by Alf the interviewer), to try numbers in a problem which he had not seen before. He quickly spotted a difference of 3 (Fig 1):

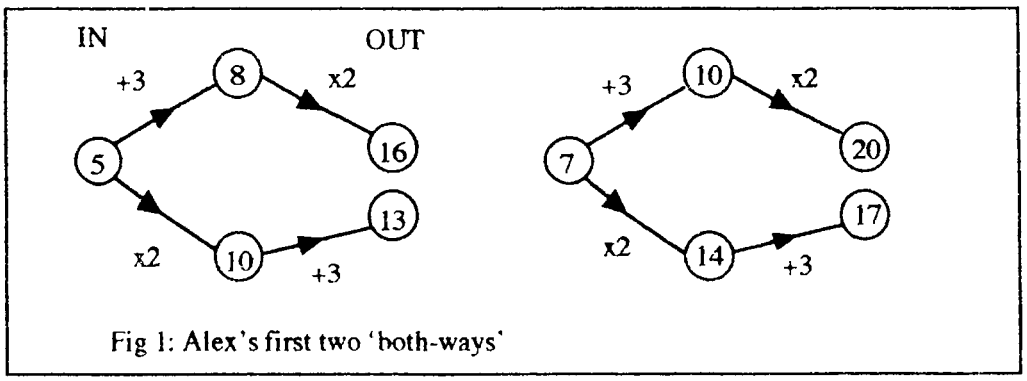

Fig 1: Alex's first two 'both-ways'

When Alf asked: *You said that being a mathematician is about asking questions so what's your immediate question?* Alex replied: *Does that happen with every number you put in?* In working on this question he tried out 'minus numbers' and decimals. It was evidently not natural to let a letter stand for any number and explore the consequences.

There is evidence of generational activity here since the pattern of 'there's always a difference of three' was spotted. But despite recognising 'why' as being a mathematical question Alex does not ask himself *why* in this context and consequently does not display global meta-level awareness within this problem. Algebraic symbolism was not used so there was no evidence of transformational activity either.

Stage 2: Algebra used by pupil in response to teacher's question

Fig 2 below is taken from a half term review given to the class which involved some questions to explore how they were getting on with algebra and an end of half-term 'what have I learnt?'. Here, in response to the prompting in the text of the question, Alex is able to work through the problem using a general letter N (even though there is no explicit invitation to use N in the statement of the task) demonstrating some transformational skills. We believe he is able to share 2N + 4 by 2 to get N + 2 because of awarenesses formed through the numerical process of trying a few examples first. Alex is effectively using the skill of multiplying out brackets, but no algorithm for this has yet been taught. Alex recognises that the sequence of instructions always results in 2 and so uses generational activity.

3) Try out this trick with different numbers ... write down anything you notice ... can you prove anything about this trick?

Think of a number	1	5	100	N	The Answer always comes out as two. If you look at the sequence most are alimaneting its selve eg Think of a number, Take away the numer you first thought of!!! same with Double it and Halve your answer, if there was no "add 4" it would come to 0 but there is a "add 4" when that is halve it leaves you with "2" the answer.
↓					
Double it	2	10	200	2N	
↓					
Add 4	6	14	204	2N+4	
↓					
Halve your answer (share by 2)	3	7	102	N+2	
↓					
Take away the number you first thought of	2	2	2	+2	
↓					
ANSWER	2	2	2	2	

Fig 2: Question 3 from Alex's half term review

In commenting: *most are alimaneting its selve* (we think this means 'eliminating themselves') we would intepret a global meta-level appreciation of the structure of the trick and in reaching for the N also a global meta-level awareness of the power of using symbols, although this happens in response to another's questioning.

Stage 3: Algebra needed to answer a question posed by pupil

In the second interview with Alex, at the end of the first term, Alf posed the same problem as in the first interview, but with different numbers. Alex tried one more example and commented: *The one I've just done was 6 difference and the same for that one there.* As in the first two incidents, Alex displays generational activity in noticing a numerical pattern. In response to: *What questions are around for you as you notice a pattern like that?* He replies in a similar way to before: *Does it work for all of them?* Previously this statement led him to try out decimals and 'minus numbers' but after one more numerical example, without speaking, this time he produced the following algebraic solution (Fig 3):

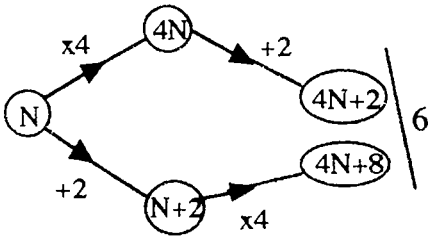

Fig 3: Alex's algebraic 'both-ways'

There is certainly evidence here of transformational activity and this feels like the 18 year olds' interview because Alex gains control of the process before using algebraic skills. Even more surprisingly Alex returned to a numercial problem and said: *I know what's making it 6 difference now, with the N. Because the bottom way - I can't say it. But that 7 it's going to be more than just timesing it by 4 straight away and adding two on the end. Really you're timesing the 2 plus the 5 by the 4 that way. It's hard to explain. So, that one would be 4n plus 8. So, these two cancel out each other leaving 6 behind. So now you know every one's going to go to 6.*

Alex clearly shows evidence here of insight into the structure of the problem, a global meta-level awareness, which, unlike at the half-term review, is also articulated. The difference that strikes us here, compared to the first two incidents, is that the algebra has arisen from a question of Alex's. In recognising a pattern and asking himself 'why?' in this new context he creates a need. His experiences over the term allow him to answer this need with the use of a letter N to stand for a general number. As he worked through the general case the structure of the problem was illuminated: *I know what's making it 6 difference now, with the N.*

In commenting on the process of his solution, Alex recognised the power of N standing for any number: *I should have done that first off.* Alf, in reply during the interview, tells him that it is good to start with the process and we would argue that Alex's need for algebra came through the posing of his own question: *why?* and that this came out of a pattern spotted (generational activity) after the process of doing a few examples.

588

His transformational skills, in contrast to the second stage, appear less dependent on numerical awarenesses since it is in the transforming that he gains structural insight. It is beginning to feel as though Alex will not need to be taught algorithmically many of the transformational skills needed in secondary school eg how to multiply out brackets.

Conclusion

The question we are working on for the TTA is whether 11 year old pupils would be able to operate algebraically like the18 year olds in our pilot study by the time they were 15 years old. Evidence so far would suggest that some of the pupils will be able to achieve this facility much earlier than age 15. Alex has developed over 15 weeks from no experience of algebraic thinking to using algebra to illuminate his thinking in relation to a problem. The cognition here is in the developing practices and language of 'being a mathematician' and the theories *for* our practice as teachers are in the stressing of the importance of writing to encourage the pupils' awareness of awareness and working together on why the patterns within problems and structures exist.

TEACHERS' DOUBTS ABOUT INVENTED ALGORITHMS

Anne Buzeika and Kathryn C. Irwin

Auckland College of Education and University of Auckland

Two teachers experimented with allowing their students to invent ways of doing multi-digit calculation. The students showed considerable success and number sense in doing this, impressing their teachers. The methods that the students chose were closely related to teachers' statements or example. Despite seeing the value of this to the children, the teachers were uneasy about continuing to allow them this opportunity in the face of existing socio-historical practice and beliefs. We argue that the strength of socially and institutionally sanctioned mathematical practices prevented them from seeing this activity as central to children's developing number sense.

In many parts of the world, the concern that children understand calculation has led to an emphasis on developing number sense rather than mere fluency in the use of algorithms. It has been well documented that children develop a meaningful understanding of numbers if given the opportunity to use their own procedures (e.g. Carpenter, Frenke, Jacobs, Fennema & Epsom, 1998; Kamii, 1989). However, teachers vary in their willingness and ability to teach in a manner that encourages children to understand numbers rather than use an algorithm.

This study followed two teachers as they encouraged their children to develop their own ways of doing multi-digit computation. It views not only the classroom as a site of social construction of concepts, but also the teachers' wider community as a site in which beliefs and pedagogical practice are constructed. We argue that the beliefs of this wider community had a strong influence on their ability to allow children to develop their own calculation procedures. Using a Vygotskian analysis, the group knowledge of teachers in this country is of a pedagogy that leads only to use of a traditional algorithm. The underlying number sense behind this pedagogy has not become sufficiently individualised for individual change. This point is

related to that made by Ensor (1998) who discusses teachers' belief systems as social rather than individual.

New Zealand has had a mathematics curriculum since 1992 that suggests that students develop their own ways of calculating and develop flexibility and creativity in applying mathematical ideas (Ministry of Education, 1992). No where does it recommend teaching the traditional algorithm. However, the vast majority of teachers continue to teach algorithmic methods for multi-digit addition, subtraction, multiplication, and division. The debate in teaching circles in this country continues to centre on the use of regrouping as opposed to the equal additions method that the teachers themselves used as students. This persists despite the fact that the work of authors recommending emphasis on number sense and invented algorithms is well known by mathematics educators in this country.

For many years in New Zealand it has been the tradition to teach children how to do multi-digit calculation through the use of place value blocks. The method of instruction required students first to add double-digit numbers where no regrouping of the blocks was required. The next step was to solve a problem in which there were too many unit blocks, which then needed to be regrouped. Although educators were initially exited about this teaching procedure, it appears to have become an algorithm in itself rather than being seen as one way that place value could be demonstrated.

Discussion of Procedure

The first author volunteered to provide professional development for a school, demonstrating invented algorithms as a way of encouraging number sense. The school had a policy of encouraging independent thought, the principal welcomed the offer, and two teachers volunteered to introduce multi-digit computation in this manner. This professional development took place over six months, with three initial meetings with interested teachers followed by a period in which teachers were

observed and aided in their classrooms, with interviews and less formal contacts thereafter. The two classes that are the focus of this report were a Year 3 class (aged 7 – 8) and a Year 3 & 4 class (aged 7 – 9).

Both of the teachers were experienced. Ms N, who taught the Year 3 class (Class 1), had 14 years of experience, but relatively low confidence in her ability to teach mathematics. Mr C, who taught the Year 3 & 4 class (Class 2), had 20 years of experience and an above average level of confidence in mathematics. He was a popular teacher who could be described as having a certain charisma with the children.

The methodology of the study was a case study of two classrooms, with a participant observer. Classes were videotaped and audiotaped for a five-week period when the children were working on multi-digit computation. Samples of children's work were collected every 3 or 4 school days. These samples form the basis of the data in Tables 1 and 2.

Ms N chose to introduce this unit of work through revising basic facts and recording various ways a number could be written, for example 9+10=19. She then discussed two-digit place value with the class (52 is 5 tens and 2 ones). She presented problems for the children orally, primarily as word problems Initially she asked children to add two-digit numbers in which the units always summed to less than 10. Children were encouraged to use any method that worked to get the right answers, and to share their methods with their peers. She then focused the children's attention on how basic facts could be used to solve problems with larger numbers, for example if 3+4=7 then 30+40=70 and 300+400=700. Only after she saw that the students were successful with their own methods of addition did she give the children problems for which the units equaled more than ten. Similarly, she only introduced subtraction after children had been working with addition for four weeks, and even then, because it was suggested to her. When introducing subtraction she

said, *"Part of me wants to get out the equipment and show you how to work it out, but I'm going to let you have a think about it first"*.

It is interesting to note that in her planning she was restricted by the same factors that would have governed her introduction of multi-digit calculation with the conventional algorithm using place value blocks. She had always used the place value blocks to model this exercise, and her thinking continued to follow this pattern. She doubted that the children would be able to do more difficult calculations, and did not want them to fail. She did not support flexible thinking in which addition and subtraction were seen as inverse operations. However, she expressed considerable interest in children's methods of working, encouraging them to demonstrate different methods to their peers.

Mr C started his program at a more advanced level. He initially assessed multi-digit addition and subtraction through word problemsthat required combining quantities such as 53 and 39 or taking a group of 27 from 62. These weregiven as homework, and Mr C emphasised that the children could get the answer in any way they chose. Next he had them work on different ways in which numbers could be decomposed through an exercise in which children thought of four numbers that could be added to make a given number, such as 42 = 14+12+10+6. After this exploration with numbers he went on to practice with basic facts in all four operations, emphasising the inverse relationship of multiplication and division. This was followed by a discussion of the strategies that many peopleused, based on knowledge of doubles, derived facts and decomposing numbers to the nearest tens. He gave verbal problems or provided a Lucky Dip from which children picked numbers for addition, as well as some open-ended problems from a common text. He encouraged students to use mental methods as well as record the way in which they worked, and the students took delight in being able to do problems mentally. Although he said that he was committed to students developing their own ways of calculating, he lost his confidence and commitment at the time of the fourth data

collection point. He was concerned that he was wasting time and that parents and the next teacher would find his children ill prepared in their algorithmic skill. At this point he demonstrated the way that he would do a problem, on the board. This demonstration had a marked effect on students' methods.

From his plan it appears that this teacher was much more flexible and connectionist in his use of numbers than was Ms N. He was not tied to the procedures used with place value blocks. However, his students became less flexible in their operations than were the children in the other class.

Discussion of Results

Children in both classes demonstrated a range of strategies in their calculation: counting on, addition by place value, using compensation, various types of decomposition, etc. Some children in Mr C's class used conventional algorithms in their first sample, done as homework. Tables 1 shows the way in which children placed the numbers to be calculated, and Table 2 shows whether the students started with the tens (or larger values) or the units when calculating.

Data Collection Point	1	2	3	4	5	6	7
Class 1 Horizontal	91%	100%	100%	95%	95%	77%	95%
Class 1 Vertical	9%	0	0	0	0	0	4%
Class 2 Horizontal	39%	70%	78%	43%	43%	56%	56%
Class 2 Vertical	57%	30%	17%	57%	57%	43%	43%

Table 1. Percent of children using horizontal and vertical formats for calculating at each data collection point, over 5 weeks. Class 1: n=22, Class 2: n=23.

Most of the children in Class 1 used a horizontal format throughout, with a slight dip at point 6 when subtraction was introduced and several children did not show their working. The children in Class 2 started with work done as homework, and about half of them turned in standard vertical calculations, presumably taught by parents or siblings. The percentage using this method decreased when developing

individual ways was praised in class, but as soon as their teacher demonstrated the way in which he worked, the percentage of children using his vertical format increased.

Data Collection Point	1	2	3	4	5	6	7
Class 1 Tens before units	59%	82%	82%	73%	77%	27%	41%
Class 1 Units before tens	14%	4%	4%	0	0	0	4%
Class 2 Tens before units	39%	22%	35%	4%	0	0	0
Class 2 Units before tens	26%	22%	0	4%	13%	17%	26%

Table 2. Percentage of children in each class who calculated the tens before the units versus the units before the tens in each class, at each data collection point, over 5 weeks. Class 1: N = 22, Class 2: n=23.

Table 2 demonstrates dramatically the effect of the teachers' statements or demonstrations on children's working and accuracy. The majority of children in Class 1 operated with tens before units until they started subtraction, when the majority stopped showing their method of working. An example of their method of working was, for 47 + 28: *"I put the 40 and the 20 = 60 and 7 + 8 = 15 and the 10 from the 15 = 70 and 70 + 5 = 75"*. At Point 6 when Ms N expressed her doubts about the students' ability to do subtraction, they attempted to use the same strategy that they had used for addition. This direct transfer led to a drop in accuracy from a range between 86% - 100%, to an accuracy of 59%. Despite the encouragement of the author and students' subsequent improvement, she felt that her doubts about children's ability were confirmed.

In Class 2, 22% - 39% of the children worked with the tens before the ones on the first three samples. The marked change came at the fourth data collection point, when he demonstrated how he would do vertical calculation, starting with the units. After one demonstration of the conventional algorithm no one showed working with tens before units. Students were eager to calculate in his way, which probably was that demonstrated by their parents. While the accuracy of these students had been 91%-100% at the first three data collection points it dropped to

35%-82% for the next three points. Few children showed their working, making it very difficult for the teacher to gauge their number sense.

Discussion

Despite the fact that the teachers had seen the benefit of children basing their multi-digit calculation on their own number sense, neither teacher was sufficiently convinced of its usefulness to change their traditional way of teaching. This appears to have been because the method was in opposition to that expected by their wider community. Both teachers feared that future teachers and especially parents would be displeased if students did not know how to use conventional algorithms. As Yackel, Cobb and Wood (1992) point out, teachers work in a context in which procedures must be institutionally sanctioned. Teachers construct their own beliefs about teaching practice in their wider community, just as children construct their own mathematical concepts. These constructions must be useful to them, in this instance, more useful than the need to please parents and other teachers. Despite the support of the principal and some of the other teachers in this school, these teachers did not see this pedagogy as useful to them, despite acknowledging its usefulness to the children.

They were also concerned by new political demands for national assessment of numeracy at age 9, which translated in their minds and that of the parents to the use of algorithms. One year later, Ms N had reverted to teaching the traditional algorithm for multi-digit calculation, using her previous methods. Although she was very impressed with the number sense that her children showed, she felt more confident in using the institutionally sanctioned methods based on place value blocks rather than encouraging wider number sense. Mr C had the confidence to understand the children's number sense, but he saw more disadvantages than advantages to altering his teaching style.

BEST COPY AVAILABLE

It may be important to note that this was not an extended teaching experiment similar to those of Carpenter et al (e.g. 1998) or Cobb, Wood & Yackel (e.g. Yackel, 1998) and did not have the same degree of external support. The fact that the teachers' commitment to the beliefs of the wider community was greater than their commitment to the development of number sense in their children emphasises the need for any change to be the focus of a much wider community than that of the classroom.

THE AMBIGUITY OF MATHEMATICS

BILL BYERS
DEPARTMENT OF MATHEMATICS AND STATISTICS
CONCORDIA UNIVERSITY
MONTREAL, CANADA H4B 1R6

This paper deals with mathematical rigor and the notion of ambiguity in mathematics. It takes the counter-intuitive position that ambiguity is of central importance to the mathematical endeavor—that it is essential and cannot be avoided. In our view, rigor and ambiguity form two complementary dimensions of mathematics—what we characterize as the surface versus the depth dimensions of the subject. This position has major implications for the teaching of mathematics since we hold that the philosophical position of the working mathematician is the single most important impediment to the improvement of the teaching of mathematics at the university level.

Introduction

One of the most intractable teaching problems faced by university mathematics departments revolve around the appropriate role of rigor in the undergraduate curriculum. Hovering around the teaching of university mathematics is the unquestioned axiom which holds the that there is a definitive version of any area of mathematics and that this definitive version of the subject is more or less identical to its rigorous presentation. In her interviews with mathematicians Sfard (1994) concludes that "there seems to be another mode of thinking about mathematical concepts, a mode which has little to do with systematic deduction." Nevertheless, in their role as classroom teachers, mathematicians often revert to a formal, rigorous presentation. Even if a teacher of an elementary course, such as calculus, teaches little theory, nevertheless, in the background there is the rigorous theory which is, for the teacher, definitive. This notion that rigorous mathematics is definitive infiltrates the classroom in many ways and contributes to making it the sterile learning environment that it unfortunately often is.

In some other writing (Byers 1983, 1984) I have tried to address the discrepancy between the subject as it is taught and the subject as it is understood. In particular, the rigorous, static, formal version of the subject does not match the dynamic and human dimensions of learning, understanding and creating mathematics. One eminent mathematician said that what we are doing as mathematicians is "constructing better ways of thinking," (Thurston 1994), thus thrusting to the fore the

idea that mathematics is something that cannot be understood independently of the human beings who create and use mathematics. Attempts to demystify mathematics (and Platonism is surely a myth) and bring it back into the human realm is an important tendency in mathematics education (Triadafillidis 1998). It is consistent with the movement to revive the philosophy of mathematics by setting aside questions of foundations and focusing instead on actual mathematical practice (Hersh 1997, 1998).

To the working mathematician it is evident that mathematics is *not* merely tautological. Thurston's statement that, "...what we are doing is finding ways for *people* to understand and think about mathematics" (1994), raises the question of where this understanding comes from? Surely it cannot be derived from the formal structure of the subject. As a consequence when the mathematician, as teacher, identifies the subject with its formal presentation he often does not consciously make a goal of developing understanding or of providing a fertile ground in which insight might flourish.

In order to dramatize the point that mathematics is not logic *and* to indicate an approach to the subject which would include understanding and to what I call below the depth dimension of mathematics, I have, in all seriousness, put the word ambiguity into the title of the paper. Mathematics is deep and powerful because it is multi-faceted. Thus mathematics transcends logic yet logic is an essential ingredient in it. Similarly one could say that mathematics is neither completely objective (as a formalist or a Platonist would claim) nor is it completely subjective or constructed by the individual (c.f. Lakoff and Johnson 1980).

Ambiguity and Depth

Anyone who has done some creative work in mathematics will agree that some pieces of mathematics are "deeper" or more profound than others. Often in a piece of mathematics or in a proof one asks questions like, "What is really going on here?" or "What is the basic idea?" These questions go in the direction of depth. The most complimentary thing that one can say about a mathematical idea is that is "deep." So mathematics has more than one dimension. On the one hand there is the dimension of the logical structure, what we will call the "surface structure", (which we will take to include instrumental or algorithmic aspects) but on the other there is the dimension of depth. Of course the division between the two is not so simple but for the purposes of this discussion the distinction is clear enough to talk about. When one says that mathematics is basically tautological or that logic is the essence of mathematics one is referring to the surface structure (which mathematicians usually

take for granted). The power of mathematics clearly comes from the other dimension, that of depth. When we ask what mathematics is we must specify which dimension we are talking about. When we teach mathematics we must also specify in which domain our teaching objectives lie. When we talk about the ambiguity of mathematics we are trying to get a handle on the phenomenon of depth.

What is ambiguity?

People often take ambiguity to be synonymous with incomprehensibility. However we shall primarily focus on the following part of the dictionary definition of ambiguity: "admitting more than one interpretation or explanation: having a double meaning or reference."(Oxford 1993). The definition of ambiguity also has a secondary meaning, that of being "indistinct, obscure, not clearly defined". The kind of obscurity we are thinking of is, for example, when one is doing research and one feels that there is a theorem lurking somewhere but one doesn't yet see exactly what it is. The sense in which we use the term "ambiguity" will be further clarified by the examples which follow. To return to the notion of depth, the relationship between ambiguity and depth can be understood by considering the metaphor of binocular vision. Seeing through one eye produces only a flat, two-dimensional image; it requires two images to produce depth. The existence of a double perspective creates a situation which may lead to understanding or even creativity.

Ambiguity in mathematics: strength or weakness?

We often understand ambiguity as mere confusion or lack of clarity which we consider to be undesirable. Sometimes this confusion is unnecessary and should be clarified (Hillel 1989). But is it always possible to avoid ambiguity? We tend to react to every presence of ambiguity by attempting to remove it rather than by working with it. We maintain that ambiguity, viewed as the existence of a multiple perspective, can be an opportunity and not just a problem. Ambiguity functions in mathematics in a way which is analogous to the poetic function in language (James, Kent and Noss 1997). Consider the following situations:

Square roots

$\sqrt{2}$ is ambiguous. Is it an arithmetical, counting number or a geometric, measuring number? Which world does it belong to? The irrationality of $\sqrt{2}$ is one instance of "a continuous feature of the history of mathematics. . .the prevailing tension between the arithmetic and the geometric" [Dunham 1990] We claim that the tension arising from the fundamental arithmetic/geometric ambiguity was a spur to the development

of much of mathematics. Though the irrationality of $\sqrt{2}$ destroyed once and for all the hope of the Greek mathematician/philosophers for a "rational" universe, it was an opportunity as well. The problem which the ambiguity of $\sqrt{2}$ presented to the mathematical world was ultimately resolved by the creation of the real number system.

Matrices

A matrix leads a double life. On the one hand it is a collection of numbers arranged in a rectangular array, on the other, it is a function, a linear transformation. (It also has many other interpretations but these two are sufficient for us to make our point.) Whereas we add matrices as though they were collections of numbers, we multiply matrices in the way that we do because we are composing them as functions. Often, in linear algebra, we jump back and forth between these two points of view. Rank, for example, can be looked at from both points of view. Or, think of the representation of a linear transformation, **T**, as a matrix relative to a certain pair of bases. Since **T** is usually given by a matrix the whole situation is fraught with ambiguity. It is the existence of this multiple perspective which gives the student so much trouble. They often ask: "When do you think of a matrix in one way, when in the other? How do you know which way to think of a matrix in a given problem?" However, it is precisely this ambiguous point of view which gives the concept of a matrix its depth. The successful student has learned to alternate easily between these two ways of looking at a matrix. In fact when we think of a matrix it has become a mathematical concept with an independent existence which can be looked in a multiplicity of ways. No one of these ways is the exclusive or the correct way of understanding what a matrix is.

Infinite Series and Real Numbers

Even the notation for an infinite series is ambiguous. The summation notation, $\sum_{n=1}^{\infty} a_n$ conventionally stands both for the formal series **and** for the sum of the series (if it converges). Even the word "sum" is used ambiguously since it describes both an operation, the verb 'to sum', and a thing, the noun, 'the sum'. This ambiguity is compounded when we write real numbers as infinite decimals, as in .999... . As above the real number is a thing, either a quantity or a point on the real line. But it is also a process, the sum of a series or a series of successive approximations. (Sfard 1994) would refer to this as the problem of reification, of "treating a process as its own product" but we would add that the problem is not only that the "process" of the infinite sum is replaced by the "product" of the real number but that process and

product are equated (as in .999... = 1) in a statement which is ambiguous. One could say that .999... is only a representation for 1 but then how can one write that this representation is "equal" to 1. If you say that the numeral "1" is also a representation for 1 then this gives rise to yet another ambiguity: that between the numeral and the number represented by that numeral.

The difficulty here is similar to the difficulty that has been pointed about by various authors (e.g. [Kieren 1981]) concerning children's propensity to understand the equality sign in simple sums like '2 + 3 = 1 + 4' in operational terms. Gray and Tall [1994] have discussed these "process-product" ambiguities in mathematical notation. They stress that the learner's grasp of these ambiguities is central to their success or failure in mathematics.

Functions

The notion of a function is ambiguous. There are many equivalent definitions but let us focus on two . There is the ordered pair, graphical definition of a function. This is a static definition: the function is a set (of ordered pairs) or a picture (the graph) or a table.. However there is also the mapping definition, which is related to the black box, input-output definition. This latter is a dynamic definition. Here the 'x' is transformed into the 'y'. This definition is the one which is used in thinking of a function as an iterative process or a dynamical system or a machine.

Again mathematicians go back and forth from one of these representations to the other. New developments in mathematics may entail looking at a concept in a new way. The input-output model was crucial to looking at functions as the generators of iterative processes. It came into its own with the development of computers. The graphical representation of a function is of little value when one wishes to study the orbit structure which the function generates.

At a higher level one puts sets of functions together to form function spaces. In fact one of the conceptual breakthroughs in analysis is the idea that a function may be considered a point in such a function space. Here again the initial barrier to understanding, namely that a function could also be thought of as a point, turns into an insight. That is, it is precisely the ambiguous way in which a function is viewed which is the insight. Once a function is seen as a point in a metric space, we can talk about the distance between functions, the convergence of functions, about functions of functions, etc. This sort of dual representation is often present in situations of mathematical abstraction.

Fundamental Theorem of Calculus

The fundamental theorem is a non-trivial application of the above discussion on ambiguity. Differential Calculus and Integral Calculus can (and historically were) developed independently of one another. The Fundamental Theorem says, of course, that these processes are inverses of one another. This means that differentiation is not more fundamental than integration nor is the opposite true (at least for functions of one variable). Actually the theorem says that there is, in fact, one calculus process which is integration when we look at it in one way and differentiation when we look at it in another. That is, there is a multiple perspective which is essential to an understanding of calculus.

How is this multiple perspective used? Consider, for example, the proof of the existence theorem for the differential equation

$$\frac{dy}{dx} = f(x,y); \quad y = y_0 \text{ when } x = x_0$$

One proof proceeds by rewriting the equation as an integral equation

$$y(x) = y_0 + \int_{x_0}^{x} f(t, y(t))dt$$

and then seeing that the solution is a fixed point of the contraction mapping

$$T(y)(x) = y_0 + \int_{x_0}^{x} f(t, y(t))dt \quad .$$

This proof is possible because of the dual representation of the calculus as derivative/integral. Mathematics is full of such dualities . Each of them adds depth and power to mathematics.

In summary these examples bring out the following points:

1. Many familiar mathematical concepts have an ambiguous or multi-dimensional nature. For example Thurston in the above quoted paper lists eight different ways of "thinking about or conceiving of the derivative." He insists that these are not different logical definitions. They are, however, different *insights* into the concept of derivative. Importantly Thurston warns us that "unless great efforts are made to maintain the tone and flavor of the original human insights, the differences start to evaporate as soon as the mental concepts are translated into precise, formal and explicit definitions." I interpret his comments to mean that the concept of the derivative is ambiguous. We may have many insights into the notion of derivative each of which teaches us something new about what a derivative is. These different insights may reduce down to the same formal definition but in doing so something of value is lost. That is, while the precision of formal, logically precise mathematics is

valuable, it is obtained at the expense of the loss of some insight or intuition which is also mathematically valuable.

2. This ambiguity is neither accidental nor deliberate but an essential characteristic of the conceptual development of the subject as well as of the person attempting to master the subject.

3. The ambiguity is not resolved by designating one meaning or one point of view as correct and then suppressing the others (although this is usually the student's preferred course of action). The ambiguity is "resolved" by the creation of a larger meaning which contains the original meanings and reduces to them in special cases. This process requires a creative act of understanding or insight.

4. Thus ambiguity can be the doorway to understanding, the doorway to creativity.

Conclusions

In conclusion let me point out that the whole of the above discussion is self-referential: not only is ambiguity part of mathematics but mathematics *itself* is ambiguous. Its nature is also multi-dimensional. There is the logical surface structure and the deeper dimensions of understanding, insight and creativity. It is not possible to imagine mathematics without its computational and formal aspects but to focus exclusively on them destroys the subject. Ambiguity, even paradox, push us out of our air-tight logical mental compartments and open the door to new ideas, new insights, deeper understanding.

Even the implicit "model" which might seem to be lurking in these pages is not correct. The different aspects of mathematics which we have described are in continual interaction, continual evolution. An idea like derivative is formalized. Thus in a sense the multiple possibilities contained in the informal idea are reduced to one. Then the formal idea can be understood in various ways, some of these retrieving some of the viewpoints that were inherent in the original preformal situation, others arise out of the interpretation of the formal definition of derivat[illegible]. These new ideas can themselves be formalized and so the whole chain is set in motion again. So a more complete way of looking at the situation is to say that though logic does tend to rigidify a situation, it also contains the seeds of further development.

Logic moves in one direction, the direction of clarity, coherence, structure. Ambiguity moves in the other, that of fluidity, openness, release. Mathematics

moves back and forth between these two poles. Mathematics is not a fixed, static entity which can be structured definitively. It is dynamic, alive: its dynamism a function of the relationship between the two poles which we have described above. It is the interactions between these different aspects which gives mathematics its power, its "unreasonable effectiveness." (Wigner 1960).

DISCOVERING THE STORY BEHIND THE SNAPSHOT: USING LIFE HISTORIES TO GIVE A HUMAN FACE TO STATISTICAL INTERPRETATIONS

Jean Carroll RMIT University, Melbourne, Australia

This paper reports on a study of primary school teachers' views of their own knowledge of and feelings about mathematics teaching and learning. A survey and statistical methods of analysis were used to gain a broad view of the different dispositions of 100 teachers in suburban schools in Melbourne, Australia. Eight different teacher types were identified and represented in a teacher type table. Life histories were then collected from five teachers, representing five of the teacher types, in an attempt to further understand the professional development of the teachers and the origins of their current cognitive and affective views. The interaction between the qualitative and quantitative methods of data collection and analysis are discussed in the process.

Not all questions that an educational researcher might be interested in answering can be answered by statistical study designs. Even where statistical methods are applicable, the educational researcher will often want to use qualitative data to help formulate interpretations of any particular statistical analysis. Interpretations of statistical studies in education are generally interpretations about the experience of actual people. This is a major reason for some form of qualitative data analysis to be a part of any educational study. The researcher's understanding of the lived experiences of the people she is researching is a significant contributor to the relevance of the findings to the practice of teaching.

The study presented here was designed to investigate the question: What are primary school teachers' views of mathematics and mathematics teaching and how do these views change? The importance of primary school teachers' understanding of and feelings about mathematics and mathematics teaching have been widely discussed (Carroll, 1997; Fennema and Franke, 1992; Kanes & Nisbet, 1994). One of the constructs at issue in this study was, what is the relationship between cognitive and affective factors in the teaching and learning of mathematics for primary teachers? Relevant literature (Leder, 1993; McLeod, 1992) and the research reported in this paper suggest that cognitive and affective studies remain incomplete and are theoretically reductive if the interaction of the two isn't acknowledged.

The initial phase of this research was quantitative and the results were presented in the form of a teacher type table (Table 1) that shows tendencies in primary teachers' perceptions of their ongoing professional ongoing learning and feelings about teaching mathematics. To understand the actual experiences referenced by the teacher type table, I collected a number of personal life stories which, when read in conjunction with the teacher types, gave a very human face to the teacher type table.

It is the process of seeing the human face behind research results that I wish to illustrate in this paper. To do this I will: briefly outline a methodological rationale for

BEST COPY AVAILABLE

taking life histories; describe the collection of the data; give the thematic analysis of the life histories; present the teacher type table; and then give a reading of the table in terms of the themes uncovered in the life histories.

Taking Life Histories

The stories of our experiences that we tell ourselves or others are a large part of what we take as our identity. There are a great many problems for a researcher in finding useful and controllable ways of accessing these stories. No person's full story is going to be exhausted in one interview session or indeed in the fullest written autobiography. In approaching the problem of collecting this data I made use of the methodology offered by Van Manen (1990). The method of data collection I chose was what Van Manen called "protocol writing". He defined protocol writing as, "the generating of original texts on which the researcher can work" (1990, p. 63). These "original texts" are ideally descriptions of experiences without causal explanations, generalisations, or abstract interpretations. They are not meant to be works of literature. How adequate the data is will depend on how well the researcher has conveyed her intentions for the piece to the participant and how able the participant is to respond.

Five teachers who worked at suburban primary schools in Melbourne expressed their willingness to participate in this study. They were asked to write a mathematical life history (Chapman, 1993) and given the following instructions:

> I would like you to write about your mathematical life history. Could you describe your experiences and feelings as you were learning maths at school and college/uni (etc) and your feelings about teaching mathematics to children over the years. I am interested particularly in the times when your feelings or understanding changed (either for the better or worse) and what or who you attribute the changes to. If you can remember any events that seem significant to you, please describe them in as much detail as you can remember. The mathematical life history is like a story of your recollections about maths and maths teaching. You should make it as long or as short as you feel is suitable.

Thematic Analysis of Life Histories

I analysed the data using a thematic approach. The notion of what a theme is and how one actually identifies it is not at all straightforward. Indeed themes, as used here, are as murky as lived experience itself. Uncovering a theme in a piece of protocol writing requires the empathetic understanding of the researcher. To understand why two humans can understand each other is to enter to the very heart of the present debate about the validity of human science research. An interpretation of text may, in fact, say more about the interpreter than the text or its author (for example, see Pimm, 1994). Thankfully, there is a practical solution to these concerns: if the meaning I see in a text, you also see in the text then we will take it to be there. What I'll mean by a theme is a phrase or word that seems to capture the point of a sentence or group of sentences as they are found in a number of stories.

Van Manen gave three practical approaches to discovering themes: the holistic or sententious approach; the selective or highlighting approach and the detailed or line by line approach. (Van Manen, 1990, pp. 92-93). The approach I adopted was what he called the highlighting approach. For each of the stories I would read them quietly and highlight key phrases, that is, the phrases I found to be particularly apt in expressing the experience being described.

Before presenting the analysis of this data I will give a summary of the results of the statistical analysis of a questionnaire, the Mathematics Attitude and Knowledge Scale (MAKS), designed for and administered to 100 Melbourne primary school teachers (88 females and 12 males). The MAKS was constructed to probe the interrelationships between cognitive and affective factors in the mathematics teaching of primary teachers (for a detailed account and analysis of this questionnaire see Carroll, 1998).

The Development of a Teacher Type Table

Factor analysis of the questionnaire data led to a four factor solution (using oblimin rotation on the pattern matrix of the factor analysis) which provided information about how the teachers: felt about mathematics teaching (Factor F); viewed their knowledge and feelings about mathematics (Factor M); perceived their knowledge of mathematics teaching (Factor K) and conceived of mathematics and mathematics teaching (Factor C). The teachers' scores on each of these factors were used to develop a teacher type table which identified different types of teachers and described tendencies related to mathematics teaching and learning. Only the first three factors (Factors F, M and K) were considered in developing the teacher types because these three contributed to the underlying construct; knowledge and feelings about mathematics and mathematics teaching, as identified in a principal components analysis. Factor C relating to the teachers' conceptions of mathematics and mathematics teaching was not included in the analysis of teacher types, since the items included in it showed little correlation with the principal construct.

The teachers' scores for each factor were said to be positive if they were above the mean factor score and negative if they were below the mean. These statistics were used to allocate teachers to one of eight teacher types which are shown in Table 1. The percentages indicate the proportion of teachers in each type.

Themes in the Life Histories

Life histories were collected from Ann, Betty, Cathy, Dot and Ellen who represented the teacher types; F-M-K-, F-M+K-, F-M-K+, F+M+K- and F+M+K+ respectively. These were the largest categories. The small size of the other categories made selection of teachers willing to participate difficult. The five teachers were female as none of the male teachers volunteered to take part in this aspect of the study. To report on the data contained in the life histories is a verbose procedure. To accommodate this to the present space constraints, I will briefly illustrate the themes

Table 1 Teacher Type Table

F-M-K- (23%) F- Negative **feelings about teaching mathematics** including lack of confidence and enjoyment and finding it threatening **M-** Knowledge and feelings about **doing or studying mathematics** are negative; have not done well at maths, maths is not the best subject and find doing maths problems frustrating. **K-** Lacking in **knowledge about the approaches for teaching mathematics to primary school children**	**F+M-K-** (3%) **F+** Positive **feelings about teaching mathematics** including confidence, enjoyment, excitement and finding it non threatening. **M-** Knowledge and feelings about **doing or studying mathematics** are negative; have not done well at maths, maths is not the best subject and find doing maths problems frustrating. **K-** Lacking in **knowledge about the approaches for teaching mathematics to primary school children.**
F-M+K- (13%) **F-** Negative **feelings about teaching mathematics** including lack of confidence and enjoyment and finding it threatening **M+** Knowledge and feelings about **doing or studying mathematics** are positive; have done well at maths, better in maths than other subjects and find maths problems interesting and challenging **K-** Lacking in **knowledge about the approaches for teaching mathematics to primary school children**	**F+M+K-** (8%) **F+** Positive **feelings about teaching mathematics** including confidence, enjoyment, excitement and finding it non threatening. **M+** Knowledge and feelings about **doing or studying mathematics** are positive; have done well at maths, better in maths than other subjects and find maths problems interesting and challenging **K-** Lacking in **knowledge about the approaches for teaching mathematics to primary school children**
F-M-K+ (11%) **F-** Negative **feelings about teaching mathematics** including lack of confidence, lack of enjoyment and finding it threatening **M-** Knowledge and feelings about **doing or studying mathematics** are negative; have not done well at maths, maths is not the best subject and find doing maths problems frustrating. **K+** Knowledgeable about the approaches for teaching mathematics to primary school children	**F+M-K+** (6%) **F+** Positive **feelings about teaching mathematics** including confidence, enjoyment, excitement, challenging and finding it non threatening. **M-** Knowledge and feelings about **doing or studying mathematics** are negative; have not done well at maths, maths is not the best subject and find doing maths problems frustrating. **K+** Knowledgeable about the approaches for teaching mathematics to primary school children.
F-M+K+ (5%) **F-** Negative **feelings about teaching mathematics** including lack of confidence and enjoyment and finding it threatening **M+** Knowledge and feelings about **doing or studying mathematics** are positive; have done well at maths, better in maths than other subjects and find maths problems interesting and challenging **K+** Knowledgeable about the approaches for teaching mathematics to primary school children	**F+M+K+** (31%) **F+** Positive **feelings about teaching mathematics** including confidence, enjoyment, excitement, challenging and finding it non threatening. **M+** Knowledge and feelings about **doing or studying mathematics** are positive; have done well at maths, better in maths than other subjects and find maths problems interesting and challenging **K+** Knowledgeable about the approaches for teaching mathematics to primary school children.

found in the data. A summary of the key dispositions expressed in each of the life histories in respect of each of these three themes is presented in Table 2.

Experiences as Students Each of the teachers wrote of significant experiences which occurred during their own school years in which their remembered perceptions of an event has seemingly influenced their self concept. For example, Ann wrote, "I remember reciting tables, however, to my father, and I know I knew them well...My father said I knew them well, but only because I had a good memory - he was right! - and I really didn't have a mathematical mind, as he did." Betty spoke about her school experiences, "My early years at the local technical school give me memories of challenging and enjoyable maths sessions and I seemed to 'breeze through'. I think in about year 9, I undertook Maths A and B and did very well in both."

For Ann, who has been teaching for over 30 years, the experience of learning tables with her father seems to have left her feeling that even though she could do her tables she couldn't do maths. On the other hand Betty's report gives the impression of thinking herself capable mathematically.

Personal Philosophy "Personal philosophy" in this context is considered here to be the expression of positions that convey a sense of coherence in self-understanding regarding teaching practice and personal history. For example, Betty says, "In conclusion, I think that it wasn't until I was teaching maths myself that I realised that there were better ways to teach/learn maths. As a student myself I don't think I knew any different... Maths skills are essential to our everyday lives so we have to ensure that students want to participate and learn the concepts involved." Betty's belief that mathematics should be personally relevant appears to stem from the lack of relevance of her experiences as a learner.

Ellen, in discussing the student teachers who work with her, says, "Comments from student teachers are interesting. 'I never knew why you did that until being here', is a common one and applies to basic concepts such as subtraction (decomposition). People still don't know why they do things! Rote still goes on!" It seems that Ellen does not believe in rote learning and is continually surprised that student teachers unquestioningly accept their own rote learning until being shown the reasons for procedures they have learned. Each of these quotations expresses a position and a reason for giving it. Insofar as position and reason are connected I take these quotations to be expressions of personal philosophies.

Significant Influences Significant influences are taken here to mean the descriptions of experiences that the writer takes as having informed an on-going change in her teaching practice and consequent self-understanding. For example, from Dot, "Lecturers during my teacher training were quite influential in helping me to develop in my teaching of maths, the qualities and approaches which had lacked in my own maths teachers." Ann commented on notable events that had improved her teaching, "Really getting into the team teaching area, guided by a very gifted and tactful coordinator. We did this for terms at a time, and although he took the maths measurement component,... he explained his operation in detail, and gave us such useful notes, that we were able to follow a similar model in future years. when he had gone into admin."

Interaction of themes In any particular piece of writing the themes are often woven very closely together and it would be a mistake to see them tied to particular sentences or paragraphs. The nature of a life history as a present expression of a complex past is illustrated well in this longer quote from Cathy:

> I also remember very clearly being very frightened in my maths in grade 4 because the teacher would come around with a ruler and the ruler was on its side and if you got things incorrect he would take the ruler and smash it against your knuckles so what I tended to do was be very very quiet, and try not to participate too much so that he would forget I was there, because I was very very scared of making a mistake. So of course, there was no push to have a go at it, like making mistakes are a part of life and I think that is something that I have learnt through my own experiences and its something I'm very conscious of in my own class - actually encourage the kids to be risk takers and they get rewarded for the tries that they have even if they're nowhere near correct, because otherwise they're going to do what I did and just go into the background and that's the end of that.

In this quote we see woven together the themes of "Experiences as Students" (grade 4...) "Personal Philosophy" (making mistakes is part of life...) and "Significant Influences" (in my own class...).

Table 2 Summary of Life Histories

Type	Ann F-M-K-	Betty F-M+K-	Cathy F-M-K-	Dot F+M+K-	Ellen F+M+K+
Training	2 years	4 years	2 years	3 years	2 years
Years teaching	31 years	7 years	17 years	10 years	30 years
Highest maths	Year 10	Year 12	Year 11	Year 12	Year 12
School experience	Negative episode recalled vividly. believes she is not mathematicall y minded	Positive, did well	Felt that she did not understand maths, all rote learning, vivid recollection of upsetting experience.	Positive experiences at school left feeling confident of her knowledge	Loved maths and did well although she didn't always understand
Personal philosophy	Not evident	Has ideas about how maths should be taught but finds them difficult to implement	Clearly developed based on own negative experiences a learner.	Reflection of lecturer's philosophy	Evident, well developed
Significant influences	Colleagues, team teaching, inspiring EMIC tutor, gifted tactful coordinator, the experience of teaching	Inservices, team teaching, publications, own experiences as a learner	Teachers' college, experience as a teacher, experiences as a learner, curriculum documents	Lecturer at teachers' college, own experiences as a learner EMIC program	Loved maths at school, very involved in professional development, her role of maths coordinator

A Reading of the Teacher Type Table in Terms of Selected Life Histories

The data collected in the life histories and thematised in Table 2 allows us to see the complex procedure of identity formation which is reflected in the snapshot of dispositions caught in the teacher type table. Connecting the themes with the types is necessary if the teacher type table is to be of use as an instrument of change for practising teachers. The life histories give a human underpinning to the scales expressed in the teacher types.

The life history data suggests that school experiences were important determinants of the teachers' present attitudes towards mathematics and views of their knowledge of mathematics. Ann and Cathy, whose scores were negative on Factor M (knowledge and feelings about doing or studying mathematics) in the teacher type table, described negative experiences of learning mathematics at school and described themselves as lacking in confidence in their knowledge of mathematics. They recalled mathematics learning as a predominantly negative experience involving memorising procedures of which they had little understanding. The frustration and lack of enjoyment that stemmed from these experiences was apparent in their histories which were written years later. Betty, Dot and Ellen, who were positive on Factor M, recalled school mathematics learning as involving more enjoyable experiences and rated their mathematical knowledge more highly. They also inferred that their knowledge of mathematics today is adequate or better.

Schuck (1997) identified different voices when teachers speak, which are apparent in the words of these teachers. She discussed "self as student" and "self as teacher" as two of the voices that teachers use. It is evident from the life histories and the teacher type data that the "self as student" continues to speak many years after the teachers have ceased to be students. The feelings about the "self as student" of mathematics appear to remain relatively unaffected by subsequent experiences of " self as teacher". Professional development for teachers like Ann and Cathy may need to allow them to acknowledge and understand this voice which continues to influence their views so strongly.

These views of mathematical knowledge and the associated feelings described by the teachers reinforce the notion that affective and cognitive factors are interwoven in the learning of mathematics. The interaction of cognitive and affective factors was also evident in the factor analysis when items loading on factor M consisted of those concerning feelings about learning and doing mathematics and as well as items related to knowledge of mathematics.

In discussing the influences on their professional development, the five teachers described situations in which significant personal relationships were established between themselves and a more knowledgeable person. The histories suggest that effective professional development occurs in a context of personal interaction. The interactions described were with lecturers, presenters, tutors, coordinators, peers, principals and other colleagues and were mostly the result of ongoing relationships, which ranged in duration from several months (in the case of lecturers and tutors) to several years (for relationships with peers and colleagues). These relationships were

important when they valued the teachers' experiences, included a climate of mutual respect and enabled learning to be collaborative.

The development of a personal philosophy appears to be linked to the development of the teachers' confidence in their knowledge of the approaches for teaching and learning mathematics. The life histories of Cathy and Ellen contain clearly enunciated personal philosophies for teaching. These two teachers were positive on Factor K (Knowledge of the approach for teaching mathematics). Ann, Betty and Dot's philosophies were less well developed and their teacher type indicated they lacked confidence in their knowledge of mathematics pedagogy.

Conclusions

The teacher type table was built from a statistical analysis. As pure research it could have been left as a completed entity. What I hope I have shown in this paper is that reading the table in terms of the actual lived experience of some of the teachers who participated in the study, gives the teacher types a meaning beyond the abstract and has the power to make the types personal for other teachers and provide information for those interested in professional development. Personal stories bring an understanding beyond the cognitive and their affective dimension often gives access to changed practice where a purely cognitive understanding does not.

RESEARCHING MATHEMATICS TEACHER THINKING

Olive Chapman
University of Calgary

This paper is a theoretical essay on researching mathematics teacher thinking. The focus is on a humanistic perspective of defining and researching teacher thinking and research tools that can be used to gain new insights about mathematics teachers= thinking and actions from the teacher=s perspective. Data collection using story and role play and the analysis process are highlighted and illustrated. This research approach has potential to contribute to understanding teachers and the teaching of mathematics in ways that could lead to more meaningful and effective teacher development experiences in order to facilitate meaningful reforms in mathematics education.

Introduction

If we accept that teacher thinking determines how the curriculum gets interpreted and delivered to students, then the nature of mathematics teachers= thinking becomes a key factor in any movement to reform the teaching of mathematics. A shift to a problem-solving approach to the teaching of mathematics, for example, will unlikely occur if teachers= thinking about the nature of mathematics and the teaching and learning of mathematics, consciously or unconsciously, is different from the intended theoretical perspective of such an approach. In recent years, there has been significant recognition of the teacher as the ultimate key to educational change. Teachers are not inert conduits through which the curriculum is delivered. Instead, it is what teachers think and do in the classroom that ultimately determines the kind of learning that students acquire. At a time when major reforms are being advocated in mathematics education it is, thus, of significant importance to focus on the mathematics teacher in order to facilitate the successful implementation of these reform recommendations. This paper is a theoretical essay on researching mathematics teacher thinking. The focus is on a humanistic perspective of defining and researching teacher thinking and research tools that can be used to gain new insights about mathematics teachers= thinking and actions from the teacher=s perspective.

Research on the Mathematics Teacher

Studies on the mathematics teacher have traditionally focused on deficiencies in teachers= behaviors and knowledge, i.e., what teachers do not do or do not know. One limitation of many of these studies is that they employed universal measures of teachers= knowledge that were not directly related to instruction in the mathematics classroom. Thus, it was often easy to find deficiencies since teachers= actions and knowledge were not necessarily considered in the context of the explicit goal of the curriculum or standardized assessment of students. For example, teachers would be tested on their conceptual understanding of mathematics when they came from a system that taught and tested computational skills. In recent years, most of these studies have focused on preservice teachers (e.g., Ball, 1990; Even, 1993; Graeber, Tirosh & Glover, 1989; Simon, 1993). But there has also been a shift to focusing on the beliefs of inservice teachers (Ernest, 1989; Thompson, 1992).

There now seems to be growing interest in understanding the mathematics teacher in terms of her or his beliefs/conceptions and the relationship between these beliefs and her or his teaching. But the tendency is still to judge the teacher by highlighting what are considered by researchers to be inappropriate and inconsistent beliefs. Although these studies produce useful insights about the mathematics teacher, they tend to provide a fragmented and decontextualized view of mathematics teachers= thinking. One reason for this is the narrow scope in which teacher thinking is defined and the nature of the research process being used. The intent of this paper is to suggest alternative ways for considering teacher thinking and its investigation that could make a meaningful contribution to our understanding of the teaching of mathematics as a lived experience in classrooms.

Defining Teacher Thinking

The description of what constitutes teacher thinking is not simple because of the philosophical and psychological considerations involved, and the growing number of viewpoints that are being adapted. In mathematics education, teacher thinking seems to be be equated with teacher beliefs/conceptions and teacher knowledge. But more generally, from a humanistic perspective, teacher thinking is defined to reflect the lenses teachers construct and use to make sense of their teaching. It refers to ideas in the mind of the teacher and ideas in practice. These ideas are the meanings the teacher uses to organize his or her knowledge of teaching and his or her behavior in the classroom. Thus, in addition to beliefs/conceptions, teacher thinking has been described in a variety of related ways, for e.g., frames (Barnes, 1992), images (Clandinin, 1985),personal practical knowledge (Connelly & Clandinin, 1988),practical knowledge (Elbaz, 1983), perspective (Janesick, 1982), and personal knowledge (Lampert, 1985).

Barnes defined frame as the clustered set of standard expectations through which all adults organize, not only their knowledge of the world but their behavior in it. Clandinin defined image as something within our experiences, embodied in us as persons and expressed and enacted in our practices and actions. Connelly and Clandinin defined personal practical knowledge as a moral, affective, and aesthetic way of knowing life=s educational situations. Elbaz defined practical knowledge as theoretical and practical components of teacher=s knowledge; knowledge as experiential, embodied and based in the narrative of experience. Janesick defined perspective as a reflective, socially derived interpretation of experience that combines beliefs, intentions, interpretations, and behavior and serves as a basis for subsequent actions. Finally, Lampert defined personal knowledge as knowledge used by a teacher in accomplishing what she/ he cares about, what students want, and what the curriculum requires. The underlying assumption to these viewpoints, then, is that what teachers do and think within their professional lives depends on the meanings they hold and interpret within their personal, social, and professional realities.

Humanistic Perspective of Research on Teacher Thinking

Research on teacher thinking can be considered in terms of an analytic/positivistic perspective or a humanistic perspective (Brown, Cooney, & Jones, 1990)where the former focuses on discovering reality in the form of value-free theory and the latter on understanding the contexts that shape a person=s perception of his or her reality. The

focus in this paper is on the humanistic perspective (e.g., Ellis & Flaherty, 1992).

Genuine humanistic studies on teacher thinking tend to focus on a teacher=s perspective of his or her classroom behavior, instead of a theoretical researcher=s perspective, in order to make sense of teaching. The theoretical researcher=s perspective considers teacher thinking in terms of predetermined categories imposed by the researcher.It focuses on a researcher=s view of how teachers think about their classroom behaviors based on models of teaching and teachers generated by researchers independent of teachers.These categories or models are generally embodied in surveys, questionnaires, observation instruments, and coding schemes. Teachers are generally seen to fit well within these models that are often set prior to data collection.

Studies based on the teacher=s perspective, in contrast to the theoretical researcher=s perspective, seek to understand teachers from their own perspective. The intent is to understand how particular individual teachers understand their work, for e.g., how does a teacher makes sense of the teaching of mathematics or of implementing mathematics reform? In this context, Chapman (1997) investigated how three teachers made sense of the teaching of mathematical problem solving. In general, studies based on the teacher=s perspective view teachers in a humanistic way, i.e., as persons who have something of value to contribute and not as objects of study. Teachers= actions are seen to have meaning in their situations or contexts. Thus, the focus of these studies is on conceptualizing the experiential knowledge of teachers and providing plausible explanations of teaching processes as they are for the teacher. In particular, teaching behaviors have to be understood in relation to the intentions of the teachers and to the situational complexity. For e.g., it is not the frequency of the questions in the classroom that is important, but, rather, what questions about what content is asked at what moment to what student.

Humanistic Research Process

In this section, the humanistic research process used in the studies on mathematics teacher thinking on the teaching of problem solving (Chapman, 1997; 1998) and an ongoing project investigating teacher thinking in teaching mathematical word problems will be used as a basis to consider some specific aspects of this process in the context of mathematics education. Given the constraint on space, the focus will be on general descriptions of two humanistic tools for collecting data (i.e., stories and role play) and of the analysis process.

Data collection

Whereas teachers= actions are observable, their thinking is not and must be inferred from what they say they do, what they say about what they do, and what they actually do in their classrooms. Thus, studies tend to depend on in-depth, open-ended interviews and classroom observations. Interviews are used, for e.g., to probe the constructs or meanings which teachers bring to their teaching and the relationships among these constructs. The teachers give their account on their own terms and not on terms imposed by the researcher. However, since taken-for-granted, underlying meanings of teachers= thinking are not readily accessible by the teacher and have to be accessed indirectly, it is important that these accounts include situations that embody such implicit meanings. Two ways found to be useful in the Chapman studies in this endeavor are

story and role play.

Story as Data: Story has been described as a Asymbolized account of actions of human beings that has a temporal dimension≅ (Sarbin, 1986, p. 3). A[It] is concerned with the explication of human intentions in the context of action≅(Bruner, 1986, p.100). Based on this view, in recent years, story has been promoted as a relevant form for expressing teachers' practical understandings because teachers' knowledge is event structured and stories would provide special access to that knowledge (Carter, 1993). Story/narrative has also been conceptualized as, Aa [cognitive] scheme by means of which human beings give meaning to their experience of temporality and personal actions ... a framework for understanding the past events of one's life and for planning future actions≅(Polkinghorne 1988, p.11). In general, then, the stories we tell reflect who we are and what we may become. They provide a basis for meaning recovery and meaning construction of our act-ions. Thus, they can facilitate interpretation and understanding of teachers= experiences.

Participants of a study could be asked to write or tell stories (and anecdotes) about past, present, and future experiences with mathematics and the teaching of mathematics. The stories should focus on the teachers= learning/doing of mathematics and teaching/ facilitating the learning of mathematics in the classroom. The participants could tell stories of their choice, for e.g., from different periods of their teaching career; of personal experiences with Agood≅ and Abad≅ teaching of mathematics; of mathematics lessons they enjoyed/liked/did not like teaching. They could also tell stories to support generalized claims they make during the research interview.The stories should describe a specific situation or event as they lived through it. So they should avoid causal explanations, generalizations, or abstract interpretations and describe the experience from the inside, i.e.,including feelings, emotions, and thoughts in action. These stories should include accounts of complete mathematics lessons that involve the teaching of a mathematics concept for the first time to a particular set of students. Such accounts should describe the lessons from beginning to end and provide as much detail as possible on what the teacher and students did and said in dealing with the mathematics and how the mathematics content was dealt with or presented.

Role Play as Data: Role play has similar characteristics to story telling in that it involves acting out the story and not just telling it. Thus instead of living out a situation only mentally by telling the story, one lives it out physically and mentally. The role play allows the teacher and researcher to experience and capture the teacher=s thinking and instructional strategies from different angles. It also provides opportunities to magnify specific aspects of the teacher=s classroom behaviors that could reveal underlying meanings of the behaviors. The role play, then, should follow observations of the participant=s behavior in the classroom. Such observations should be used to get a sense of the tone of the participant=s classroom and teaching and to identify specific situations that set this tone. Examples of such situations are:

(i) teacher modeling a mathematics concept or procedure;
(ii) teacher-student discourse used to develop a mathematics concept/procedure;
(iii) teacher intervention: (a) when students are not experiencing difficulties with the concept or procedure, (b) when students are experiencing difficulties with the

concept or procedure,(c) during individual student work, (d) during group work. These situations become themes for the role play. Thus the role play is guided by the participant=s lived experiences. For example, one participant=s teaching may involve situations (i) and (iii) a, b, c, while another may involve (ii) and (iii) a, b, d.

Using situation (i) (i.e., modeling a mathematics concept) as an example, the role play can unfold as follows: First, the participant teaches a mathematics concept from her or his curriculum in the way she or he would to a whole class. The researcher observes the teaching process focusing on what he or she would do in order to reproduce it. Second, the researcher plays the role of teacher and teaches the same concept under the direction of the participant in order to teach the lesson like him or her. Third, the researcher re-teaches the lesson without any help from the participant, using the participant=s approach. The participant observes the teaching process focusing on points of conflicts with his or her expectations. Finally, the researcher teaches the lesson using an alternative approach while the participant focuses on identifying points of conflicts with his or her teaching. Each of these stages is accompanied by a discussion with the participant on his or her intentions or reason behind his or her thinking.

Analysis

Making sense of the data collected is a crucial and difficult aspect of qualitative inquiries. One large area of choice is that of level of interpretation to be employed. However, to be prescriptive regarding the analysis process is problematic because, for humanistic studies, the context of a particular case significantly influences how the analysis actually unfolds and such contexts cannot be generalized (i.e., to generalize will be to revert to a positivistic framework). Thus, what is presented here is one way in which the analysis can unfold based on the approach that evolved from Chapman=s work on the mathematics teacher. This approach consists of four related phases.

The first phase makes explicit the researcher=s original meanings. These meanings are the researcher=s initial, spontaneous interpretation of how the teacher thinks and acts in the classroom in teaching mathematics. This interpretation tends to evolve during data collection while the researcher is listening to or observing the participant, and before reflecting on the transcripts. It is usually judgmental, based on a view unintentionally imposed by the researcher in response to an apparent, familiar pattern of behavior that seems to be obvious. Thus this interpretation attends to surface meanings and does not take into account the teacher=s assumptions and intentions. It forms a baseline beyond which the researcher aims to reach in order to understand the teacher=s meaning and not simply to justify that of the researcher. The second phase of the analysis focuses on the participant=s explicit or espoused meanings. These meanings are determined by reviewing the data in order to identify explicit statements about the teacher=s beliefs, intentions, and expectations. These statements are then clustered to form themes that are characteristic of the teacher=s thinking and behavior. These themes become the basis for understanding the teacher=s perspective but are not in themselves necessarily the underlying meanings.

The third phase of the analysis focuses on the participant=s implicit meanings. This involve reflecting on the data in order to identify plausible explanations and descriptions of the meanings underlying the themes from the second phase. Since these

meanings are implicit, the stories and role play become very important for providing indirect access to them and to make them explicit. Thus, the stories, anecdotes, and role-play transcripts are reviewed in order to identify, for e.g., similarities in plots for different stories, points of strong emotions, and statements and actions that convey personal meanings (e.g., those that reflect personal judgement, intention, expectations and values of the participants) that reoccur in the various events described. During this review, new themes can emerge from the data in addition to those in the second phase. This review leads to particular meanings behind the teacher=s instructional behaviors and understanding of the themes in terms of the teacher=s lived experiences in the classroom. Finally, the fourth phase of the analysis focuses on the configuration of meanings and themes. This involves identifying coherent patterns from separate meanings and themes, as understood by the researcher, in order to provide a holistic perspective of the teacher=s thinking.

It is important that the participants play a role in the data analysis if the goal is to gain understanding from their perspectives. This role can be very involved, as in Chapman (1997), or minimally involved, as in Chapman (1998). In the former, the researcher collaborates with the participants in the third and fourth phases. Thus, for example, the participants can independently identify meanings/themes implicit in their actions, which the researcher use to compare with hers or his and negotiate differences with the participants. In the minimum involvement, the participants comment on the findings by the researcher in the third and fourth phases. In general, the outcome of the analysis should make sense to the participants in that if it provides a plausible way of understanding their thinking, they should be able to resonate with it explicitly and implicitly/intuitively.

An Example

This section presents a very small part of Tad=s case as an example to illustrate the methodological considerations previously discussed, focusing on the four phases of the analysis process. Tad is one of the participants in an ongoing project on teacher thinking in the teaching of mathematical word problems. Tad is an experienced high school teacher who is considered to be a very good teacher.

Phase 1 of analysis: The focus of the researcher=s original meaning was that Tad=s teaching seemed to be very traditional. He would model two examples of the word problems then have students work individually on practice questions while he circulated and provided help. During the modeling he seldom asked questions but students could ask questions for which he provided the answer.

Phase 2 of analysis: One of Tad=s explicit meanings was that his teaching was interactive, i.e., he liked to get the students involved in the lesson. Tad=s explanation of what he meant by interactive was that it involved getting students to ask questions. In general, Tad saw himself as a student-centered teacher. What interactive meant from Tad=s perspective was considered a theme for further investigation.

Phase 3 of analysis: Tad=s implicit meaning for this theme was determined by examining teacher-student discourse in the data, e.g., the nature of questions he asked/encouraged, the nature of his responses to questions, the nature of his intention of

his responses, and his emotions associated with questioning. The outcome of this examination included the following:

Tad viewed interactive teaching in terms of the quantity and nature of questions asked by the students and not by the teacher. He felt good when the students asked a lot of questions about the mathematics concept being presented and disappointed when they did not. He liked to be asked questions that involved higher level thinking, e.g., Awhy≅ questions. The role play created conflicts for him when no Awhy≅ questions were asked. Although Tad did not ask questions to reveal students= thinking during the presentation of the mathematics concept, his teaching was dependent on the students= questions that he encouraged. Tad used the nature of the students= questions as an indication of their thinking. But he also wanted to be asked questions in order to display his thought process and not just factual knowledge. He wanted students to learn from his thought process and not just his telling. He expected students to resonate with his thought process in order to compare their thinking, but not to just mimic a specific set of procedures. Students could use their own procedures that made sense to them. Thus it was during individual work, when students needed help, that Tad would ask them to reveal their thinking in order to allow him to intervene effectively. The Awhy≅ questions asked by students allowed Tad to elaborate on his thinking in terms of what the students wanted to know. In this sense, his teaching was student-centered in that the students determined the scope of what he presented. From his perspective, students will learn mathematics with understanding by seeing the thought process of the teacher in solving a problem in terms of what both the teacher and students considered to be important. Thus his teaching was a collaboration between him and the students.

Phase 4 of analysis: The analysis of Tad=s case is still in progress, therefore a configuration of themes has not been determined. However, in Chapman (1997), the configuration of themes was presented in the form of metaphors. For e.g., Aadventure≅ was used to portray one of the participants= teaching of problem solving in a holistic way in terms of the underlying meanings framing her classroom behavior. The configuration of themes could also be presented in the form of case narratives.

This sample of the analysis of Tad=s teaching, although only a small part, suggests that while his teaching seemed to be traditional on the surface, the underlying meanings provided a different understanding that begins to reflect how and why his approach was considered successful in helping students to learn senior high school mathematics. Tad=s case also begins to provide insights about teacher-student discourse that could contribute to understanding teaching approaches for high school mathematics and form a basis of future research or teacher development activities.

Conclusion

A genuine humanistic perspective to researching mathematics teachers aims at understanding the teaching of mathematics from a teacher=s perspective. Thus it requires the researcher to not be judgmental, but to seek understanding of the teacher in a holistic way. This research approach has potential to contribute to understanding teachers and the teaching of mathematics in more realistic ways than research that studies the teacher as objects. It can also provide insights to enhance professional development experiences of mathematics teachers in order to facilitate meaningful reforms in mathematics education.

WHAT KIND OF MATHEMATICAL KNOWLEDGE SUPPORTS TEACHING FOR "CONCEPTUAL UNDERSTANDING"? PRESERVICE TEACHERS AND THE SOLVING OF EQUATIONS

Daniel Chazan, Cesar Larriva, & Dara Sandow

Michigan State University

In this paper, we explore the appropriation of categories for describing classroom activity and student understanding which exist in the literature for use in the task of describing qualities of teachers' substantive knowledge of the mathematics they teach. In characterizing the resources which teachers have for use in their teaching, such a description of teachers' mathematical knowledge seems potentially more useful than cataloguing the amount of coursework taken. In particular, we use tasks which have been explored in the existing literature on the solving of equations and questions about teaching students to solve linear equations in order to surface preservice teachers' substantive knowledge of this sort of task. In the paper, we raise the question of whether finer distinctions are necessary for describing teachers' substantive knowledge of the mathematics they teach.

Objectives/purpose

When discussing the mathematical preparation of teachers, the amount of coursework taken is often used as a crude measure of prospective teachers' content knowledge (Ball, 1992) and of the mathematical resources which they bring to teaching tasks. This exploratory study builds on work describing students' understandings of mathematical topics with the goal of learning to describe qualities of teachers' substantive knowledge of mathematics (not their pedagogical content knowledge or their knowledge about the nature of mathematics). As part of a larger study of the impact of different clinical settings on the nature of preservice mathematics teachers' substantive mathematical knowledge, we seek a vocabulary for describing differences in the qualities of teachers' knowledge of a particular mathematical topic, rather than relying on the quantity of coursework they have completed. In this part of the study, we raise questions about categories currently available in the literature for this task.

We have chosen to examine the issue of the qualities of teachers' knowledge of mathematical content by exploring preservice teachers' knowledge related to teaching the solving of equations. We would like to explore connections between the nature of a teacher's own understandings of solving equations and systems of equations and their notions of how to help students understand why some linear equations have no solution or infinitely many such solutions (for example, why solving such equations symbolically results in equations like $0 = 0$ or $2 = 0$). With the current North American secondary school focus on graphing calculators and

functions-based approaches to algebra, preservice teachers may choose to view the literal symbols in such equations as either variable quantities or unknown numbers; they may have seen approaches to solving linear equations by graphing each side of the equation, as well as methods which focus on the writing of equivalent expressions. As a result, this particular topic challenges us to develop descriptions of teachers' content knowledge which are applicable across different approaches to conceptualizing the same content, rather than simply assuming that a particular approach necessarily is an indication of a particular type of mathematical understanding (Masingila, 1998). For this reason, this topic is especially valuable and challenging as a locus for the study.

Perspective or theoretical framework

As part of attempts to change the nature of mathematics classrooms, there have been efforts to indicate ways in which mathematical activity in classrooms can differ. Skemp (1976) proposes that there are two sorts of understandings of mathematics that are the goals of classroom activity (Incidentally, this reading was used with the preservice teachers (interns) studied in this project and influences some of the interview comments presented below.). For Skemp, *relational understanding* includes an *instrumental understanding* of what to do in order to solve mathematical problems plus an understanding of why such procedures work. In passing, he suggests that "nothing else but relational understanding can ever be adequate for a teacher" (p. 13). Hiebert and Lefevre (1986) use different terms. They suggest that *conceptual knowledge* "is characterized most clearly as knowledge that is rich in relationships" (p. 3), while *procedural knowledge* consists of knowledge of the representations systems used in mathematics and algorithms for completing mathematical tasks (p. 6). They view these two types of knowledge as intimately connected. Similarly, in order to describe differences in classroom discourse and in teachers' instructional goals, Thompson, Philipp, Thompson, and Boyd (1994) distinguish between *calculational* and *conceptual* (as well as, in passing, *computational*) *orientations in the teaching of mathematics*. Building on this work, Cobb (1998) uses the terms *calculational* and *conceptual discourse* to describe differences observed in classrooms.

All of these sets of terms are aimed at creating categories to describe differences in classroom activity which are experientially vivid to the authors. And, in general, they have been used to encourage greater attention to issues of relational understanding or conceptual knowledge. Perhaps because examples of attention in classrooms to such understanding is relatively rare, it is easier to describe the instrumental, procedural, or calculational part of the divide. These adjectives describe orientations towards teaching, individual knowledge, understanding, or classroom discourse which are prevalent in many classrooms and focus on procedures for calculating the solutions to given mathematical tasks. It is the relational, or conceptual, side of the divide whose definition is more complex. But, it is precisely this side of the divide that we require in order to understand whether

teachers have subject matter knowledge which will support teaching for conceptual understanding. For example, Skemp (1976) and Hiebert and Lefevre (1986) use a criterion of interrelationship. Yet, this criterion is clearly not sufficient for distinguishing conceptual from procedural knowledge. Procedures can become quite complex and related to a host of other procedures and symbols systems without necessarily involving a conceptual understanding or orientation.

When faced with this difficulty, Thompson et al. (1994) use vignettes involving a traditional word problem to distinguish between calculational and conceptual orientations to mathematics teaching. In the context of this sort of problem, they point to ways in which one teacher continually asked students to refer their calculations back to the situation described in the word problem. The other teacher let the classroom discourse focus on the calculations and not their meaning in the situation (p. 86). However, these criteria are limited to discussion of classroom activity that results from a problem that is situated in some sort of extra-mathematical context.

Chazan (in press) takes a different approach. In discussing standard exercises not situated in an extra-mathematical context, he focuses on whether or not an approach to teaching a particular content area identifies the mathematical objects of that content area and provides students with task instructions that identify the goal of the task in terms of these objects.

Methods of inquiry

In this study, we explore whether the sets of terms proposed in this literature seem useful in describing preservice teachers' understandings of tasks involving the solving of equations and their notions of how to help their students with such tasks. To explore these issues, we have created an interview focused on the solving of equations and systems of equations. The interview consists of two parts. The first part focuses on a phenomenon of teaching. Early in their internship year, the preservice teachers were asked how they might help a student who does not understand why one sometimes gets 0=0 or 2=0 as the solution of a linear equation when solving with algebraic symbols.

The second part of the interview asks the preservice teachers to tackle mathematical problems which have been used in research on student understanding of the solving of equations (From Sfard & Linchevski (1994, p. 218): Will the following system of equations always have a solution? k-y=2 and x+y=k; from Schoenfeld (1985): What is the solution set for $x^2y+y^2x = 1$?). This part of the interview attempts to elicit whether the prospective teachers view the x's and y's in equations as variable quantities or unknowns and to explore the nature of the representations which they feel can be used to solve such problems.

A final question asks the interviewees to indicate what equations are and what it means to solve equations.

This paper will describe the data from one interviewee whose understandings are difficult to categorize. We will use this data to raise questions about the utility of distinctions made in the literature for the task of identifying qualities of teachers' content knowledge.

Presentation and analysis of the data

At the end of the interview, when the intern was asked what she would tell students an equation is or what solving equations means, this intern's perspective was based in the interpretation of literal symbols as unknown numbers. She said: "...that's how I define an equation, is that it has an equal sign in it." and similarly "To solve an equation means you find the unknown value that makes both sides of your equation equal, that's what solving an equation is.... You're looking for the unknown value ... that makes both sides of the equation true." Yet, in other parts of the interview, she used techniques that might be viewed as in tension with this perspective.

When faced with the question of helping a student understand the meaning of the solution to $3x+7 = 2(x+5)+x-1$, this intern indicated that such questions were about to come up in one of the classes she is teaching. Her responses involved the use of graphical representations using a two dimensional Cartesian plane. Such an approach was suggested by her textbook, but she had her own preferences which differed slightly from the book:

> ... what the textbook does is teaches them to subtract everything over so that one side is zero and then graph it so that the solutions will be the x-intercepts.... Actually, just the x coordinates.... I'm going to be a rebel, I think and I'm going to make my students do this instead, graph y equal to this side as one equation and y equal to this side as one equation and see where the lines intersect.... That's where the x and the y are both the same. If the y's are the same, then these two have outputs that are the same.... So looking at these two [the expressions on either side of the equation as she's rewritten it, $3x+7 = 3x+9$], I have parallel lines. I have both slope 3 and different y intercepts. So that's how I'm getting, how I'm not getting the solution for x.

Her focus on graphical representations seemed to flow from a desire to help students develop a deeper understanding of the solving of equations: "If they were solving this equation, I think they're just solving for an unknown, and if they're doing this algebraically, it's really procedural and I don't know if they have a great understanding of what's going on." She seemed aware that the use of this sort of graphical technique involved a different interpretation of literal symbols. On the other hand, the notion of functions was not explicitly part of her discussion; $y=3x+7$ and $y=2(x+5)+x-1$ are both viewed as equations and not as functions. Thus, in her view, when graphing these two "equations," one now has a system of equations. However, by considering the solution to the "system" of equations $3x+7=2(x+5)+x-1$ as the x coordinate of the intersection of the two "equations," she

is treating the "system" like a single equation whose solution is a set of values, rather than a system of equations whose solution would be the coordinates of a set of points.

> I guess it's thinking about a variable in a really different way, so. But when you're solving this kind of a system, the x is an unknown, but when you're graphing, you're thinking about y and x, all possible solutions, kind of different concepts. I wonder if that makes it confusing at all for students.... Now [indicating y=3x+7 and y=3x+9], I have a system of equations.

But, it wasn't that these sorts of graphical techniques were a "trick" that was somehow new to her repertoire. Graphing seemed a strong and integrated part of her approach to the solving of equations that were more complex mathematically. Thus, when approaching a system of equations in two variables with one literal coefficient, k-y=2 and x+y=k, she solved the problem graphically. Her solution was quick and confident, though she only answered the question as posed and did not go on to characterize the nature of the solution set (as do some of the interviewees in Sfard (1994)).

> ... what you're asking is for every k, is there a solution x and y? Okay, well I was looking at this and thinking this is a system of two lines and then I just noticed that I have k - y=2. That line is a specific y equals line... y= k-2. ... if this one has a slope zero, so that's going to make it a lot easier to think about this one as y = -x + k. So if I'm thinking about graphing this ... that hits, my intercept is k and the slope is negative, so I'm going to get a line like this, so there is a specific point of intersection. So there is a solution, now is there a solution for every k? Well, if I vary k along the y axis, it seems like there would always be a solution to me.

Similarly, when approaching the single equation in two variables in which the variables cannot be untangled, $x^2y + y^2x = 1$, she immediately thought of graphing each side on a three dimensional coordinate system. Though she did not produce a solution, she was not overwhelmed by the problem and made productive strides towards describing the nature of the solution set.

> ...either one of them can't be zero, so I'm never going to have that type of a solution. Okay, this looks three-dimensional.... It does because, well then I can graph this [the left side of the equation] and it's some kind of plane intersecting with a plane z=1. So maybe if I fooled around, I could figure out, you know, what x and y would have to be to equal one, but maybe there' s not any solutions, or maybe there's a lot of different ones that occur different places. Cause this type of thing being $z = x^2y + y^2x$, might be really wavy. I'm not really sure what it looks like. Because I have, my variables are multiplied together, so that's kind of something that I'd have to sit and think about (laughs)

> for a really long time before I could get a picture. I think that I would go right to my computer and graph that... I have a 3-d graphing calculator on my computer at home.... It would probably be easier if I chose certain planes for y. Say, y equals one, and then look at what I'm left with, I'm left with $x^2 + x$ and $x^2 + x$ is just a parabola, so I have for the plane y = 1. That's this plane, I get some kind of a parabola. I think I did that right. And if I chose x =1, then I would just be getting in the x =1 plane, I would be getting $y + y^2$, which is also an upward parabola. So it looks like there is a couple different places where it's going to cross.

Frustrated by her inability to present the interviewer with a solution, the intern then said:

> I am thinking maybe I did some stuff like this in multivariable calculus. And that I am just not clicking with remembering the procedures for figuring out. I think that I have a relational understanding of what's going on with the situation.

To what extent does this intern's substantive mathematical knowledge support teaching for a conceptual or relational understanding of the solving of equations?

At the level of espoused beliefs, this intern has a conceptual orientation towards teaching. In discussing the solving of equations, she explicitly refers to a relational understanding and would like to offer her students more than what seems to her to be procedural skill. Though we may argue about exactly where to draw the line for conceptual understanding, arguably this intern has a conceptual understanding of this topic. She is able to solve a variety of problems involving the solving of equations. In doing so, she makes use of a similar strategy throughout and seems to have a well-connected understanding of relationships between problems of different types. She strives to answer the question of why a particular equation in one variable would not have a solution and why a particular system of equations will have a solution for any value of k. She can explain the goal of solving linear equations and how graphing both "sides" of the equation helps one find the unknown number for which one was searching. Though there are some tensions between the method that she chooses to solve equations and the way in which she defines the nature of the task, perhaps this is only natural. After all, Sfard and Linchevski (1994) suggest that competence in algebra involves versatility and adaptability in the interpretation of symbols. They suggest that in solving algebra problems a person oscillates between operational approaches and a variety of structural ones.

However, we are concerned that this intern's substantive mathematical knowledge does not provide sufficient resources for the development of her students' conceptual understanding. As she pointed out, and we concur, one might be concerned that her students will become confused. If any string of symbols with an equal sign is an equation, and thus some functions can be represented by equations,

how does this fit with the notion that only some equations are functions? If one solves an equation in one unknown by adding an implicit unknown and then solving a "system" of two equations in two unknowns by looking at the intersection point of two lines, how will students understand why the solution to such "systems" are different than the solutions to problems which begin with a system of equations in two unknowns?

In addition to the potential for confusion, we wonder whether, by teaching this graphical strategy, this intern would simply be teaching a new procedure for the solving of equations, rather than helping her students develop a conceptual understanding. Would she be able to articulate why this procedure works and why it is a legitimate way to seek the solution to an equation? We are not sure. We might argue that though this intern may have a conceptual orientation towards teaching, there is a fundamental confusion within her conceptual understanding. Contra Sfard and Linchevski, we might argue that there is a contradiction between her definition of an equation and its solution and her methods for solving equations.

Is it that a functions-based approach reduces simply to a different procedure for solving equations and doesn't offer a qualitatively different understanding of the domain (as we felt in reading Massingila, 1998)? We would disagree (see Chazan, in press). Perhaps, in this case, if the intern had made more explicit connection of this graphing technique to functions rather than equations, we might be more sanguine. Alternatively, perhaps our interview's focus on a particular problem type was too limited. Maybe if we had asked the intern how instruction over the course of the year would help students become prepared for this sort of task, then she might have been able to articulate how they would come to learn this technique in integrated way and not as an isolated procedure.

These concerns make us wonder about using descriptions like conceptual or procedural understanding for an examination of teachers' substantive knowledge of mathematics. Perhaps the difficulty is that conceptual understanding is not an "achievement," that is, something that one either has or does not have. Instead maybe one can have conceptual understandings of different kinds, including partial, or confused, conceptual understandings. Perhaps, discussions of the sorts of understandings useful for supporting teaching for conceptual understanding might be more usefully organized around a set of dimensions, for example: To what degree is the teacher able to articulate the goals of a problem in terms of relevant mathematical objects? To what degree is the teacher able to relate situations and the mathematics used to model situations? To what degree is the teacher able to provide justification for why procedures work? To what degree are there matches between the teacher's definition of the goal of a task and the procedures used to reach those goals? To what degree is the teacher aware of inconsistencies in his/her own understandings? In this sense, having a conceptual orientation to teaching and a conceptual understanding of a topic might not mean that one has sufficient subject matter resources for teaching that topic.

A RECIPROCAL MODEL RELATING SELF ESTEEM AND MATHEMATICS ACHIEVEMENT

Constantinos Christou*, George Philippou*, Maria Heliophotou**
*University of Cyprus, P.O Box 537, Nicosia Cyprus, **Cyprus College

In this study we developed a model relating general self-esteem and mathematics achievement through basic intervening variables supported by social cognitive theory. A structural equation model was developed to examine the paths from mathematics achievement to general self-esteem and vice versa trough mediating variables. The data, collected from 308 preservice primary school teachers, provided a good fit to the developed model, indicating an indirect reciprocal causal relationship between self-esteem and mathematics achievement.

Background and aims

Knowledge, skill, and prior attainments are often poor predictors of subsequent success because self-perceptions powerfully influence behavior. The beliefs that people have about themselves are key elements in personal self-evaluation and behavior prediction. Bandura (1986) considered self-reflection and self-evaluation to be the most unique human abilities and believed them to include perceptions of self-esteem. The concept of self-esteem is not uniquely defined in the literature. Kahne (1996) considers self-concept (SC), self-esteem (SE) and values to comprise the three dimensions of self-perception. SC refers to the descriptions we hold for ourselves and SE refers to the level of satisfaction we attach to those descriptions. Similarly, Kohn (1994) defines SE in terms of the "personal judgement of worthiness that is expressed in attitudes the individual hold for himself" (p.273). On a rather different line, Byrne seems to equate SC to "perceptions of ourselves" and in specific terms as "our attitudes, feelings and knowledge about our abilities, skills, appearance and social acceptability" (1984, p.429).

Self-esteem judgements reflect evaluations that can be either task oriented or ego oriented (Kahne, 1996). Task oriented evaluations are based on self-efficacy beliefs while ego oriented beliefs derive from perceived social differential characteristics. The issue in the former case is to enhance skills, while in the latter case, the issue is to establish superiority over one's mates. In either case SE is postulated to affect behavior, as people tend to engage in tasks in which they feel competent and avoid tasks in which they do not. High SE helps to create an environment in which individuals choose to undertake difficult tasks and activities, while feelings of low SE develop a sense that the obstacles are insurmountable, foster stress, and narrow the vision. Consequently, SE can be considered both as a determinant and a predictor of the level of accomplishment that individuals finally attain.

Studies of the causal relationships between academic achievement (AA) and general self-esteem (GSE) have tended to focus on connections between AA and

GSE via academic self-concept (ASC). Early research reports have mentioned causal connections leading from AA to ASC and then to GSE (Byrne, 1984). On the other hand, causal paths have also been found flowing from GSE or ASC to AA (Marsh, 1990). An increasing number of reports have come to agree that the causal relationships are reciprocal rather than unidirectional (Marsh, 1993).

For some time attempts to examine reciprocity paid little attention to subject specificity (Marsh & Yeung, 1997). Though a generalized academic affect may be appropriate in some situations, there is an implicit underlying assumption that measures of affect vary substantially over different school subjects. Marsh and Yeung (1997) rejected the idea of a model that posited a single higher order dimension of academic self-concept, and described a model in which SC is subject specific. Moreover, Marsh (1993) referred to a growing body of research showing that verbal and mathematics SCs are nearly uncorrelated. He concluded by rejecting the usefulness of measures of general academic self-concept as a summary of SCs in specific school subjects, when there is no correlation among th[illegible].

In this study, we examine the reciprocal relationships between MA and GSE of preservice teachers, considering that the relationship between AA and SE is subject specific. What is new in this study is the inclusion of intervening variables that refer to preservice teachers' confidence in doing and teaching mathematics. Thus, the main purpose of this study was to examine how specific variables of teaching mathematics influence the GSE of teachers by including intervening variables that are more suitable for the pre-service teachers. To this effect, we developed another construct, the teacher's self-esteem of mathematics, which is hypothesized to influence their GSE. Specifically, the study addressed the following questions: Are the relationships between MA and GSE reciprocal? If yes, what variables mediate this reciprocal relationship? Are there differences in the structure of pre-service teachers' GSE in terms of their gender? The latter question is related to earlier findings that general and academic self-concepts are more highly correlated with the mathematics SC for boys and more highly correlated with the verbal SC for girls (Marsh, 1993).

Method

To answer the research questions we estimated a theoretically informed multivariate causal model in which the hypothesized reciprocal relationships are decomposed through the introduction of mediating psychological constructs. The proposed model is based on the theoretical assumption that views SE as both a "social force" and a "social product". In the context of mathematics learning and teaching, SE is seen both as influencing and being influenced by the mathematics achievement of pre-service teachers. The model assumed that MA (F4) affects students' GSE (F1) through four intervening latent factors:

- Students' perceptions of teachers' appraisals about their own capabilities in mathematics (F5).

- Students' perceptions of their comparative performance in mathematics (F6),
- Students' perceptions of their ability to teach mathematics as compared to their classmates (F7),
- Students' confidence in teaching mathematics (F8).

Similarly, we proposed that GSE enhance MA through two mediating factors: motivation (F2), and anxiety (F3).

The model was tested against the data collected from all freshmen and sophomore preservice teachers admitted at the University of Cyprus in 1977 on the basis of competitive examination scores. Using listwise deletion of missing values, the final sample included 308 students. Of these 28% were males and 72% females. Mostly we used three observed variables to identify each latent variable (F1 to F8), since a larger number is technically unnecessary. Table 1 shows the latent variables, and the loadings on each item for males and females.

Results

All indicators load strongly and distinctly on each of the latent constructs for both groups. Table 1 shows that the standardized loadings are all above .35 with the exception of the first variable on the Motivation factor, which are quite low for both groups (.142 for females and .114 for males). These findings indicate that the hypothesized structures can be adequately represented through the first-order factors. More precisely, we found that the reciprocal relationship between GSE and MA can be represented by the hypothesized 8 first order factors. The negative sign of the third indicator of the GSE factor, which holds true for both the male and the students, reaffirms previous results that students' GSE is lower when they feel that they should respect themselves more than they do.

The analyses were conducted with covariance matrices, since the focus of the study was on the testing of the invariance of factor loadings and factor regressions across the male and female pre-service teachers. We began with the least restrictive model in which only the form of the model, i.e., the pattern of fixed and non-fixed parameters is invariant across groups. The initial baseline model is "totally non-invariant", as no between-groups invariance constraints were imposed on estimated parameters (Table 2). This model provided the basis for all subsequent models in the invariance hierarchy.

In the first stage we tested the ability of the model to fit the data separately for each of the two groups with no invariance constraints. The parameter estimates were reasonable for both groups in that all factor loadings were large and statistically significant and the patterns of correlations were logical and consistent with previous research. Moreover, the goodness of fit index was good in relation to typical standards. Table 2 shows that the Comparative Fit Index (CFI) for the total sample was .914, which indicates a "good fit".

We pursued two more specific tests imposing invariance constraints for sets of parameters (factor loadings, and regression correlations and factor variances) across the two groups, to test for gender differences. We began with tests of the

Table 1: The Factors, and the Factor Loadings of the Observed Variables

Factors	Items	Factor Loadings	
		Females	Males
F1. General Self-esteem	On the whole, I am satisfied with myself.	.666	736
	I take a positive attitude toward myself.	.689	.756
	I wish I could have more respect for myself.	-.427	-.436
F2 Motivation	I have had the feeling of wanting to quit school.	.142	.114
	I have had the feeling of wanting to quit university.	.445	.450
	I was not interested in school maths at high school.	.771	.791
F3 Anxiety	I feel nervous when doing mathematics.	890	.886
	I feel my hands sweating when working with problem solving.	.864	.860
	During the past year, I felt that I was going to have a nervous breakdown due to mathematics.	.764	.787
F4: Mathematics Achievement	Grades in mathematics at high school.	.747	.709
	Grades in mathematics in university math courses.	.365	228
F5: Perceived Teachers' Appraisals	My math teachers were not interested in what I did in maths.	.355	.325
	By my teachers' standards I was not good in maths.	.751	.924
	My teachers did not appreciate my abilities in maths.	.606	.614
F6 Perceived Comparative Performance in Mathematics	I believe that in maths I am better than many of my classmates.	.797	.857
	I believe that I can understand mathematics better than my classmates.	.940	.911
	I believe that I am one of the best students in maths	.741	.673
F7 Confidence in Teaching Mathematics	I feel confidence in teaching maths.	.677	658
	I feel confidence in explaining maths.	884	876
	I believe that I will become a good math teacher	.758	.777
F8 Perceived Comparative Ability of Teaching Mathematics	I believe that I can teach mathematics better than my colleagues.	883	.911
	I believe that I will become a better math teacher than my colleagues.	.909	890

equality of factor loadings across the two groups, followed by tests of regression correlations and factor variances. The "totally non-invariant" model indicated a good fit for the whole sample as well as for each of the two groups separately: $\underline{x}^2$ =

648.9, with 426 df (degrees of freedom) for the total, x^2 = 335.7 with 213 df for females, and x^2 = 313.3 with 213 df for the male model ($p < 0.001$ in all cases). The introduction of factor loadings invariance resulted in a change of x^2 by 2.796 and a change in df of 15 ($p>.001$) with a good fit (CFI = .919). Finally, the introduction of the invariance of regression correlations resulted in a change of x^2 by 11.694 and a change in df of 14 ($p>.01$) with a better fit (CFI = .920). The conclusion is that the measures between the two samples are equivalent, meaning that the model has an equally good fit for females and males.

Table 2. Goodness of Fit for Separate Solutions for Each Group with no Invariance Constraints and for Invariance Constraints Imposed across the Two Groups (males and females).

Model	x^2	df	CFI	p	x^2_d	df_d	p
No invariance							
Males	313.259	213	.909	001			
Females	335.689	213	.918	.001			
Total	648.948	426	.914	001			
FL invariance	651.744	441	.919	.001	2.796	15**	$p > .001$
FL, FC, invariance	663.438	455	920	001	11.694	14**	$p > .001$

Overall, the fitting indices are almost the same for each step in the hierarchy, none of the changes in the chi-square values were found to be statistically significant. This means that the constrained model can adequately explain the structure of interrelationships among the factors and the directions of the paths in both groups. In other words, the restrictive model seems to be identical in the two groups.

Figure 1 shows that the teachers' GSE is influenced by their MA through the four intervening variables. The first path indicates that GSE is influenced indirectly by MA through the perception of teachers' feedback so that high MA elicits positive teacher appraisals: regression correlations (RC: .760 and .780 for females and males, respectively). These responses contribute to positive feelings with respect to the mathematics SC and perceived comparative performance in mathematics (RC: .850 and .930), and also through the teaching confidence (RC: .486, .369). The former leads to positive math teaching SC (RC: .800 and .901), though the perceived relative MA leads to GSE through the confidence in teaching mathematics (RC: .870 and .780) and to the perceived comparative ability of teaching (RC: .985 and .990). The latter factor (relative teaching ability) leads directly to confidence in teaching mathematics (RC: .416 and .369) and indirectly to GSE. What is interesting to note is that all the three intervening variables: teachers' appraisals, perceived relative performance in mathematics and perceived relative ability of teaching mathematics, lead directly to teaching mathematics

confidence, which in turn leads directly to GSE. The direction of each indirect causal path is consistent with the hypothesized positive effect of MA on GSE and confidence in teaching mathematics.

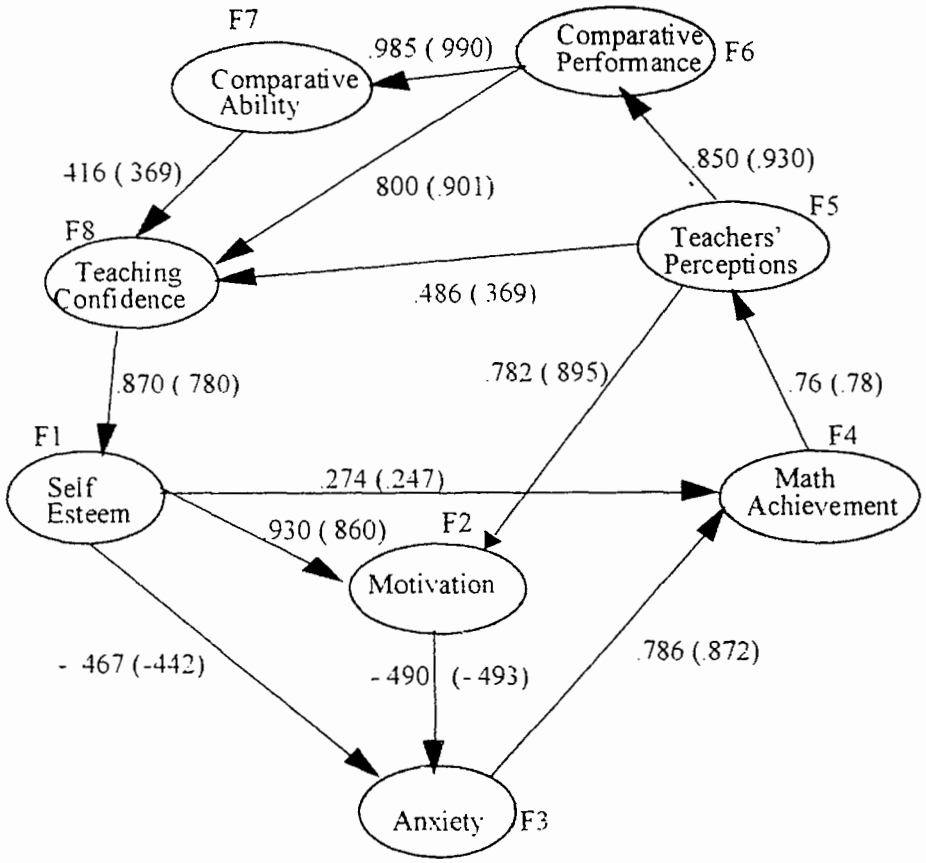

Figure 1: The Model with Regression Correlations.(Numbers in parentheses indicate males' parameters).

The hypothesized paths involving GSE, mediating variables, and MA are all significant. GSE has a significant negative effect on anxiety (RC: - .467 and - .442 respectively) so that low general self-esteem leads to high anxiety. Anxiety in turn has a direct effect on MA, indicating that high anxiety contributes to positive mathematics achievement, reaffirming previous studies. GSE has a significant positive effect on motivation (RC: .930 and .860), which in turn affects MA indirectly through anxiety. Specifically, motivation has a significant negative effect on anxiety (RC: - .490 and - .493 respectively) meaning that low motivation leads to high anxiety. Furthermore, GSE affects MA in a direct way, indicating that high GSE leads to high MA (RC: .274 and .247). The directions of all these paths are again consistent with the hypothesized effect of GSE on MA. Examination of the modification indices suggests an indirect effect of teachers' appraisals on mathematics anxiety through motivation (RC: .782 and .895) reflecting the idea that negative feedback from teachers results in an increase in the mathematics anxiety of students.

Conclusions

In summarizing the results of the present investigation, the most important findings are the critical paths relating mathematics achievement and general self-esteem of pre-service teachers through intervening variables that are closely related to the professional development of teachers. The present study is in line with the results of previous studies indicating that self-esteem is formed and influenced by evaluations of significant others for one's own behavior (Marsh & Yeung, 1997). In this context, the results provide a strong case for the role of educators in the formation of pre-service teachers' perceptions of themselves both as students and future teachers of mathematics. These perceptions are the outcome of mathematics achievement and consequently influence the way pre-service teachers think about themselves as mathematics learners and mathematics teachers.

In agreement with this perspective, the nature of the model developed in the present study indicates that general self-esteem is important for pre-service teachers both as an outcome and as a mediating variable that helps to explain other outcomes such as mathematics achievement. The results of this study are consistent with most longitudinal studies which support the model in which prior academic achievement influences subsequent self-esteem and prior self-esteem influences subsequent achievement (Byrne, 1996). However, the present study is more specific than previous ones in that it examines the nature of a particular school subject and general self-esteem, and explores the specific intervening variables through which general self-esteem influences mathematics achievement.

A major finding of the present study is that pre-service teachers' general self-esteem is formed in relation to an external social comparison reference point on the basis of which teachers compare their self-perceived performance in mathematics with the perceived performance of other students in the same subject. The relationships found are consistent with principles of social comparison and reflected appraisals, which postulate that one's self concepts and self-attitudes are outcomes of social relationships and processes. The principle of reflected appraisals argues that people are to a great extent, influenced by the evaluations or judgments of significant others (Bishop, Brew, Leder, & Pearn, 1996). In social interaction, not only do people tend to perceive themselves on the basis of feedback received by others, but they are also likely to internalize these responses and evaluate themselves, in part influenced by the responses of others that are communicated to them. In the same way, their feelings and attitudes towards themselves will be gradually formed on the basis of perceptions and observations made by them. In mathematics achievement, students tend to perceive their own successes or failures from the various approvals or disapproval of teachers as these are reflected in grades and comments. These in turn become the bases on which the students judge themselves and form their self-concept as students. The specific judgment that the students form of themselves, based on their academic achievement, will also contribute to their overall self-feelings. For many pre-service teachers the mere possession of high ability signifies self-worth, which in

turn leads to a high mathematics teaching self-concept and mathematics confidence.

The second important finding of the present study is that the reciprocal nature of pre-service teachers' relationships between self-esteem and mathematics achievement is the same for both males and females. Self-esteem and self-concept researchers evaluate gender effects in mean levels of self-esteem and self-concept (Hattie, 1992), but insufficient attention has been given to gender differences in the factor structure of self-esteem and mathematics achievement among pre-service teachers. Thus, one of the main concerns of the present study was a more fundamental issue relating to the factor structure underlying self-esteem and mathematics achievement, i.e. as to whether responses to the same instrument have the same meaning for male and female pre-service teachers. It was found that the same reciprocal model represents the responses of both male and female pre-service teachers as far as mathematics achievement and self-esteem are concerned.

TEACHERS' VIEWS ON PUPIL COLLABORATION IN COMPUTER BASED GROUPWORK SETTINGS IN THE CLASSROOM

A. Chronaki* and C. Kynigos**
Open University, Milton Keynes, UK*
University of Athens, School of Philosophy, Dept of Education and Computer Technology Institute, Athens, Greece**

Abstract: *Pupils' collaborative work has recently regained attention due to an increase in classroom use of modes of group and project work often required by computer based environments. The significance of this type of social structuring in lessons has been appreciated as an important factor for teaching and learning mathematics. The present paper discusses the issue of 'collaborative work' from the teachers' point of view and focuses on identifying and interpreting the types of teacher's views concerning the collaborative work of pupils. In particular, it examines how teachers themselves describe pupils' collaboration and how they see their role in shaping interactions and managing collaboration amongst pupils within a group situation.*

1: Theoretical Orientation

Learning in collaborative settings has attracted a lot of interest as researchers are moving on from constructivist to interactionist and socio-cultural viewpoints to interpret mathematical teaching and learning processes and are appreciating the role of the social setting in which learning takes place. Recent studies, however, attempt to combine Piagetian and Vygotskian perspectives, rather than to generate theory focused on learning in specific collaborative situations (Kynigos and Theodosopoulou, in press, Yackel and Cobb, 1996). In this study we espouse a socio-cultural view of teaching and learning in the sense that we conceptualise this double process as a set of social interactions taking place within the cultural environment of a classroom. Learning is seen as culturally embedded and it occurs in dialogic exchanges between peers and more knowledgeable members of culture (Bauersfeld, 1990, Lerman, 1993 and Confrey, 1995). We address learning situations where small groups of pupils collaborate in computer-based mathematical projects with their normal teachers within a school based innovation programme. Collaboration in computer based learning environments can be used to augment ways of acting which generate common meanings regarding the activity. For instance, in a study carried out by Hoyles et al. (1992), pupil activity generated by groupwork based on the use of exploratory software for mathematics included the negotiation of goals and processes, the need for justification of ideas and actions to partners, the development of a shared language for communicating actions to be taken and the brainstorming of solution strategies. In this study we focus on the meanings for the nature of pupil collaboration created by their teachers during their involvement in this school innovation programme, as they express them in the course of a set of semi-structured interviews combined with extensive lesson observation[1].

---

[1] The study was carried out in the framework of project YDEES: "Development of Popular Computational

In the last decade there has been a major shift in research paradigms involving the teacher and the teaching profession (Hoyles, 1992). Early studies took the stance that teaching is the technical implementation or conveying of a curriculum or pedagogy designed outside the classroom and that the study of teaching is directly informed by the extent to which the process and the results are close to the prescribed ones. The studies were also restricted to studying the teacher-pupil dyad rather than settings involving a variety of social interactions in the classroom. These studies were followed by ones addressing the teacher as a reflective practitioner directly shaping teaching process and content, and took teacher beliefs, views and epistemologies seriously into consideration (Olson, 1989, Lerman, 1992). Teachers' personal images (thinking, views, beliefs, intentions, ideologies), are influencing the shaping of the context of teaching and learning. The reason for studying the views of teachers is grounded in the assumption that these have a significant influence on their planning and actions during lessons. Views and attitudes act as a sort of filter and they can be indispensable in forming and organising the meaning of things, but on the other hand they can block the perception of new realities and the identification of new problems and solutions. As a result, researching into how teachers themselves conceptualise pupils' collaborative learning may offer insights concerning the motives they carry along to their interactions with the pupils. One could then be in a position of making some sense about the potential type of collaboration that teachers can ultimately structure for their pupils. Adopting this theoretical orientation in the present study, we look at the views on the nature of pupil collaboration, formed by teachers involved in implementing pedagogical innovation in a weekly course on computer based mathematical projects.

2: Research setting

The research took place in a Greek primary school project which has been going on for over a decade and involves the use of computer technology for a weekly "investigations" hour from year 3 to 6. From the start, the project was seen at the school level as the infusion of a pedagogical innovation together with the use of computer technology. The researcher played the role of teacher educator and consistently held seminars at the beginning and the end of the school year and meetings of a varying frequency during the year. The project set off explicitly focused on the idea of providing pupils with the opportunity to collaborate in small groups, gain some autonomy from the teacher and become more active in their thinking, constructing and problem solving (Kynigos, 1992). This was socially mediated and agreed upon by the school's direction and staff and all teachers took part with their own class. They used Logo as a means of expressing ideas, constructing and experimenting and a word processor and a drawing application for composing reports on their projects. A study

Tools for General Education: The Computer as Medium for Investigation, Expression and Communication for All in the School". General Secretariat for Research and Technology, #726, E.P.E.T. II, 1995-1998.

of teacher strategies six years into the project showed that it was informative to describe these in terms of a) the aspects of the learning situation addressed by the teacher and b) the kind of pupil activity their comments intended to encourage (Kynigos, 1996). For instance, more than half of the teachers´ comments (54%) did not focus on specific mathematical content but dealt with process related issues (such as social interactions, use of tasks and resources).

We thus felt that it was important to ask how the teachers themselves interpreted and experienced the meaning of their pupils´ collaborative work. We did this by means of semi structured interviews with five of the more experienced teachers, at a time when - in the framework of a larger project - we were participating in teaching experiments in the classroom. This shared experience of planning and delivering lessons helped us increase our understandings and insights concerning the meaning of their narratives and minimised the effect of contextual factors (i.e. the nature of different tasks) on interpretations. The interviews aimed to address questions of the type: What is the 'mental context´ of collaborative learning that teachers construct through their narratives about pupils´ work and interactions? What different styles of descriptions about collaboration exist amongst teachers? How do they view their interaction with pupils in collaborative activity? Coding of teachers´ answers was oriented about the two main interview questions: a) what collaborative work meant to them and b) how would they explain their interventions in group settings so that to encourage collaboration. More details concerning the methodology for data collection and analysis can be found in Chronaki (1998).

3: Three ways of viewing pupils´ collaboration

All teachers were relatively confident in using the computer as a tool for teaching, but a few still expressed reservations about using this medium at all times. Difficulties with various technicalities and lack of time in planning and organising lessons were mentioned. When asked about their views regarding the value of collaboration, they all agreed that it is a vital component for pupils´ learning (this can also be attributed to an influence of their training). However, looking in more detail at the answers provided, one can discern variations in their mental images about what true collaborative work may mean for them. In terms of differences, three modes of teachers´ talking and thinking over their pupils´ collaborative work were identified through the data of the interviews (collaboration as aiming towards the work-outcome, as based on human relations and as a common-sense activity). There is always a difficulty with putting textual data (transcripts of interviews) into neat categories. Hence, there is no claim here that the three distinctive clusters of views, discussed below, are in any way exhaustive in describing teachers´ perceptions about collaborative learning in a general sense. However, these three modes characterise the main themes of teachers´ thinking met in the particular school community studied.

4.1: Collaboration is geared towards the work-outcome

Kostas and Michalis are both senior teachers, well respected by the pupils and both can be described as firm and formal in their relations with pupils. These two teachers perceive collaboration as a means to accomplish a particular mathematical activity. For them, pupils´ goals within collaboration should be the completion of mathematical tasks in the lessons. Kostas: *'Collaboration is based on effective work relations´*, and Michalis: *'They have an aim, and they use the views and help of the others so as to achieve this aim. The aim and the task need to be the focus and not the relations´*. Both stressed, as can be seen in the extracts below, that pupils need to learn to distinguish between friendship and collaboration and they felt strongly responsible for assisting them in realising this. For example, Kostas said: *'Pupils need to realise the difference between friendship and cooperation. Cooperation means that I can work with somebody on a particular subject even though s/he is not a friend´*. Their belief is that the pupils in the group need to put their feelings and sentiments aside and to get on with organising their roles and activities. For them collaboration is solely devoted towards the completion of the tasks in hand. The goal needs to be oriented towards work. Moreover, they saw this as a main pedagogical gain, implying that people need to collaborate almost at any cost. The view of collaboration as a gathering of people working towards the end product was also reflected in the ways they saw their intervening role in fostering pupils´ collaboration, which can be described as a managerial one. Kostas explained: *'My role is to show them that friendship is different from collaboration. This is very stressful for children. For example, it´s very difficult for them to realise that they haven´t dealt well with a situation, they are not mature enough for controlling their emotions´*. And Michalis: *'I see my role as supporting the pupils to carry out their activities. In terms of the team´s structure, I believe that the teacher needs to control its function. The teacher needs to make sure that things work smoothly and the pupils work towards achieving something´*. In short, they saw themselves as providing explicit explanations, as redirecting and focusing pupils´ energy towards the goals and objectives of the activity. However, their focus is on managing pupils´ work as end-product, not managing the relations of the pupils who work (i.e. the process of working).

4.2: Collaboration is about human relations, too.

Petros and Natasa took a different stance. They described 'collaboration´ as deeply rooted in pupils´ relations and feelings. Although, they have different experiences in teaching. Petros is a relatively new teacher (less than 5 years of teaching experience) whilst Natasa is more senior, they both are creative teachers who like to get involved with new ideas in their teaching. They have relaxed and friendly relations with their pupils and at times they are not hesitant to express affection. These two teachers talking about collaboration was lengthy and they used a rich and sophisticated

vocabulary to describe their thoughts. They saw collaboration as being based on pupils´ human interactions, but they also talked about the work as a core of attention in the collaborative activity. For example, Petros said: '*It´s very difficult to define collaborative learning, to describe it. It is never the same. It changes and develops all the time. There exist interactions and relations between pupils and the participants need to get new roles. Many times these roles are not stable during the lesson. They change (and they need to change) depending on what a particular pupil has to offer and also on what the specific task demands. One basic drawback is that pupils hesitate to make decisions and to organise their roles. Effective collaboration for me is to encourage the listening and discussion of all different views. To give equal opportunities to different voices. It is important that all pupils have the opportunity and also the responsibility to make explicit and communicative their thoughts with the other members of the team. These thoughts and views then need to be respected by the others, they need to find processes, ways and routines for making decisions. It is true that it is not easy to reach some consensus. It is difficult for all three pupils to agree. There are always diverging views. But, the issue is that with the realisation of these differences, they can find specific mechanisms and methods so as to synthesise and to construct a commonly agreed line. Then, they all need to follow this line without feeling rejected. And this is the most difficult part´.* And Natasa:'*Collaborative learning means that there is no pupil who tries to control the team at all times. It is important that all participants discuss the problems of the task and also the problems, the difficulties of their collaboration. In this way they are called on to provide solutions through their collaboration. These solutions need to be the outcome of discussion and not the imposition of the pupils or even the teacher´.*

With regard to their role in structuring pupils´ collaborative work, these two teachers seemed to possess a repertoire of skills and tools for intervening with groups and showed a flexibility in their approaches. During observations, they talked using examples from their teaching in varied lessons and narrated a variety of ways they had tried in the past to encourage collaboration in groups. Amongst the tools that they often used they mentioned: restructuring the groups when necessary, focusing their pupils attention on the process of collaboration, its change and development, discussing with pupils, listening to their concerns, encouraging the opening up of personal aims, thoughts and motives to others, and respecting each others feelings. Overall they emphasised a strong and genuine concern about pupils relating to each other.

4.3: Collaboration is collaboration

Erato, is also a senior teacher who describes herself as a traditional teacher with modern ideas. By this she means that she prefers to mix and match new and old methods in her teaching according to what fits better into her lessons. Talking with her about collaboration, it was difficult to get her to articulate and unpack a description of the term. Her response was along the line of, 'collaboration is really collaboration´.

implying that collaboration is a common sense word (everybody should really know its meaning) that does not need further explanation. Erato says: '*It is very simple. If you are not able to collaborate, you cannot produce. And this is something that all kids need to realise very well, especially when they cannot achieve their goals during the lesson. The lesson depends on their cooperation, and there are times that they were not able to finish their project because of their inability to collaborate'...I had to rearrange the teams many times. They couldn't fit. They couldn't. It was impossible. They were too competitive with a negative sense. This resulted in them being very mean to each other. For example, one would say to the others. I am clever! You, stop talking now! You are stupid! Stay out!. Further more they are often unable to sustain their roles or they mix up their roles. They cannot organise themselves within the team'.*

Talking more with her about her ways for intervening with pupils in assisting them to collaborate one could notice that although Erato was aware about the difficulties that pupils have in collaboration, she is not confident with her ways for dealing with these difficulties. She spoke very emotionally about her attempts (or even struggles) to put pupils into order when they worked in a group. She confessed that helping them cultivate good relations with each other was almost an impossible task.

4: Discussion

Three modes of teachers' viewing of collaboration were presented in the previous section; collaboration as work-outcome, as relations and as common-sense activity. A common theme all teachers talked about was how difficult, stressful and painful the experience of collaboration was for pupils. For instance, they noted that pupils can be harsh to each other, immature and sometimes irresponsible for work and feelings. They held the view that constructive collaboration amongst pupils in group settings is rare, and they emphasised the difficulty, the complexity and also the importance for encouraging collaboration as a tool for fostering mathematical exploration and discussion. This commonly expressed concern about the problematic status of collaboration (and communication) in maths lessons in this educational setting suggests the need for further study into the nature of teachers' views on such social interactions in classroom situations. Apart from this common concern about pupils' difficulty to collaborate, teachers differed in their views about the nature of collaboration and about their role in coping with this situation, which they portrayed as one where the unexpected reactions of pupils within the group, 'disturbed' the smooth process of the mathematical activity during the lesson. Some would portray a work-oriented view of collaboration and see their role as 'managers' who need to employ clear-cut methods, preferring to distance themselves from pupils' personal lives and to focus on doing the mathematical tasks instead (e.g. as in the case of Kostas and Michalis). Others, like Petros and Natasa, would adopt a 'human relations' orientation manifested by getting

involved with their pupils' lives and feeling enthusiastic about exploring possibilities for dealing with challenging situations. Finally, others like Erato, held a non-explicit and non-articulated view of collaboration conveying feelings of frustration about the dead-ends presented by difficult pupil interactions.

The first and third mode are 'work-outcome' oriented and teachers seemed to have a certain 'agenda' in mind about how the pupils should do tasks in the group (i.e. not being disruptive, not wasting time, producing what is required). Teachers in the first mode (the 'managers') felt they knew the tricks for dealing with pupils and through exercising their authority could eventually manage to get the groups sitting quietly and producing the expected work. The 'ground rule' that they make explicit for their pupils is of the type: *'I want you to finish the task'*. Their structuring of pupils' collaboration is mainly focused on allocating tasks and making sure that the group completes the work. And even though the work will finally be produced by the group, they placed no emphasis on guaranteeing that all pupils have contributed. Other studies have shown that it may well be the case that: a) pupils are seated as a group but work individually (Bennett, 1991), or b) pupils rely on a few competent ones in the group to do the work for all (see Hoyles and Sutherland, 1989). These teachers seemed to adopt a role of directing their pupils rather than collaborating with them, focusing on the end product of their activity and thus de-emphasising the importance of collaboration itself. The teacher in the third mode, not knowing what to do with pupils' disruptive behaviour, got very disheartened. Apart from her statements that she did not want to be directive (or authoritative) with pupils, she did not have any explicit strategies to foster their collaboration. As a result, she felt frustrated because she realised that she could not 'control' the situation (i.e. get the group working smoothly together). This could be due to a) her interpersonal relations with the pupils in the group and b) her own perception about collaborative work itself. In the first and third mode 'ground rules' about collaboration itself are not expressed explicitly to the group and attempts to communicate them with pupils were not made. The reasons for this can be either a) lack of awareness about its features and therefore not being in a position for making them explicit (see Erato) or b) non-appreciation of the importance of talking and exploring collaboration due to over-focus on the end product (see Kostas and Michalis).

The views of teachers in the second mode could be described in terms of the notion of 'communities of practice' coined by Lave and Wagner (1991). In this case, an important part of the object of teacher-pupil discussion was collaboration itself. Both teachers (Petros and Natasa) realised the importance of exploring collaboration with their pupils and revealed their enthusiasm and willingness to learn more about their pupils' lives, relations and problems. Teachers in this mode have an explicit, wide-angled, image in mind about pupils' collaboration and expressed an ability to talk about

BEST COPY AVAILABLE

its features and explore its complexities. Placing sensitivity on the process of collaboration itself suggests that these teachers are in a better position to encourage pupils´ exploratory activity.

This study is part of an ongoing research into teachers views on aspects of learning situations and is thus used to generate further enquiry into their view of collaboration and the respective nature of their teaching. Knowing more about how teachers themselves view such situations (through their experience) and how they perceive their role in dealing with the entailed complexities 1) may be used as instruments for reflection and re-orientation of perceptions and conceptualisations about collaboration and 2) may enable them to identify and suggest instructional intervention.

Abductive Inference: Connections between Problem Posing and Solving

Victor Cifarelli

Department of Mathematics
The University of North Carolina at Charlotte

Using the Peircean construct of abductive reasoning, this paper examines the novel problem solving actions of a college student. The analysis documents and explains how the solver's solution activity is constituted by an intermingling of problem solving and problem posing, with the solver's abductions providing the "cognitive fuel" needed to sustain their co-evolution.

Introduction

Accounts of mathematics learning have long acknowledged the importance of autonomous cognitive activity, with particular emphasis on learners' ability to initiate and sustain productive patterns of reasoning in problem solving situations (Cobb, 1988; Mason, 1995; Schoenfeld, 1985). Nevertheless, most accounts of problem solving performance have been explained in terms of inductive and deductive reasoning, containing little explanation of the novel actions solvers often perform prior to introducing formal algorithmic procedures into their actions. For example, cognitive models of problem solving seldom address the solver's idiosyncratic activity such as the generation of novel hypotheses, intuitions, and conjectures, even though these seen processes are seen as crucial tools through which mathematicians ply their craft (Anderson, 1995; Burton, 1984; Mason, 1995).

In contrast to inductive and deductive reasoning, Charles Saunders Peirce (1839-1914) asserted the existence of another kind of reasoning, *abduction*, which furnishes the reasoner with a novel hypothesis to account for surprising facts. It is the initial proposal of a plausible hypothesis on probation to account for the facts, whereas deduction explicates hypotheses, deducing from them the necessary consequences, which may be tested inductively. According to Peirce, abduction is the only logical operation which introduces any new ideas, "for induction does nothing but determine a value, and deduction merely evolves the necessary consequences of a pure hypothesis" (Peirce, 1891, p. 303).

The Generation of Hypotheses to Facilitate Problem Posing and Solving

While few studies of mathematical problem solving have specified precisely the role of abductive actions in the novel solution activity of solvers, the research on problem posing (Silver, 1994; Brown and Walter, 1990) suggests ways that hypotheses play a prominent role in solvers' novel solution activity. According to Brown and Walter (1990), problem posing and problem solving are naturally related in the sense that new questions emerge as one is problem solving, that "we need not wait until *after* we have solved a problem to generate new questions; rather, we are logically obligated to generate a new question or pose a new problem in order to solve a problem *in the first place*" (Brown and Walter, 1990, p. 114). Furthermore, Silver (1994) asserted that this kind of problem posing, "problem formulation or

re-formulation, occurs within the process of problem solving" (Silver, 1994, p. 19). Finally, the cognitive activity of "within-solution posing, in which one reformulates a problem as it is being solved" (Silver and Cai, 1996, p. 523) may aid the solver to consider "hypothesis-based" questions and situations (Silver and Cai, 1996, p. 529). This illustrates both the dynamic, yet tentative nature of solvers' solution activity as well as the propensity of solvers to abduce novel ideas about problems while in the process of solving them.

Objectives

The purpose of the study was to analyze the problem posing and solving processes of learners in mathematical problem solving situations, with particular focus on ways that the learner's emerging abductions or hypotheses help to facilitate their novel solution activity. The perspective taken here is that problem solving situations are self-generated by solvers, arising from their interpretations of the tasks given to them. Their interpretations of a particular task may suggest to them additional questions and uncertainties, the consideration of which helps them construct goals for purposeful action. Successful completion of the task may involve many such problem posings, all generated by the solver in the course of their on-going activity and each having the potential to alter the solver's current goals and purposes. In the course of generating problems, the solver may monitor potential solution activity for its usefulness. In this way, problem solving can be viewed as a form of abductive reasoning through which solvers mentally reflect upon and contemplate viable strategies to relieve cognitive tension, involving no less than their ability to form conceptions of, transform, and elaborate the problematic situations they face.

In an earlier study (Cifarelli and Sáenz-Ludlow, 1996), examples of abductive reasoning activity were discussed, highlighting its mediating role in the mathematical activity of learners. This work has been elaborated and extended in a series of research studies which have analyzed the qualitatively different kinds of abductions that mathematical learners demonstrate (Sáenz-Ludlow, 1997), the evolving structure of solution activity that results from abductive reasoning in problem solving situations (Cifarelli, 1997a), and the transformational influence of abduction in problem solving situations (Cifarelli, 1997b). The current study sought to extend these results by explaining the ways that learners' abductions foster an intermingling of problem posing and problem solving activities.

Methodology

Five graduate students in Mathematics Education participated in the study. The students were enrolled in a class, taught by the researcher, the Use of Technology to Teach Middle and Secondary Mathematics. The students were interviewed on 3 occasions throughout the course. These interviews took the form of problem solving sessions, where students solved a variety of algebraic and non-algebraic word problems while "thinking aloud". All interviews were videotaped for subsequent analysis. In addition to the video protocols, written

transcripts of the subjects' verbal responses as well as their paper-and-pencil activity were used in the analysis.

Based on the analysis of the verbal and written protocols, a case study was prepared for each solver. The solvers' protocols were examined to identify episodes where they faced genuinely problematic situations. Previous studies conducted by the researcher characterized abduction as a structuring resource utilized by problem solvers (Cifarelli, 1997a, Cifarelli, 1997b). Specifically, while resolving problematic situations, the solvers were inferred to have generated abductive inferences which served to organize, re-organize, and transform their mathematical actions. These structuring actions, which often introduced the formation of new problems or re-organization of previous problems, were interpreted as acts of problem posing that had profound influence on the solvers' overall solution activity, thus establishing a connection between solvers' problem posing and problem solving (Brown and Walter, 1990).

The current study examined more thoroughly the novel actions of solvers, with particular focus on identifying additional interconnections between problem posing and problem solving processes.

Analysis

The following paragraphs contain episodes from interviews conducted with Jessica. Jessica was a secondary mathematics teacher in her second year of teaching and proved to be among the strongest mathematics students in the class, achieving high scores on all class exams and assignments. She demonstrated strong problem solving activity throughout the interviews, as indicated by the novelty of her actions in completing the tasks.

Jessica's Abductive Activity. Jessica was required to solve a variety of non-algebraic problems during the initial interview. One of the tasks involved a person paddling a canoe on a river:

> **Sally, an avid canoeist, decided one day to paddle upstream 6 miles. In 1 hour, she could travel 2 miles upstream, using her strongest stroke. After such strenuous activity, she needed to rest for 1 hour, during which time the canoe floated downstream 1 mile. In this manner of paddling for 1 hour and resting for 1 hour, she traveled 6 miles upstream. How long did it take her to make this trip ?**

Upon reading the problem, Jessica commented that she had seen a similar problem before but had not solved it.

> **Jessica:** *I have had one like this ... and I'm not sure. I had a similar one in Dr. L's class. Upstream-downstream, airplane flying with the wind behind them. Professor L gave us a list of 100 problems. I looked them over and did not choose this one. I didn't do it, but I did watch other students do it. So I have not technically done this problem. (appears confident she can do it')* **(re-reads the problem; several seconds of reflection)**

[1] Comments in boldface describe the non-verbal actions of the solver as inferred by the researcher.

Jessica: *Okay, distance is 6 miles. Let's see ...total time is 2 hours ... we have to modify this because upstream means you are getting help and downstream means you're not ... Oh, wait ...* ***(reflection)*** *1 hour she travels 2 miles up ... and she rests 1 hour ... so it is not total is 2 hours. I read the last sentence ... and I totally forgot what I was supposed to find .. the total time . Okay ... distance equals rate x time, so 1 hour, okay the distance is 2 miles, time is 1, and rate ...* ***(long reflection)*** *... resting distance is -1, equals rate ...1 um ... so* ***(reflection, appears frustrated)*** *...I know I have to set up an equation then ... I could ...****(reflection; facial expressions suggest she is puzzled)***

Jessica's comments indicate that even though she had seen others solve the problem before, she still had some difficulty solving the same problem. She continued to reflect upon the situation and then had an idea to do something different to solve the problem:

Jessica: (long reflection, makes motions with her hands) Okay! So she paddles first, then she rests. She goes +2, then -1, she goes +2, -1, she goes +2 and 1, 3, and she goes + 2 again. So that's 1,2,.. .9 hours she makes the trip. That's not how they did it in class.

The interviewer questioned Jessica about her reasoning:

Interviewer: *Ah, so you were thinking back to how they did it ?*

Jessica: *Well this reminded me of that problem. I was trying to do what they did. But when I tried to do it their way, and try to get some equation going, it didn't work. I had to try something else. So just apply logic to it, it's +2, -1, +2, -1, then set up an equation (sic) to see if it works.*

In summary, Jessica experienced cognitive tension when her initial strategy of generating an equation did not appear to work. Her explanation indicated both the provisional aspect of her reasoning as well as the belief on her part that her ideas still needed to be verified to "to see if it works". More precisely, she abduced an idea of what the problem might be about and then initiated appropriate solution activity to test her abductive hypothesis.

To further probe her understanding, the interviewer asked Jessica to solve an extension of the canoe problem:

Suppose after 4 hours on the river, Sally took a lunch break for 1 hour, during which time she floated downstream. How long did it take her to go the 6 miles up the river ?

Jessica solved the follow-up task routinely. However, her solution surprised her and she demonstrated abductive reasoning in "making sense" of her solution.

Jessica: *Okay, ... so paddling is +2, resting is -1, so she rests another hour for lunch that's another -1 so first hour is +2, -1, +2, -1, and she did lunch, so that's another -1. So, 1 there ....she rests an hour, and another hour, so those 2 cancel out going back to 1 hour. So we have +2, -1, +2, -1, ... 1, 2, ... 6 ... 11, 12 hours to make trip with lunch break.*

Jessica: *What!? **(She appears surprised by her result; long period of reflection)** Yeah, I guess that 1 hour sets you back. **(several seconds of reflection)***

Interviewer: *What are you thinking ?*

Jessica: *Well, I was going to say that it would have been 10 hours, but I guess ... maybe you have to add a whole 'nother cycle? **(reflection)** Let's see. **(she annotates her diagram)** Yeah, you add +2, -1 to make up for that resting time, that one -1, to put an extra 2 plus -1 in there, cause that just cancels that whole one out there, and gives 3 more than 9 total. So I guess it is 12, yeah! ... Sally's crazy! 12 hours.*

While Jessica's interpretation of the problem posed no difficulty for her in generating a solution, her results clashed with what she had initially expected (i.e., that the one hour of rest would add only one additional hour to her previous solution, making the solution to the follow-up task 9 + 1 = 10 hours). Her expression of surprise was followed by her abduction that the discrepancy (between what she initially expected, a solution 10 hours, and what she actually computed, 12 hours) had to do with the cumulative effect of inserting the one hour rest period in the middle of the schematic she used as a diagram. She commenced to test her hypothesis and verify her hypothesis and confirm some certainty on her solution.

In solving both the Canoe and extension tasks, Jessica's abductions helped her make sense of surprising results. Specifically, in solving the initial task, her abduction helped her make sense of her realization that the way she had seen others solve a similar problem would not work. And upon solving the extension of the canoe problem, her abduction helped her make sense of the surprising fact that inserting a one-hour rest time into the previous task changed the solution by 3 hours (and not a mere 1 hour like she initially expected).

Jessica was asked to solve several algebraic and proportion problems during the second interview, including the following proportion problem:

At a Chinese dinner every 4 guests shared a dish of rice, every 3 guests shared a dish of vegetables, and every 2 guests shared a dish of meat. There were 65 dishes in all. How many guests were there ?

Jessica: *Okay, let's see. **(reflection)** Every dish of rice has 4 guests, every dish of vegetables has 3 guests, every dish of meat has 2 guests. **(draws diagram and reflects on it)** Okay, let's see ... Um ... That doesn't help **(re-reads)** Okay, so rice plus vegetable plus meat is 65.*

After reflecting on the situation, she commented:

Jessica: *I have no idea what to do, how to start this.* ***(reflection)*** *I guess my problem is that I feel like I need another relation between rice, vegetables, and meat. I'm trying, in my own version to set-up a system of equations, then I could get something out of it. But with 3 of them* ***(points to diagram of the 3 dishes)****. I'm not sure where I'm going ... because I don't know ...*

Interviewer: *We can come back to this one later if you like ?*

Jessica: *Wait.* ***(more reflection)*** *! Let's see. If I have 12 guests that means ... I have 3 dishes of rice, 4 vegetables, and 6 meat dishes, ... Ah!* ***(smile appears on her face)***

Interviewer: *What are you thinking ?*

Jessica: *Um ... I'm trying to find a nice even number of guests, so that I can figure out exactly how exactly how many dishes of rice, vegetables, and meat they need. I'm going backwards from the way I thought ... I thought I needed to start with the number of dishes. But if I have 12 guests, then I have* ***(Points to her diagram and counts)*** *3, 4, 5, 6, ..., 12, 13 dishes. So if there's 13 dishes, ... then that means 13 times 5 is 65 dishes. So I multiply guests by 5, that would be 60 guests. So I have 65 dishes ...* ***(long reflection)*** *... that doesn't seem right.*

Jessica: *Let's see. 13 went into 65 5 times, if I just multiply that by 5, I get 65. So, I should just be able to multiply that* ***(points to number guests on her diagram, 12)*** *by 5 to get 60 guests.*

Jessica: *Yeah! .. But it seems like you should have more guests than dishes ....* ***(reflects, appears to "run through" her reasoning)*** *I guess not!*

As was the case in solving the canoe problem, Jessica generated abductions to both solve the problem as originally stated and, upon having constructed a solution, to make sense of her solution.

Discussion

Table 1 summarizes the researcher's inferences about Jessica's problem posing and solving for the Canoe task.

Table 1: Jessica's problem posing and solving

Task	Goals and Purposes	Result of action
Canoe	· construct equations of form d = rt (no expectation of problem)	surprised when she cannot construct viable equation (she has a problem!)
	· H_1: the problem might involve linear displacement	uses linear iteration scheme to compute distance traveled (hypothesis testing -- problem solved)
Follow-up	· integrate new information into into linear scheme (no expectation of problem)	confident of her reasoning but surprised with result (she has a problem!)
	· H_2 the problem might involve ways incremental lengths were computed	re-constructs prior solution activity incorporating new information (hypothesis testing -- problem solved)

Table 1 characterizes Jessica's solution activity in terms of a series of episodes that involved problem posing, problem re-formulation, hypothesis generation, and hypothesis testing. Jessica experienced problems whenever her expectations of how she would proceed clashed with her actual computed results. For example, when her initial goal of generating a viable equation to solve the Canoe task was not achieved, she re-formulated, or *re-posed* the problem, whereby she transformed the original problem situation into one that involved linear displacements. With this re-formulation of the problem Jessica also expressed a hypothesis, $\mathbf{H_1}$ (of what the problem might be about), which was followed by her intention to explore the implications of adopting her hypothesis ("to see if it works"). The results of her 'testing' served as feedback to her hypothesis, thereby contributing to her subsequent solution.

Jessica's solution activity to complete the Canoe task was interpreted as involving *within-solution problem posing*, whereupon she re-formulated her goals and purposes in the course of her on-going activity, transforming the situation into a new problem for her solve. This result is compatible with previous research on problem posing (English, 1997; Silver, 1994; Silver and Cai, 1996). However, in solving the follow-up task, Jessica demonstrated a form of novel problem posing that has not been addressed in the problem solving research literature. Specifically, in completing the follow-up task, Jessica computed a result that was a surprise to her. In particular, when she incorporated the new information (that Sally rests for a one-hour period after 4 hours on the river) into her linear iteration scheme, she computed a result of 12 hours, which clashed with what she initially expected (a solution of 10 hours). She then hypothesized the possible reason for this apparent discrepancy ($\mathbf{H_2}$), in the process formulating a novel problem for her explore. She commenced to test her hypothesis by re-exploring her prior solution, focusing on the implications of incorporating the new information into her linear iteration scheme. This scrutinizing and evaluating of her prior solution in view of the new information was interpreted as a case of Jessica achieving a heightened awareness concerning the efficacy of her prior solution activity. This type of problem posing, which lead Jessica to re-examine her prior solution in the face of a new problem situation, suggests that problems are never completely solved; new situations present opportunities for solvers to connect directly with previous problem solving through the generation of and consideration of new questions and problems.[2]

The purpose of this paper is to develop a means to illustrate and analyse the cognitive paths taken by students in solving problems. The approach is built upon the notion of cognitive unit (small enough to be consciously manipulated). Our interest is in the nature of the student's cognitive units and the connections between them. We find that a student may have an overall strategy and even formulate goals to achieve all or part of a solution. However, if conceptual structures are too diffuse, the student may concentrate on procedures that occupy most of the focus of attention. This may cause them to lose touch with the ultimate goal and be faced with sequences of activity that are longer, more detailed, and more likely to break down.

Introduction

Why is it that some students find algebra so essentially simple, yet others struggle so badly that they fail in school and need to take remedial algebra courses in college? The literature abounds in distinctions between the conceptual thinking of some students and the procedural thinking of others (e.g. Hiebert & Lefevre, 1986). But *why* does this occur? What is the nature of procedural thinking that makes it the default position for so many? Hiebert and Carpenter (1992) suggest two metaphors for cognitive structures, as *vertical hierarchies* or as *webs:*

> We believe it is useful to think about the networks in terms of two metaphors ... structured like vertical hierarchies or ... like webs. When networks are structured like hierarchies, some representations subsume other representations, representations fit as details underneath or within more general representations. Generalisations are examples of overarching or umbrella representations, whereas special cases are examples of details. In the second metaphor a network may be structured like a spider's web. The junctures, or nodes, can be thought of as the pieces or represented information, and the threads between them as the connections or relationships. Hiebert & Carpenter (1992, p. 67)

Such ideas have long been part of mathematics education. However, they are often used as general philosophical structures rather than explicit techniques to analyse empirical evidence. Our plan here is to extend these ideas and use the extended theory to analyse the specific solution processes for specific individuals in specific contexts. Here we focus on the activities of students working in college algebra.

Varifocal webs and cognitive units

Skemp (1979) proposed a "varifocal learning theory" in which the nodes of webs are themselves subtly connected schemas when viewed in detail. With this in mind, webs

and hierarchies may occur within the same model. As an example, consider the equation "$y=mx+b$". As a concept it can be viewed in more detail with a network of internal ideas: that m is the slope, b the intercept; that any linear equation can be represented by substituting numbers for the parameters m and b; that the graph can be drawn if one knows two points on it, or one point and the slope, etc. Some students therefore may see "$y=mx+b$" as a *single structure* with rich connections easily brought to the focus of attention.

Barnard & Tall (1997) introduced the notion of "cognitive unit" as "a piece of cognitive structure that can be held in the focus of attention all at one time". We see cognitive units as forming the nodes of a cognitive structure linked to other units using the web metaphor of Hiebert and Carpenter, incorporating the varifocal element of Skemp. There is a great deal of flexibility as to how the units and their connections may be laid out in a diagram. The notion of whether a link is "internal" within a unit, or "external" between units is largely a matter of personal choice. The actual connections within the brain are not topologically divided into an inside and an outside.

However, there are situations in which the idea of "inside" and "outside" can be helpful as a metaphor to represent the different strengths of connections, as we now consider. For instance, any of the following:

- the equation $y = 3x+5$,
- the equation $3x-y = -5$,
- the equation $y-8 = 3(x-1)$,
- the graph of $y = 3x+5$ as a line,
- the line through (0,5) with slope 3,
- the line through the points (1,8), (0,5),

may be considered as cognitive units which can be linked together as representing the same underlying concept—the single straight line or equivalent linear relation between x and y. This may be represented diagrammatically as six separate nodes with appropriate connections between each. In this sense the connections are *external* to the six cognitive units. However, an alternative, more powerful, view is to consider all six ideas to be various aspects of the same phenomenon, the linear relation/equation or straight line which all of them represent. This allows the separate ideas to be seen as different aspects of a *single entity* that is itself a single node in a larger network.

The move from conceiving of separate ideas to a single idea with different aspects is called "conceptual compression" (Thurston, 1990, Gray & Tall, 1994). For conceptual compression to occur, the individual's cognitive structure must have matured in such a way that the separate elements have an intimate connection enabling the individual to move flexibly from one to another. It is not just that there is a cognitive link between, say, the line through (0,5) with slope 3 and the line with equation $y = 3x+5$, but that both describe exactly the same thing—they are different aspects of the same entity.

In terms of Skemp's varifocal theory, this entity is itself a concept which has internal links as a schema in its own right. What is important to be able to compress a collection of related ideas into a cognitive unit is that the whole entity can be conceived as a unit that is "small enough" to be considered consciously, all at one time. The way that the human mind usually copes with this is to give it a *name* or *symbol*. The name or symbol (assuming it is "small enough") can be held in the focus of attention and manipulated. Such a concept has rich interiority through carrying "within" it many powerful links that enable it to be manipulated and invoked to solve problems.

If the diverse elements are not connected sufficiently fluently, then it may be impossible for the individual to regard the totality as a cognitive unit. It follows that it may be impossible for the individual to make links to it, simply because there is no "it". Any links that are made by such an individual are not made to a flexible conceptual entity but to one element in a loosely connected structure. We conjecture that it is this situation that underlies the often-heard cries of the remedial student saying "don't explain it to me, just tell me how to do it." An explanation—which may be perfectly clear to the teacher with a rich personal cognitive structure—is not perceived as an "explanation" to the student hearing words which do not link to adequate cognitive units in the student's mind.

Focus of attention and working memory

The way in which the human brain works enables certain ways of thinking and constrains others. Crick (1994) views the brain as a complex, multi-processing system which can be used coherently only if much of its activity is suppressed at any given time to focus consciously on a small number of important ideas (cognitive units). These in turn are linked to others that can be brought into focus as appropriate. This idea was expressed succinctly over a century ago:

> There seems to be a presence-chamber in my mind where full consciousness holds court, and where two or three ideas are at the same time in audience, and an ante-chamber full of more or less allied ideas, which is situated just beyond the full ken of consciousness. Out of this ante-chamber the ideas most nearly allied to those in the presence chamber appear to be summoned in a mechanically logical way, and to have their turn of audience.
>
> (Galton, *Inquiries into human faculty and its development*, 1883)

The "presence-chamber" of Galton is the current focus of attention and its "ante-chamber" extends it to the *working memory* consisting of closely linked cognitive units that can be evoked for problem-solving. However, it is important not to allow the physical metaphor of a "chamber" to suggest a single fixed area of activity in the brain. The "focus of attention" may be spread over many disparate areas currently resonating together in conscious thought. It therefore remains susceptible to other activities that can interrupt and override the current thought process. Such interruptions may result from unrelated external sensations, such as hearing a school bell ring to end the mathematics class, or more intimately linked strategic activities, such as a mental process monitoring whether a longer-term goal is being achieved.

Skemp (1979) theorizes that a specific problem-solving context provides a goal to be achieved, in which sub-goals may be formulated to achieve parts of the solution process. He hypothesizes that a *comparator* activity occurs at various times which considers whether the solution process is getting suitably close to the goal or to one of the intervening sub-goals. When following a routine sequence of actions we conjecture that the focus on successive remembered steps may be so great as to temporarily fill the focus of attention and suspend the activity of any comparator. This would suggest that the inflexibility of procedural thinking can become so dominant as to cause the individual to lose sight of the goal and so fail to solve the problem. Skemp also suggests the dual idea of an "anti-goal", something to be avoided—such as the anti-goal of avoiding failure—bringing with it a sense of anxiety that may negatively affect creative activity.

We therefore hypothesise that the difficulties encountered by remedial students relate to the nature of their ideas: that powerful concepts—which others can compress into manipulable cognitive units—remain, for them, as more cumbersome structures too diffuse to employ in a novel context. Our empirical evidence reveals that remedial students may have goals to achieve, indeed may articulate sub-goals, but the dominant procedures they use to attempt to achieve these goals seem to take up so much conscious thought as to prevent them from making necessary cognitive links to complete the exercise. While the successful mathematical thinker may have flexible cognitive units with powerful internal relationships which allow them to be used in diverse productive ways, the less successful may therefore be faced with longer procedural routes which actually make the mathematics *harder*. In other words, the *weaker* students are following longer more detailed cognitive paths that cause *greater* cognitive stress and further increase the chance of failure.

An example

As an example consider the following problem from a college algebra course:

> Find the x-intercept and y-intercept of the graph with equation $3x+4y=12$.

For students with a sense of the symmetry between the occurrences of x *and* y in this equation, it may be possible to "see" the answers in the equation itself. For instance, to obtain the y-intercept, imagine the "$3x$" part to be zero and focus on $4y=12$ to *see* the solution $12/4=3$ (Figure 1). A similar route for the other intercept gives a compressed solution of the problem as two immediate links without any need to write down intermediate steps. However, students who do not see this instant solution may resort to formulating sub-goals using lengthier procedures.

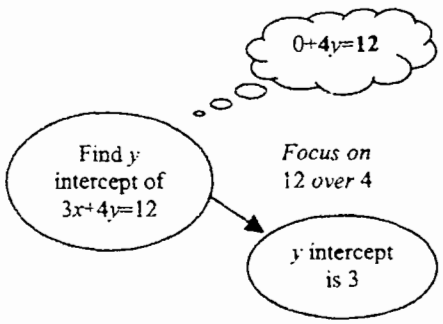

Figure 1: compressed solution

Kristi

Kristi is a community college student taking a remedial Intermediate Algebra course using a graphing calculator to produce tables and graphs. She needs to pass it before she can attempt the college mathematics courses required for her degree in psychology. She had met the concept of a straight-line equation in its various forms before the course and when interviewed afterwards she was able to discuss problems dealing with lines, their equations, slopes, graphs, etc. However, she had a strong focus on the equation in the form "$y=mx+b$", not least because she had been taught to use it to type into her graphing calculator to draw a graph. She could also read off the slope as the number before the x, and the y-intercept as the number at the end. So when asked for the slope of $y = 3x+5$ she could see this as 3, and the y-intercept as 5. For her, this standard form was the starting point for many solutions to problems, and she was frequently successful using it. She therefore began to use the sub-goal of "putting the equation into the form $y=mx+b$" before attempting the question under consideration, whether or not this was appropriate.

Her second major strategy stemmed from the first. If the standard form is known, it can be typed and the graph drawn on a graphing calculator. Kristi frequently used a graph–either a mental one, a graph on a piece of paper, or one on a calculator screen.

> If I were to just look at it, to **visualize** it in my mind—it's a line ...

The interviewer said, "what's the y-intercept on the graph?" Kristi responded

> that's where the . . . it intercepts the y- ... I know it's just a line, so I know it's going to have to cross up here somewhere.

She had a piece of paper with axes drawn on it and pointed to a spot on the y-axis of the grid on the paper, above the origin. Kristi tried to visualize it—she had a mental graph—but seemed unable to use it to solve the problem at this point. The interviewer said "Can you graph it?" and she replied:

> Yes, if I have my graphing calculator ...

She has had success graphing with her graphing calculator, and was comfortable with it. Without it, however, she could still have some success . . .

> it's like . . . I need a point. ... zero? [she seems to seek support, but then proceeds on her own] . . . if x is zero, then . . . okay, x is zero. Zero, five. Okay.

She plotted the point (0,5). Implicitly she had found the y-intercept she was seeking, *but she failed to recognise it.* Either her comparator is failing to operate or she does not (at this moment) link the point she has found to her ultimate goal, the y-intercept. She continued in her strategy to produce a line by evaluating a second point. She let x be 1, and wrote the point (1, 4). She plotted the points, drew the line through them, and decided that the y-intercept was 5.

The interviewer then asked her to find the y-intercept for $2y + x = -6$. Using her "general strategy", Kristi began to put it into slope-intercept form, "move the x over", "divide by 2". When asked to do it without putting it into slope-intercept form, she said

> I don't know what to do . . . I can't visualize it in my mind . . . like, if I get back the value, I don't know what to do unless I divide everything by 2. So far, that's what I know to do . . . put it into slope intercept.

Asking her to do the problem without putting it into slope-intercept form severed her links with her coping strategies. She attempted once more to graph the equation by plotting points.

Later in the session the researcher asked her to find both the x- and y-intercepts of $3y + x - 12 = 0$. When asked, "What would you do here?" she replied:

> Divide everything by 3. In my mind I'm visually moving everything, and dividing x by 3, its ... one third x plus ... , so the y-intercept is 4.

Once again she put the equation into slope-intercept form to find the y-intercept. Had she had the conceptual link to do so, it would have been much simpler to set x to zero to find the y-intercept. She was then asked, "What are you trying to do? What do you graph?" and she immediately plotted the point (0,4). When she was then asked how to find the x-intercept, she replied:

> on the calculator screen, where x is . . . if y is what, then hit intersect and try to find where the x is.

Her general strategy of attack is represented diagrammatically in figure 2.

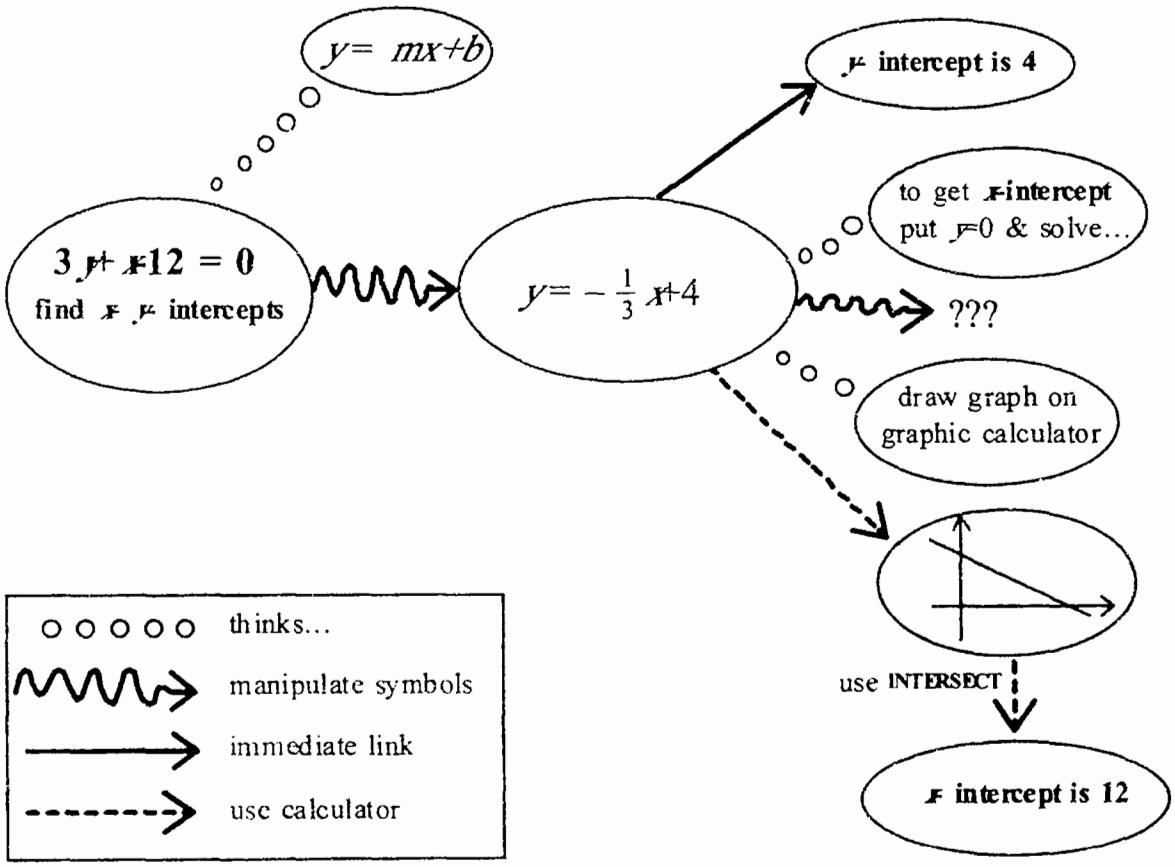

Figure 2: Kristi's strategies for finding x- and y- intercepts of $3y+x-12=0$.

BEST COPY AVAILABLE

This interview shows the complications that can appear when the student uses perfectly legitimate procedures to solve a problem. In this case, a compressed solution to find the x and y intercepts need involve only two very short computations in a symmetrical manner. However, the student's experience of the graph as a function provides an *asymmetric* relationship in which the roles of x and y (as input and output) are radically different and in which the methods of finding the corresponding intercepts are radically different. Kirsti thinks about the sub-goal of putting the equation into her favored slope-intercept form, itself a procedure requiring effort. From this the y-intercept is easily read off but the x-intercept requires a second lengthy procedure. The structures of the compressed solution and the more lengthy procedure are represented in figure 3.

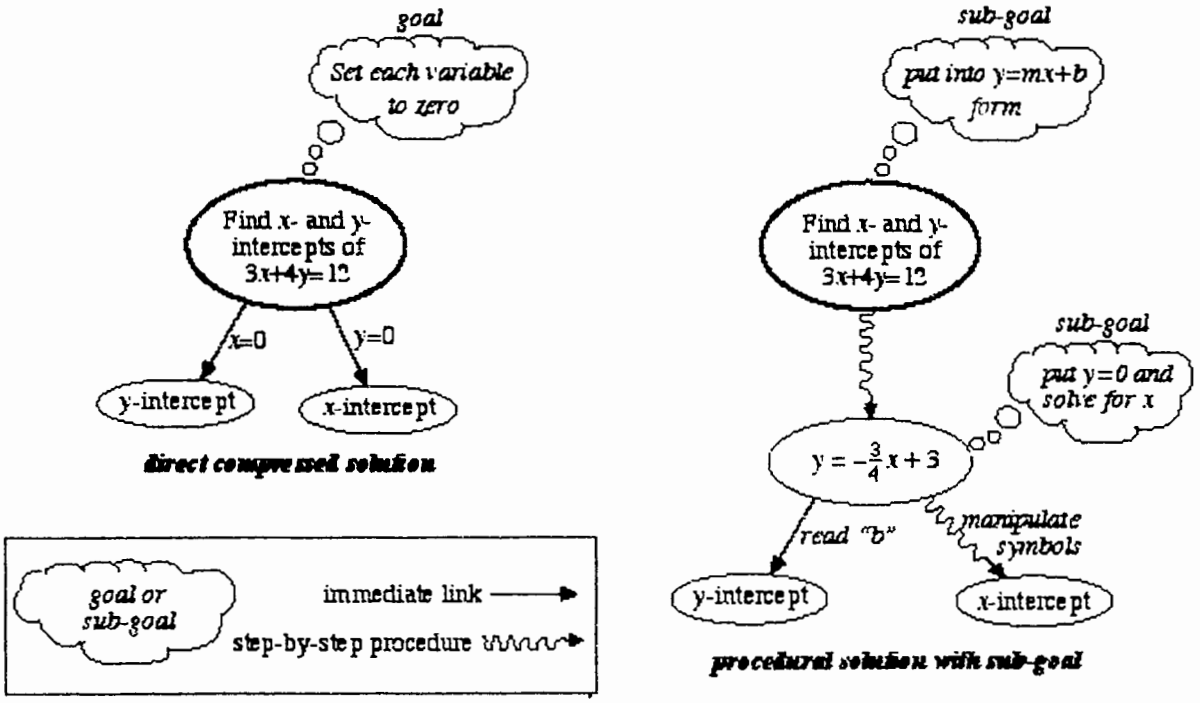

Figure 3 : compressed and procedural solutions for finding intercepts for a specific equation

This use of familiar uncompressed processes with sub-goals occurred repeatedly in Kristi's work. For example, she was asked to write the equation of the line through (1,4) and (4,–2), which she did successfully. She was then asked whether the three points (1,4), (4,–2), and (5,2) were on the same line. Rather than check (as the interviewer expected) whether the third point satisfied the equation of the line she had just found, she calculated the line through (1,4) and (5,2) and compared it with the one she had, saying:

> The way I know how to do it is to take the slope that I got, and get the line through these two points, and see if they are the same. That's the only way I know how to do it.

She used the idea of a line through two points again, repeating a familiar activity that had just been successful. However, she did not exhibit the flexibility that she needed to cope with different problems in new contexts.

BEST COPY AVAILABLE

The inflexible use of procedures occurred in many other students. Sometimes they were even more diffuse and error-prone than those attempted by Kristi. Kim, for instance, solved the equation $3y + x - 12 = 0$ to obtain:

$$y = -\tfrac{1}{3}x + \tfrac{12}{3}.$$

For this student the equation was doubly difficult; it involved not only fractions, but also negative numbers. We can hypothesise that the notions of fractions and negatives have not become cognitive units that can be used fluently. Kim therefore compounds (at least) two levels of difficulty. First there are the uncompressed, inflexible procedures that are onerous to handle. Within these are uncompressed conceptual structures for negatives and fractions that render the difficulties even more burdensome.

Summary and reflections

In this paper we have highlighted the difference between the use of flexible cognitive units on the one hand and more diffuse uncompressed structures on the other. We give evidence that a student who has yet to compress external relationships between concepts into tight cognitive units with strong internal links will find it more difficult to cope with problems requiring their use. The case studied here showed that a simple problem of finding intercepts of a linear equation contains subtleties easily handled by a student with a compressed cognitive unit encompassing the properties of algebra and the graph of a linear equation. The student with a more diffuse cognitive structure is at a serious disadvantage; this places a strain on the focus of attention at this stage and may prevent powerful theory building for the future. In this way there develops a spectrum of performance in which those who are struggling use even more complicated solution processes that place them in greater danger of failure.

MEASURING STUDENTS' PROVING ABILITY BY MEANS OF HAREL AND SOWDER'S PROOF-CATEGORIZATION

Csaba A. Csíkos

Department of Education

Attila József University, Szeged, Hungary

In this paper proving ability - according to the Lakatosian sense of proof - refers to the ability to make something evident. A test of proving ability was administered to 2572 students in Hungary. A dichotomous evaluation system allows for both hierarchical and non-hierarchical evaluation of proving ability. An hierarchical evaluation can be based on Harel and Sowder's proof-categorization. The results show that there is a positive correlation between proof types of different content domains (using the above-mentioned hierarchical model), suggesting that Harel and Sowder' taxonomy can be a powerful tool for measuring proving ability.

AIMS

Proofs are used in mathematics, in philosophy, in jurisprudence, and in everyday life. This study addresses the evaluation of proving ability. In this paper the term 'proof' will be used in the Lakatosian sense of 'making something evident' (Lakatos, 1976), and proving ability will refer to the ability to construct proofs.

There can be different approaches to characterizing proving ability. Proving ability processes can be defined as a combination of 'simplier' human abilities. On the other hand they can be a metacognitive-metadeductive ability. For the purpose of this study, proving ability will not be thought of as either a combination of abilities appearing in different well-known taxonomies (see Johnson-Laird and Byrne, 1991; Carroll, 1993), or as the results of 'meta-' processes (Johnson-Laird and Byrne (1991). Instead, it is the structure of proofs that is used to characterize proving ability.

The structure of proofs can be characterized by three variables: 1) the statement to be proven, 2) the axioms and other (formerly proven) statements used in the proving process, and 3) inference rules used in the proving process. With regards to the first variable, 'making something evident' may require similar reasoning processes regardless of the great variety in the content of the statement to be proven. Similarly, there is great diversity among proofs with respect to the number and type of axioms and other (formerly proven) statements which are used in the proving process.

Finally, the third source of variability in the structure of proofs is the use of deductive versus inductive inference rules. Models of human reasoning often use deductive inference rules to describe reasoning processes (Braine, 1978, 1990; Rips, 1983, 1994). However, even in mathematics it is not only permitted but suggested to let students „have the joy of discovery" (Saul, 1992, p. 11.; see also Pólya, 1954), that is, to encourage inductive reasoning. Thurstone (1995) went so far as to criticize the use of the DTP-model (definition→theorem→proofs) because it does not allow for inductive inferences. Also Mariotti, Bartolini Bussi, Boero, Ferri & Garuti (1997) emphasized the importance of 'dynamic exploration' in learning mathematical proofs. The three variables described above indicates a wide spectrum of proofs from axiomatic mathematical proofs to everyday verifying arguments. Even within mathematics there is a disagreement on what criteria a proof must meet. Hanna (1995, 1996), Martin and Harel (1989), Hersh (1993) and others emphasized the importance of distinguishing formal and informal proofs in mathematics.

The basic assumption of this study is that, regardless of the content of the statement to be proven, different proofs constructed by the same person will be similar with respect to the second and third variables of the structure. It is also hypothesized that students can use the reasoning skills necessary for constructing mathematical proofs in other contexts as well; the better mathematical proofs a student can construct, the better he/she can construct everyday proofs.

There are at least three approaches to the evaluation of proving ability. One means of evaluation is to start out from the so-called 'paradigm task' approach (Girotto & Light, 1993). This approach uses well-defined experimental tasks to study the nature and development of human reasoning, e. g., the Wason selection task, or logical puzzles (Johnson-Laird & Byrne, 1991; Rips, 1989). Another evaluation approach is the above-mentioned inference rule approach which concentrates on universal mental inference rules. In this study a third approach is used: Harel and Sowder (1998) proposed a model for classifying mathematics proofs that can be considered to be a combination of the approaches referred to above. There are other holistic evaluation methods for mathematics proofs (see, for example, Thompson & Senk, 1993), however, Harel and Sowder's proof categorization seems to be the most widely generalizable for non-mathematical contents.

The evaluation of proving ability calls forth special problems and difficulties. All of these approaches presume some kind of hierarchy of cognitive abilities: certain inference rules are more difficult to use, certain patterns of solutions are more advanced than others. However, in mathematics, as in other fields, there can be more than one proof of a certain theorem, and these proofs cannot be easily ranked in a hierarchy of difficulty. Hoyles (1997) pointed out that any hierarchy in evaluating proving ability can be a methodological artifact.

The aim of this study is to investigate the relationships between proof types of different contents, mathematics achievement, and school marks. It is hypothesized that there is a correlation between proving ability (using Harel and Sowder's

hierarchical classification), mathematics achievement, and school marks. The existence of a positive correlation between proof types of different contents may support the basic assumption that Harel and Sowder's proof categorization for mathematical proofs is a powerful means for measuring proving ability.

METHODOLOGY

Within a larger investigation called 'Development of mathematical abilities' six tests were administered to 2572 students, in 3 counties in Hungary, between April and May, 1998. The sample consisted of children of the 5th, 7th, 9th, and 11th grades (with ages ranging from 11 to 17 years). There were two additional questionnaries assessing personal data, school marks, and mathematics and physics academic self-concept. The tests were developed for this study, and two of them were previously piloted.

Table 1. *Arrangement of the „Development of mathematical abilities" investigation*

Test	Grade			
	5th	7th	9th	11th
Personal data (including school marks, sex etc.)	✓	✓	✓	✓
Mathematics and physics academic self-concept		✓	✓	✓
Creativity	✓	✓	✓	✓
Mathematical problem solving	✓	✓	✓	✓
Proving ability	✓	✓	✓	✓
Mathematics word problems			✓	✓
Physics achievement		✓	✓	
Mathematics achievement		✓	✓	

Among the tests of abilities, one measured proving ability. It consisted of six tasks of various types. One version of the test was administered to 5th and 7th grade students, and a second version to 9th and 11th graders, however, there were tasks common to both versions enabling better comparisons between groups.

Example I (task for 5th and 7th graders): „How can you prove that 6332 is not divisible by 3?"

(task for 9th and 11th graders): „Prove that 2 is the only prime number which is an even number!"

Example II (task for all grades): „For a long time people did not know that the Earth is round. How can you prove this for a person who does not believe this?"

Example III (task for all grades): „In an imaginery town there are people of three types: The truthful people always tell the truth, the liars always lie, and the mixed people alternately tell true and false sentences. One night somebody phones the fire-department:

- *Hello, fire department.*
- *The city hall is burning.*
- *Are you truthful?*
- *I am mixed.*

Is the city hall burning? Give your reason!

A dichotomous categorization system has been developed for each task, by which both hierarchical and non-hierarchical evaluations of students' proofs can be performed (see Figure 1).

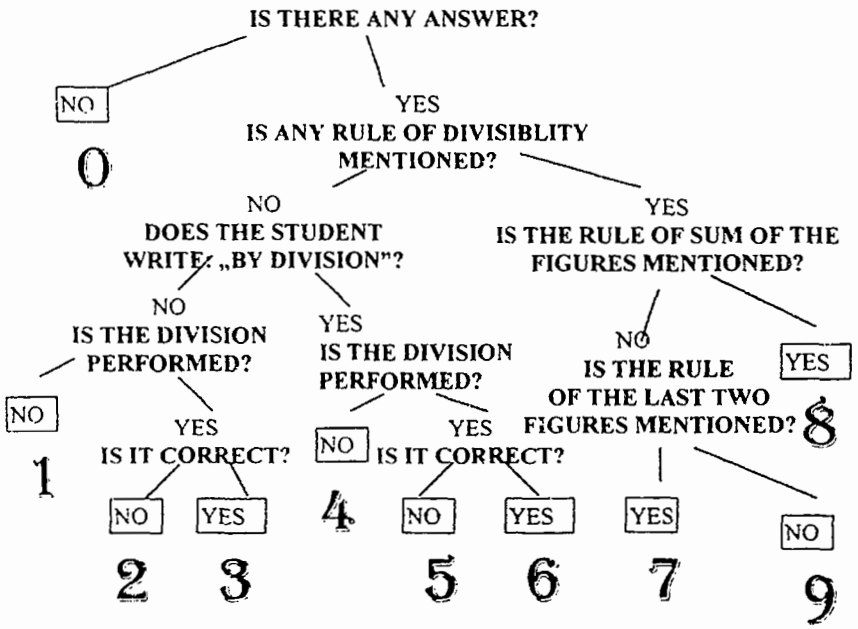

Figure 1. *Dichotomous evaluation of proof types for the task „How can you prove that 6332 is not divisible by 3?"*

The nominal categories of this dichotomous system can serve as a basis for an hierarchical evaluation of proof types: An ordinal scale measure can be developed

based on Harel and Sowder's proof-categorization system. Three hierarchically ordered stages can be identified in their model: 1) externally-based proofs, 2) empirical proofs, and 3) analytic proofs. The categories of our dichotomous system were transformed into ordinal scale categories on the basis of agreement among experts. Three expert raters independently recoded the nominal categories using an ordinal scale derived from Harel and Sowder's taxonomy. Kendall's coefficient of concordance ($W=.909$, $p<.001$) indicates a high level of agreement. In each case it was possible to recode the nominal categories into ordinal scale in 3:0 or 2:1 rate.

Table 2. *Result of the recoding process for the task „How can you prove that 6332 is not divisible by 3?*

nominal category	ordinal category (0=no response, 1=external, 2=empirical, 3=analytic)
0	0
1	1
2	1
3	2
4	2
5	2
6	2
7	1
8	3
9	1

Additional data collection is in progress investigating mathematics teachers' judgements of certain frequent proof-patterns. The ordinal scale measure constructed on the basis of teachers' judgements will provide another method for the hierarchical evaluation of proving ability.

RESULTS

Currently available data suggest that there are large within- and between-age-group differences in response-patterns: from external to analytical (using Harel and Sowder's taxonomy), and from social rule-based to logical rule-based (using a non-hierarchical taxonomy).

Kruskall-Wallis and Jonckheere-Terpstra analyses were computed on the ordinal scale measure of proof types, where the grouping variable was the grade level.

Table 3. *Results of Kruskall-Wallis and Jonckheere-Terpstra analyses of proof types measured by Harel and Sowder's taxonomy*

Task		Kruskall-Wallis analysis		Jonckheere-Terpstra analysis	
	N	χ^2	p	std. J-T	p
Round-shaped Earth	1178	7.39	.060	2.07	.038
Burning city-hall	2327	68.43	.000	8.01	.000

The results suggest that there is a tendency to construct higher-order proofs even in non-mathematical domains as a fuction of school grades.

Spearman correlation coefficients were computed to investigate relationships between proof types of different domains, and school marks in mathematics. Table 4 shows that results on the *round-shaped Earth* and *burning city-hall* tasks are significantly correlated with school marks in mathematics ($p<.001$ in each case)

Table 4. *Spearman correlation coefficients between results on two tasks, and school marks in mathematics*

	Round-shaped Earth	*Burning city-hall*
Burning city-hall	.176 (N=1178)	
Marks in mathematics	.149 (N=1120)	.242 (N=2225)

Note: p values for all correlations are less then 0.001.

Additional analyses (including latent trait analyses) will be conducted to investigate relationships between proving ability and background variables (e. g., mathematics achievement, mathematics self-concept, school marks, sex, etc.). Further non-parametric analyses will be conducted as data collection is completed.

THEORETICAL AND EDUCATIONAL IMPLICATIONS

The results presented here support the use of Harel and Sowder's proof-categorization as an effective measure of proving ability. By means of this taxonomy proofs from various content domains can be evaluated. The developmental curves of proving ability drawn from this cross-sectional study have different inflection points which appear to be determined by the content of the proof, e. g., whether the proof is a mathematical, a scientific, or an everyday proof. Further studies should address the hypothesis that mathematics proofs are the 'leaven' to foster the development of the *general* proving ability.

WHAT CAUSES IMPROPER PROPORTIONAL REASONING: THE PROBLEM OR THE PROBLEM FORMULATION?

Dirk De Bock* **, Lieven Verschaffel*, Dirk Janssens* and Rebecca Rommelaere*
University of Leuven* and EHSAL, Brussels**; Belgium

Because of its wide applicability - both in everyday situations and in scientific contexts - proportional reasoning is a major topic in mathematics education. But according to several researchers and educators, the attention given to the proportional (or linear) model may have a serious drawback: it may develop in pupils a tendency to use the linear model also in situations in which it is not applicable. In three related studies by De Bock, Verschaffel & Janssens (1998a, 1998b) this "illusion of linearity" was empirically investigated among 12-16-year old pupils working on non-linear scaling problems. But what caused these pupils' improper use of linearity? Did they incorrectly believe that the linear model was appropriate or were they simply misled by a problem formulation which they associated with the proportional scheme? In this study we found a significant influence of this formulation factor: pupils confronted with non-linear scaling problems resisted more easily the trap of proportional reasoning when these problems were formulated as unfamiliar "comparison problems" than when formulated as traditional "missing-value problems", which they have learned to associate with proportional reasoning throughout their school career.

THEORETICAL AND EMPIRICAL BACKGROUND

Pupils' tendency to apply proportional reasoning in non-proportional problem situations has been frequently described and illustrated in the literature on mathematics education. Examples of this "illusion of proportionality" relate to different domains of mathematics, such as algebra (Berté, 1993), probability (Fischbein & Schnarch, 1996; Freudenthal, 1973) and geometry (De Blocq-Docq, 1992). Best-known is the misuse of proportionality in scaling problems (Feys, 1995; Freudenthal, 1983; Rouche, 1989). In order to determine the area or volume of an enlarged (or reduced) geometrical figure with the same shape, it appears that pupils frequently use the linear scale factor instead of its square or cube. In the American *Standards*, for instance, we read in this context that "... most students in grades 5-8 incorrectly believe that if the sides of a figure are doubled to produce a similar figure, the area and volume also will be doubled" (NCTM, 1989, pp. 114-115).

Recently, this tendency towards inappropriate proportional reasoning as well as its resistance to change were empirically investigated in three related studies by De

Bock, Verschaffel & Janssens (1998a, 1998b). Large groups of 12–13- and 15–16-year old pupils were administered the same set of proportional and non-proportional items about length and area of similar plane figures under different experimental conditions. The experimental items were constructed around different types of plane figures (regular figures such as squares and circles, and irregular figures) and formulated as traditional word problems. From a structural point of view, all items were "missing-value problems" in which three of the four data were given and the task was to find the missing one. Table 1 lists an example of a proportional item (item 1) and a non-proportional item (item 2) – both dealing with square figures – used in these studies.

1. Farmer Gus needs 4 days to dig a ditch around his square pasture with a side of 100 m. How many days would he approximately need to dig a ditch around a square pasture with a side of 300 m?
   (Answer: 12 days)
2. Farmer Carl needs 8 hours to manure a square piece of land with a side of 200 m. How many hours would he approximately need to manure a square piece of land with a side of 600 m?
   (Answer: 72 hours)

Table 1. Two examples of missing-value problems (De Bock et al., 1998a)

The major results of these studies can be summarized as follows. First, the tendency to apply the linear model in the solution of non-linear scaling problems proved to be extremely strong in the age-group of 12–13-year olds, and was still very influential among 15–16-year olds: overall percentages of correct responses on the non-proportional items varied between 2% and 7% in the group of 12–13-year olds and between 17% and 22% in the group of 15–16-year olds. Second, the type of figure involved played a significant role: pupils performed better on the non-proportional items when the figure involved was regular (a square or a circle), but as a drawback they performed worse on the proportional items about these regular figures because they sometimes started to apply non-proportional reasoning on the proportional items too. Third, the provision of adequate visual as well as metacognitive support, respectively in the form of given drawings made on squared paper and an introductory task that forced the pupils to read and solve one representative non-linear item in a mindful way, yielded a significant, but unexpectedly small effect on pupils' performance on

the non-proportional items and, once again, this positive effect was compensated by worse performances on the proportional items in the supported conditions.

While these studies revealed pupils' almost irresistible tendency to apply proportional reasoning in problem situations for which it was totally inappropriate, the question remains *why* so many pupils fell into this "proportionality trap", even in the case of visual and/or metacognitive support. Most likely, there is no unique nor uniform explanation for this phenomenon. As in many other subdomains of mathematical thinking and problem solving, it seems that pupils' errors were the result of the interaction between several task and subject variables. The present study focuses on the role of one particular task variable on pupils' tendency towards unbridled proportional reasoning – namely the problem formulation – in interaction with some of the subject and task variables from our previous studies. As already mentioned, in these previous studies all proportional and non-proportional items were presented as *missing-value problems* (see, e.g., Reiss, Behr, Lesh & Post, 1985; Tourniaire & Pulos, 1985). In this problem type, three numbers (a, b and c) are given and the problem solver is asked to determine an unknown number x. In a proportional missing-value problem (such as item 1 in Table 1), the unknown x is the solution of an equation of the form $a/b = c/x$. Arguably, non-proportional tasks of the missing-value problem type (such as item 2 in Table 1) are rather unusual for most pupils; the vast majority of the missing-value problems they encountered in the upper grades of the elementary school and the lower grades of secondary school, are problems for which the linear model suits perfectly. Therefore, it could be argued that pupils' extremely weak results on the non-proportional items may not be due to intrinsic difficulties with the mathematical concept involved in these problems – namely understanding the effect of a linear enlargement on area – but merely the result of a misleading problem formulation (namely the missing-value type which calls up the overlearned solution schemes and procedures of proportional reasoning). In order to find out to what extent pupils' weak performances on the non-proportional items can be due to this formulation issue, we set up a new study in which the formulation of the problems was experimentally manipulated while keeping their intrinsic conceptual difficulties constant.

METHOD

Hundred-and-sixty-four 12–13-year old pupils and hundred-and-fifty-one 15–16-year old pupils participated in the study. All pupils were administered the same paper-and-pencil test consisting of 12 experimental items (4 proportional items and 8 non-

proportional items) about the relationships among the lengths, areas and volumes of similar figures of different kinds of shapes, and 3 buffer items. In both age-groups we worked with two equivalent subgroups of pupils that were matched on an individual basis and that were given a different version of this test. In the first subgroup (the MV-group), all 12 experimental and all 3 buffer items were presented as missing-value problems, while in the second subgroup (the CP-group), the items were formulated as comparison problems. Table 2 contains the "comparison problem" version of the two missing-value problems from Table 1.

1. Farmer Gus dug a ditch around his square pasture. Next month, he has to dig a ditch around a square pasture with a side being three times as big. How much more time would he approximately need to dig this ditch? *(Answer: three times more)*
2. Farmer Carl manured a square piece of land. Tomorrow, he has to manure a square piece of land with a side being three times as big. How much more time would he approximately need to manure this piece of land? *(Answer: nine times more)*

Table 2. Two examples of comparison problems

HYPOTHESES

First, in line with the results of De Bock et al. (1998a, 1998b), we hypothesized that the vast majority of the pupils would suffer from the "illusion of proportionality", and that they would therefore apply proportional reasoning to solve not only the proportional items but also most of the non-proportional items. Consequently, we predicted that the pupils' performance on the proportional items would be very high, while their scores on the non-proportional items would be very low.

Second, we assumed that four extra years of mathematics education should have a positive effect on pupils' ability to resist and overcome the tendency towards improper proportional reasoning. Moreover, the Flemish mathematics program for the ninth and the tenth grade (15-16-year old pupils) offers several opportunities to bring pupils into contact with non-proportional reasonings and problem types. Therefore, we predicted that these 15-16-year olds would perform better on the test in general and on the non-proportional items in particular than the 12-13-year olds.

Third, we hypothesized that the pupils of the CP-groups would perform better on the non-proportional items than those from the MV-groups. When a non-proportional task is formulated as a familiar missing-value problem, it's more likely that pupils will associate it with the kind of proportional thinking which proved to be the adequate solution strategy for the vast majority of the missing-value problems they encountered in their school career so far. With the unusual formulation as a comparison problem there is a greater chance that pupils will no longer fall back on this kind of routine-based, superficial thinking and invest more mental effort in the analysis of the problems, leading to better performance. Besides, in this "comparison condition" each problem is given with only one number, so pupils cannot take refuge in the execution of all sorts of arithmetical operations; so to speak, they have no other choice than putting their minds on the mathematical content of the problem. In line with our previous studies in which better performances on the non-proportional items in a given experimental condition were always parallelled with weaker performances on the proportional items, we hypothesized as well that the pupils in the comparison condition would perform worse on the proportional items. Accordingly, we predicted for both age-groups higher scores on the non-proportional items and weaker scores on the proportional items for the CP- than for the MV-group.

ANALYSIS

The hypotheses were tested by means of a "2 × 2 × 2" analysis of variance with "Proportionality" (proportional vs. non-proportional items), "Age" (12–13- vs. 15–16-year olds) and "Group" (MV-groups vs. CP-groups) as independent variables, and the number of "Correct answers" as the dependent variable. In addition to this quantitative analysis, in which no distinction was made between different types of correct and incorrect responses, we also executed a fine-grained analysis of pupils' errors and solution strategies, but, because of space restrictions, this more qualitative and process-oriented part of the study will not be reported here.

RESULTS

Table 3 gives an overview of the percentages of correct responses for the two groups of 12–13- and 15–16-year olds on the proportional and the non-proportional items in the test.

	12–13-year olds		15–16-year olds	
	Proportional items	Non-proportional items	Proportional items	Non-proportional items
MV-group	87	12	86	34
CP-group	62	31	75	52

Table 3. *Percentages of correct responses for the two groups of 12–13- and 15–16-year olds on the proportional and the non-proportional items in the test*

The results provided a very strong confirmation of the first hypothesis. Indeed, the analysis revealed a strong main effect of the task variable "Proportionality" ($p < .01$): for the two age-groups and the two experimental groups together, the percentages of correct responses for all proportional and for all non-proportional items were 78% and 32%, respectively.

The second hypothesis was confirmed too: the factor "Age" had a significant main influence ($p < .01$): the 15–16 year olds performed better on all experimental items than the 12–13-year olds; percentages of correct answers were, respectively, 62% and 48%. Furthermore, the predicted interaction effect between the "Age" and "Proportionality" was found too ($p < .01$): while the 15–16-year olds answered nearly twice as much non-proportional items correctly than the 12–13-year olds (43% and 22% correct responses, respectively), they outperformed the 12–13-year olds only slightly on the proportional items (81% and 75% of correct responses, respectively).

Third, the analysis of variance did not reveal a main influence of the factor "Group" on the pupils' performance: in both experimental conditions the overall percentage of correct responses on the test as a whole was exactly the same (55%). However, a significant "Group × Proportionality" interaction effect ($p < .01$) was found. The MV-groups performed considerably worse than the CP-groups on the non-proportional items (23% and 41% correct answers, respectively), but this worse performance of the MV-groups on the non-proportional items was parallelled with much better scores on the proportional items (i.e. 87% correct answers versus 68% in the CP-groups). Apperently, the item-formulation used in the CP-groups prevented pupils for falling into the proportionality trap, but as a result these pupils sometimes began to question the correctness of the proportional model for problem situations in which that model *was* appropriate - a finding that is very similar to the one obtained in our previous studies and that has been observed in several other studies about strategic and conceptual change (Siegler & Jenkins, 1989; Vosniadou, 1994). Finally,

the analysis of variance did not reveal an interaction between the factors "Group" and "Age". Nor was there a "Group × Proportionality × Age" interaction effect, which means that the reported interaction between Group and Proportionality manifested itself equally in both age-groups.

CONCLUSION

Recently, the omnipresence, strength and resistance to change of the "illusion of proportionality" with respect to scaling problems presented in a school context was demonstrated in three related studies (De Bock et al., 1998a, 1998b). In these ascertaining studies, the majority of the pupils failed on the non-proportional items, because they routinely applied proportional reasoning in a situation wherein it was not at all appropriate. However, these studies did not allow to provide an explanation for pupils' alarmingly strong tendency towards improper proportional reasoning.

The present study involves a first step in our effort to unravel the factors fostering the occurrence of this illusion of proportionality. Typically, this phenomenon is qualified as a wrong belief, as exemplified in the quotation taken from the American *Standards*, mentioned in the Introduction of this research report: pupils apply the linear model because they incorrectly believe this model is appropriate for a g en problem situation. In the present study, we demonstrated that pupils' tendency to apply proportional reasoning in problem situations for which it is not suited, is – at least partially – caused by particularities of the problem formulation that pupils learned to associate with proportional reasoning throughout their school career. The significantly better results of the CP-groups on the non-proportional items made it clear that for a lot of pupils, what lured them into the trap of proportional reasoning was not their belief in an overused mathematical model – in this case the linear function – but rather their illicit confidence in a link between that model and a certain type of problem formulation – in this case the missing-value type.

ASPECTS OF AFFECT: MATHEMATICAL INTIMACY, MATHEMATICAL INTEGRITY

Valerie A. DeBellis

East Carolina University, Greenville, NC 27858-4353 USA

Gerald A. Goldin
Center for Mathematics, Science and Computer Education
Rutgers University, Piscataway, NJ 08854-8019 USA

Affect may be regarded as an internal system of representation, interacting meaningfully with cognitive representation during learning and problem solving. This paper provides a concise theoretical overview, and then explores two aspects of affect that we propose as fundamental to the development of mathematically powerful processes: "mathematical intimacy" and "mathematical integrity." Illustrative examples are drawn from videotapes of elementary-school children solving problems during task-based interviews.

> "Thus, in a way, there is a value problem here. You can even consider it as a moral dilemma: to pretend and to get some credit or not to pretend and get zero credit? The vast majority of people that I know, including myself, will solve this dilemma without much hesitation: We will pretend. ... I would like to return now to the above situation in which an individual is not aware of the fact that he or she uses pseudo-knowledge in order to get credit. ... [This] is harder from the cognitive point of view, because the individual has no idea what a true knowledge is. He does not pretend. He assumes." (Vinner, 1997, p. 69)

Researchers of mathematical learning and problem solving increasingly recognize the importance, complexity, and depth of the affective domain. This domain goes beyond personal traits such as attitudes, beliefs, and self-concepts, and beyond the fleeting emotions accompanying cognition. We see affect as a highly structured system that encodes information, interacting fundamentally--and reciprocally--with cognition (Zajonc, 1980; Rogers, 1983; Goldin, 1988; McLeod & Adams, 1989; DeBellis & Goldin, 1993, 1997; Leder, 1993; DeBellis, 1996, 1998). Other cognitive psychologists, neuroscientists, and even information processing theorists are reaching similar perspectives: e.g., Picard (1997) suggests computers cannot achieve "genuine

intelligence" unless designed with capacity to build knowledge through "emotional" connections. But "mathematical affect" is complex and difficult to study--we have as yet only a preliminary theoretical framework. In this paper we discuss and refine the characterization of two sorts of affective structures we have inferred from observing elementary school children in task-based interviews: "mathematical intimacy," and "mathematical integrity." We offer definitions and illustrative examples, hypothesizing that these two aspects of affect are essential to the development of powerful mathematical ability.

Affect as Representation: Theoretical Framework and Interview Data

McLeod (1989, 1992) describes three components of the affective domain: emotions (unstable, intense), attitudes (reasonably stable, moderately intense), and beliefs (slowly developing and highly cognitive). Ortony, Clore, and Collins (1988) regard emotions essentially as reactions to cognitively construed events. The eliciting conditions of emotions include the cognitive representations resulting from such construals--a perhaps obvious but nevertheless essential cognitive basis for emotion. We agree this far, but we see the emotional system as much more than a reaction to cognitive inputs. Emotions occur in structures that themselves have a symbolic function--i.e., the eliciting conditions of cognitions in turn include affective representations. For instance the emotion of curiosity (crucial in our view, but essentially omitted by Ortony et al.) makes immediate sense as a condition eliciting cognition. Goldin (1987, 1988, 1998a) considers affect as one of five kinds of interacting internal systems of representation in the mature individual; the others are (1) verbal/syntactic, (2) imagistic (including visual/spatial, auditory/rhythmic, and tactile/kinesthetic), (3) formal notational (structured mathematical symbol systems), and (4) heuristic planning/executive control. Affective configurations have in our view representational capability--they can stand for, evoke, and generally interact with cognitive configurations as well as other affect, in highly context-dependent ways. The affective system includes changing states of feeling (local affect), as well as more stable, longer-term constructs (global affect). Individuals construct complex networks of affective pathways (sequences of states with accompanying meanings). These form complex networks including, but not limited to, what we call meta-affect (DeBellis, 1996; DeBellis & Goldin, 1997): emotions about and within emotional states, emotions about and within cognitive states, and the monitoring and regulation of emotion. The resulting structures influence mathematical problem-solving ability through affective interactions.

For example, feelings of frustration with a mathematical problem may evoke anxiety and fear in some students; in others, frustration may be associated with renewed or deepened determination. Frustration feelings may encode cognitively-essential information regarding the outcomes of strategies to that point--e.g., failure in a succession of trials to fulfill problem conditions, or the absence of effective record-keeping of information. The frustration feelings may in some students evoke heuristic strategies involving self-distancing and "pseudo-knowledge" (as in the quote above from Vinner). In others, they may trigger constructive heuristics for problem understanding, such as "solving a simpler related problem." Local frustration may sometimes reinforce global constructs regarding the student's sense of self or ability to do mathematics--e.g., "Nothing I ever do is going to work anyway." The immediate feelings of frustration during problem solving may occur in a meta-affective governing context of fear of failure; alternatively, the context may be the anticipation of success, so that the sense of frustration actually increases the problem solver's enjoyment as s/he realizes that the problem is a deep and interesting one. Our earlier research led us to extend McLeod's description to include a component of values/ethics/morals (Kohlberg et al., 1983), that provides the psychological sense of what is good and bad in doing mathematics, feeling in the right or justified, feeling wrong, or judging others. This assists the problem solver to evaluate internally if a mathematical argument is convincing, a proof valid, a solution correct, an understanding adequate, or an expression of approval deserved. The aspects of "mathematical intimacy" and "mathematical integrity" addressed in this paper relate to the values component of the affective domain.

We draw our illustrative examples from a series of 5 specially-designed individual task-based interviews with children aged 8 to 12, part of an exploratory longitudinal study (DeBellis, 1996; Goldin, 1998b). Inferences about affect are difficult, and no claim of reliability is made. We used ten different sources, each a kind of "window" on affect: (1) individual general background information, (2) affective verbal expression (tone of voice, timed pauses in speech, interjections, exclamations); (3) affective non-verbal expression (hand and body movements, posture, facial expressions; (4) instances of affect interacting with executive control, inferred from protocol analysis; (5) overall impressions about affect from mathematics educators who viewed the tapes; (6) cognitive analysis, with special emphasis on affective interactions, in a non-routine problem; (7) an independently-developed affective coding scheme for facial expressions; (8) evidence of instances of meta-affect; (9) evidence relating to the construct of mathematical integrity; and (10) inferring and describing affective pathways.

Mathematical Intimacy

Psychological literature on intimacy usually considers it to be interpersonal, but for some researchers the focus is on intrapsychic experience (Maslow, 1970). For us "mathematical intimacy" describes a possible intrapsychic psychological relation between an individual and (internally represented) mathematics, that connects with his or her sense of and value of self. It entails deeply-rooted engagement, not as an observer but as an emotional participant, that builds personal meaning and purpose. It involves intimate engagement through interaction, and eventually intimate relationship built on multiple intimate interactions (Prager, 1995).

Intimate mathematical interaction (DeBellis, 1998) is characterized by behaviors indicative of intimacy, and by intimate experiences inferred from behaviors. The former, depending on context, may include: the problem solver's self-placement especially close to the physical work, cradling the work with the arm or hand as if to say "this is mine," hesitation in sharing the work, closing the eyes as if to "feel" the mathematics, breathing deeply, tending with great care, or speaking in an especially halting, quiet, or excited way. Intimate experiences may include feelings of warmth, excitement, amusement, affection, sexuality, time suspension, deep satisfaction, "being special," or esthetic appreciation accompanying understanding. They may involve the person's internal representation of loved or respected ones, e.g., a sense that "My father would be proud of me for this." They are more than enjoyable; they build a bond between the learner and the mathematical content. To relate intimately to mathematics is ultimately to have access to and comprehend its "inmost" structures in a personal way. Mathematical intimacy may foster positive outcomes through powerful affect: a willingness to take risks (since intimacy may provide a sense of safety); perseverance (since intimate experiences may include feelings of loyalty, devotion, and passionate commitment); and confidence (since intimacy enhances a sense of well-being).

But intimate engagement does not guarantee a positive long-term relationship. The problem solver may feel disappointed, angry, or betrayed in the intimacy by unexpected mathematical outcomes, failures, negative reactions from loved ones, rebuke from a trusted teacher, or scorn from peers. Such "intimate betrayal" does not distinguish between the mathematically talented and the mathematically challenged individual. Even among professors, graduate students, and professional scientists--and certainly in mathematically gifted children--one finds a great deal of pain in relation to mathematics.

An illustrative example is Jerome (children's names are changed), male, age 10, in the

5th grade. In the third of five interviews, an extra videocamera recorded his facial expressions. [Small corrections to DeBellis & Goldin (1993) and additional important affective observations are included here.] Two glass jars, one with 100 green and one with 100 orange jelly beans were placed on the table. Clinician (C): "Suppose you take 10 green jelly beans from the green jar and put them into the orange jar and mix them up. Then suppose you take 10 jelly beans from the mixture and put them back into the green jar. Which jar would have more of the other color jelly beans in it?" Jerome initially indicated there would be more green jelly beans in the orange jar. Later on, he conjectured that if the number of jelly beans in the transfer is even the numbers would be the same, but if the number of jelly beans in the transfer is odd then one container will have more of the opposite-colored jelly beans than the other. Jerome then does experiments. Transferring 10 jelly beans, he finds each container has the same number of opposite-colored jelly beans. Later transferring 11 jelly beans, he counts: "Now two, four, six, eight, nine. Well they're both. they're both ... they keep on equaling the same amount even if they're odd. But ... two ... two" [inhales deeply, brushes back his hair] "green went over ... and ... two green with that and nine orange and then so nine green are left ... well, they, they still stayed the same. The same amount in each one." [4-second pause, raises his eyebrows, opens his eyes wide, shrugs his shoulders, smiles] C: "How can that be?" Jerome: "I don't know." [15-second pause, stares at jelly bean containers, raises his eyebrows, shakes his head from side to side, sits back in the chair] C: "What do you think is going on?" Jerome: "I dunno ..." C: "What are thinking about?" Jerome: "Uhhh ... I'm just trying to figure out how did this happen." [17-second pause, raises eyebrows, furrows his eyebrows, presses his lips, looks upward, shakes his head from side to side] "I dunno." Jerome's interactions, from which we infer intimate engagement, include his close proximity to the jelly beans when performing the experiments, his raised voice, his deep breaths, the gesture of brushing his hand through his hair, his shrugging of shoulders, his smiling, and the silent pauses. He sits back in his chair as if to push himself away from the experiment, to distance himself when the outcome contradicts his expectation.

Mathematical Integrity

Mathematical integrity describes an individual's affective psychological posture in relation to when mathematics is "right," when a problem is solved satisfactorily, when the learner's understanding is sufficient, or when mathematical achievement is deserving of respect or commendation. Integrity is associated with insistence on sufficient

understanding and resolution of uncertainties, and reliance on understanding in justifying the "rightness" of the work or the adequacy of a solution. It entails honesty and a degree of openness. In our view, a strong integrity structure of has the potential to enable powerful learning and problem solving--especially in interaction with mathematical intimacy.

The notion of "mathematical self-acknowledgment" (DeBellis, 1996; DeBellis and Goldin, 1997) refers to the person's ability (or willingness) to acknowledge insufficiency of mathematical understanding. Important components of this affective construct are: recognition of the insufficiency, a possible decision to take further action, and the nature of the action. The problem solver may admit that something does not make mathematical sense only to himself or herself, or to someone else (e.g., a teacher or another student). Either acknowledgment may pose specific value, moral, or ethical dilemmas. Mathematical performance may be hindered or helped by the choice of action in response to an acknowledged insufficiency: surface-level adjustments (e.g., "mathematical bluffing"), explicit efforts at deeper understanding, or a combination of both. Vinner (1997) describes "pretending" as a behavior of students trying to get credit when they "know [they] do not know," and the moral dilemma posed by educational systems that reward rapid obedience to mathematical rules over understanding. When "an individual is not aware of the fact that he or she uses pseudo-knowledge in order to get credit," the issue of integrity is more difficult. In our view, the student is not sufficiently intimate with the mathematics to recognize insufficiency in understanding.

An example is Jacqueline, female, age 9 in the 4th grade, in her first task-based interview. She was asked what the 50th card would look like, in a certain card sequence containing dots in a chevron pattern. Prior to this question she had correctly given the numbers of dots on the 4th, 5th, and 10th cards (7, 9, and 19 respectively, obtained by repeatedly "adding two" to previous cards). She appeared intimately engaged, but had not created the geometrical chevron pattern when asked to "show" what she meant. C: "How many dots do you think would be on the 50th card?" Jacqueline: [opens eyes wide, raises eyebrows] "Fifty?" C: "A huh, 50th card?" Jacqueline: [6-second pause, sits back in the chair, arches her back, opens eyes wide, raises eyebrows, presses lips together] "I think we're gonna have to multiply" ... "because we can't write 50 cards." [raises eyebrows] ... [smiles] "because that's too much. And you can't do this all the time. Sometimes you got to multiply to get finished easier." She decides to multiply 19 x 5 (19 dots on the 10th card) ... [11-second pause] "This is what I'm not good at." [smiles] ...

"Think that's right?" C: "What do you think?" Jacqueline: "I don't think so." ... "Maybe if we tried um ... maybe divide it" [looks up] "no ... this is 19." [points to the 10th row of her figure] C: "A huh." Jacqueline: "We got to 19 by 5 so it should be like" [furrows brow, sighs] "... this is ..." [points to the 5th row of her figure] "oooooohh, so like each, each 5 you add 10 to the 19." As the interview proceeds Jacqueline acknowledges an insufficiency of understanding (with integrity), makes a change, proposes a new strategy, and tries to use it, a total of 10 different times--showing great perseverance though ultimately she is persuaded by an incorrect solution: "Keep adding two and two and two and it came to a hundred, all that easy and I did all that for nothin'." [writes 100]

The Interplay between Intimacy and Integrity

Mathematical intimacy and integrity confer mathematical power, and interact to foster perseverance. With them the problem solver no longer needs cognitive and affective capacity for dissembling about insufficiencies, and no longer avoids but favors heuristics that lead to deeper understanding. Absence of integrity is a huge obstacle to intimacy. Bluffing (or pretending) blocks the individual not only from understanding but also from the experience of intimacy in relation to mathematics. Similarly the absence of intimacy reduces the individual's need for integrity, as non-intimate interaction is less likely to be experienced as posing a moral dilemma or value conflict. Lack of mathematical intimacy may also impede the problem solver's ability to distinguish knowledge from pseudo-knowledge.

To sum up, powerful affect is complex and consists of far more than positive feelings or high confidence levels. It entails structures of intimacy, integrity, and meta-affect that promote deep mathematical inquiry and understanding. Excellent teachers of mathematics appreciate, at least tacitly, the need for attention to their students' affective development. In our own research we have come to view affect as the most fundamental, and the most unrecognized in importance, of internal representational systems.

The function concept is often used as an organizing principle for algebra and beyond. Here we consider its value as a cognitive root (a concept which serves as a basis for cognitive development). current theories of multiple representations and theories of encapsulation of process as object are used to build a view of function in terms of different facets (representations) and different layers (of development via process and object). Results of interviews with three students in developmental algebra will be used to highlight the model and to discuss the value of the function concept as a cognitive foundation to growth in mathematical understanding.

Introduction

The function concept is often suggested as an organising principle in mathematics:

> We believe that function is the fundamental object of algebra and that it ought to be present in a variety of representations in algebra teaching and learning from the outset.
> (Yerushalmy & Schwartz,1993, p.41)

It has become a central concept in school and university curricula around the world. We agree that the function concept can be a powerful foundation for logical organisation, but we question its suitability as the basis for a cognitive development.

Tall (1992, p. 497) defined a *cognitive root* as a starting concept with the "dual role of being familiar to students and providing the basis for later mathematical development". He considered the function concept as a possible cognitive root, counselling that there were serious obstacles such as the encapsulation of function as a manipulable object (eg Dubinsky & Harel, 1992; Sfard, 1992) and the complexity of coordinating alternative representations (Cuoco, 1994). Here we consider these two dimensions—the links between various representational *facets* of the function concept, and the *layers* or levels of compression in process-object encapsulation (Demarois & Tall, 1996). These are traced through a remedial college algebra course based on the function concept.

Framework

The facets studied will include the function *notation* (including the meaning of $f(x)$), the *colloquial* use of a function machine as input-output box, the standard *symbolic* (algebraic formulae), *numeric* (table) and *geometric* (graphic) facets, with the *written* and *verbal*. These will be represented as sectors of a disc (figure 1) in which movement towards the centre is seen as compression through the layers *pre-procedure*, *procedure*, *process*, *object*, and *procept*. Pre-procedure denotes that the student has not attained the procedural layer. Students at the procedure layer are dependent on carrying out a sequence of step-by-step actions. Students at the process layer can accept the existence

of a process between input and output without needing to know the specific steps, and see two procedures with the same input-output as the same process. The object layer denotes the capacity to treat the idea as a manipulable mental object to which a process can be applied. The procept layer indicates the ability to move between process and mental object in a flexible way.

To allow each facet to be linked directly to any other, the picture should be seen as having individual slices (facets) that can be moved and connected in any way.

An alternative representation (figure 2) is used to show the direct links between selected facets, some of which may be non-existent or in one direction only for individual students.

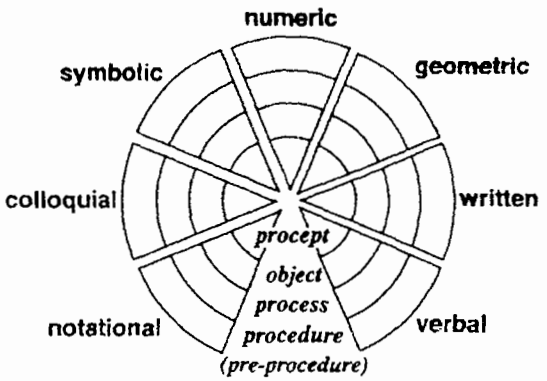

Figure 1: facets and layers of the function concept

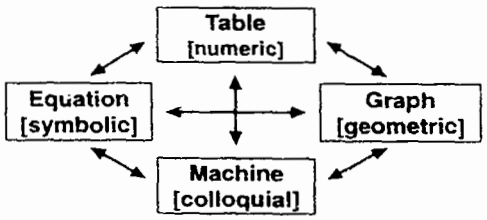

Figure 2: possible links between function facets

Student Conceptions of Function

DeMarois (1998) studied students taking a developmental algebra course at a community college. The students completed pre- and post-course function questionnaires and several participated in a post-course interview. Her, we focus on three students AF, BF and CM, where the first letter denotes the grade achieved (A, B, C) and the second denotes the gender (M or F). AF is a liberal arts student between 21 and 25 years of age. BF is a business student between 26 and 30, CM is a biology student over 30. AF had studied 1.5 years of algebra before college, BF and CM had taken 1 year. AF and BF were taking their first college mathematics course, CM had previously attended a basic mathematical skills course

. Function machines were used to analyse the colloquial facet. The majority of students displayed some understanding of function machines on the pre-test. In the individual post-course interviews, one question provided data on colloquial, verbal, numeric, and symbolic facets (figure 3).

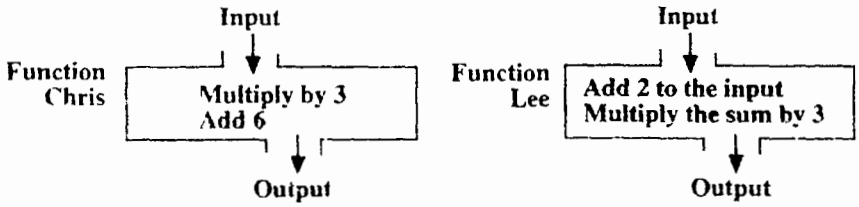

Figure 3: equivalent functions

Students were asked to write expressions for each function machine and asked whether the two function machines represented the same function (table 1).

BEST COPY AVAILABLE

	Chris	Lee	Are the functions Chris and Lee equal?
AF	$3x + 6$	$3(x + 2)$	Yes, if I distribute the 3 in Lee, I get the same function as Chris
BF	$x3 + 6$	$(x + 2)3$	Yeah, but different processes
CM	$3x - 6$	$x + 2(3x)$	No, you come up with the same answer, but they are different processes

Table 1: Function machines as procedure, process and mental object

The three responses show AF speaking in terms of a mental *object*, BF in terms of *process* and CM in terms of *procedure*. AF easily links the colloquial and algebraic facets. BF gives a literal translation of both function descriptions showing less flexibility moving from colloquial to algebraic. CM sees Chris and Lee as different procedures (in our terminology). He also gives a literal translation of the second function as "x+2 three times", revealing that he is less comfortable relating the colloquial facet to the algebraic.

Further research into links between symbolic, arithmetic, geometric and colloquial facets was performed by asking the students to respond to the following questions:

- given a specific equation, create a table, a graph, and a function machine;
- given a specific table, create an equation, a graph, and a function machine;
- given a specific function machine, create a table, a graph, and an equation; and,
- given a specific graph, create a table, an equation, and a function machine.

They were encouraged to create the other forms in any order they wished. Tables 2-4 display the results where "√" indicates a successful attempt and the numbers indicate the order in which the representations were created.

AF From ↓ to →	Equation (symbolic)	Table (numeric)	Function machine (colloquial)	Graph (Geometric)
Equation		√ (1)	√ (2)	√ (3)
Table	√ (2)		√ (3)	√ (1)
Function machine	√ (1)	√ (2)		√ (3)
Graph	√ (2)	√ (1)	√ (3)	

Table 2: Creating representations: AF

Although AF was able to start with any representation and eventually get to any another the routes taken were not always direct (see figure 4). Given the equation, AF said:

> I am much more comfortable with the function machine and the table as opposed to creating a graph on my own. I'm not as comfortable doing a graph on my own.

Given the table, AF first created the graph, but went back to the table to create the equation. She used the graph to determine the type of equation but then used the table to determine the slope using finite differences:

> I'm trying to find the finite difference. I know from the graph it looks like it will be a line so I think it will be linear which I know is $y(x) = ax+b$. So for that I need the slope and the 0 input which I already have which is –3. It looks like the slope is 2 so I get $y(x) = 2x-3$.

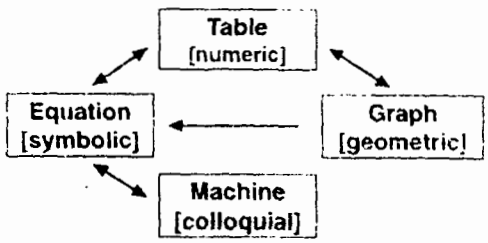

Figure 4: direct links between facets for AF

BF From ↓ to →	Equation (symbolic)	Table (numeric)	Function machine (colloquial)	Graph (Geometric)
Equation		√ (2)	√ (1)	√ (3)
Table			√ (3)	√ (1)
Function machine	√ (1)	√ (2)		√ (3)
Graph		√ (1)		

Table 3: Creating representations: BF

BF proceeded as in table 3. She could start from equation or function machine and generate all other facets, but was only able to move between table and graph when starting from one or the other. She kept trying to generate equations or function machines using only one point. She was thus unable to find the slope and could not make other links to equation or function machine (figure 5).

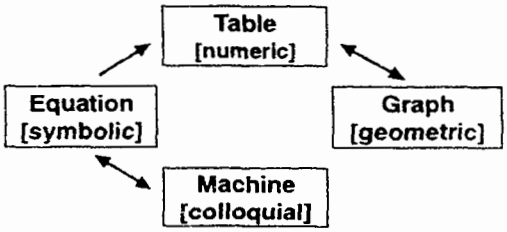

Figure 5: direct links between facets for BF

CM was also able to start from the equation or function machine and generate all other facets. Starting with a table he drew a graph, but could not cope the other way (table 4).

CM From ↓ to →	Equation (symbolic)	Table (numeric)	Function machine (colloquial)	Graph (Geometric)
Equation		√ (1)	√ (3)	√ (2)
Table				√ (1)
Function machine	√ (2)	√ (1)		√ (3)
Graph				

Table 4: Creating representations: CM

He had a limited ability to pass directly from one facet to another (figure 6). He said:

I'm not real sure on equation or function machine.

If you had to choose between the two, which would you prefer?

It doesn't matter. I don't like either. I really don't like anything that has to do with math.

[The pained look on his face and the nervous body language speak volumes.]

You like tables?

Yeah. Tables are a little bit easier for me. I trust those more than having to figure out stuff.

Given a graph he drew a table outline and said:

No. I can't do it.

You started to do a table.

Yeah ummm. If I were to sit down and think about it for a while I probably could. That's the way a lot of math is to me. I just keep trying different ways until I hit upon one that works. To save my life I probably could but I'm not real sure.

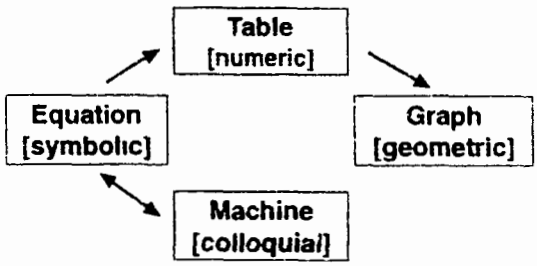

Figure 6: direct links between facets for CM

BEST COPY AVAILABLE

CM struggled throughout the course using inflexible procedures and limited connections between representations. He became frustrated and gave up easily, particularly where graphs were involved.

Overall, AF's performance on this series of questions was flawless. BF demonstrated good connections between symbolic and colloquial and between numeric and geometric, but only from the first of these pairs to the second. CM established a connection between symbolic and colloquial, but any connection to graphs was tenuous at best.

Student profiles

Visual profiles (Figure 6) of the concept images of function at the end of the course were created for each of the three students through analysing all the collected data. The shading indicates layers of each facet attained by the end of the course.

AF demonstrated knowledge during the interview that was at least equivalent to that displayed on the post-course survey. Her knowledge of the verbal facet matched her written facet since her verbal and written descriptions of function were identical. She was able to assimilate alternate definitions easily into her own concept image. AF did exhibit difficulty during the interview dealing with implicit equations as functions of one variable in terms of the other. She did not use the "uniqueness on the right" condition (Breidenbach et al., 1992, for example) in her selection of functions from a set of equations. She initially denied the constant function is a function, but later changed her mind. She displayed proceptual abilities working with both tables and function machines. She is easily able to think of them as functions (static objects) and as processes (dynamic objects). Her understanding of graphs was developing even as we conducted the interview. She did not need to know a specific procedure, recognizing each graph as representing a set of input-output pairs. She was not prototype-driven and although she did not initially seem to know how to apply the "uniqueness to the right" condition, after some instruction, she

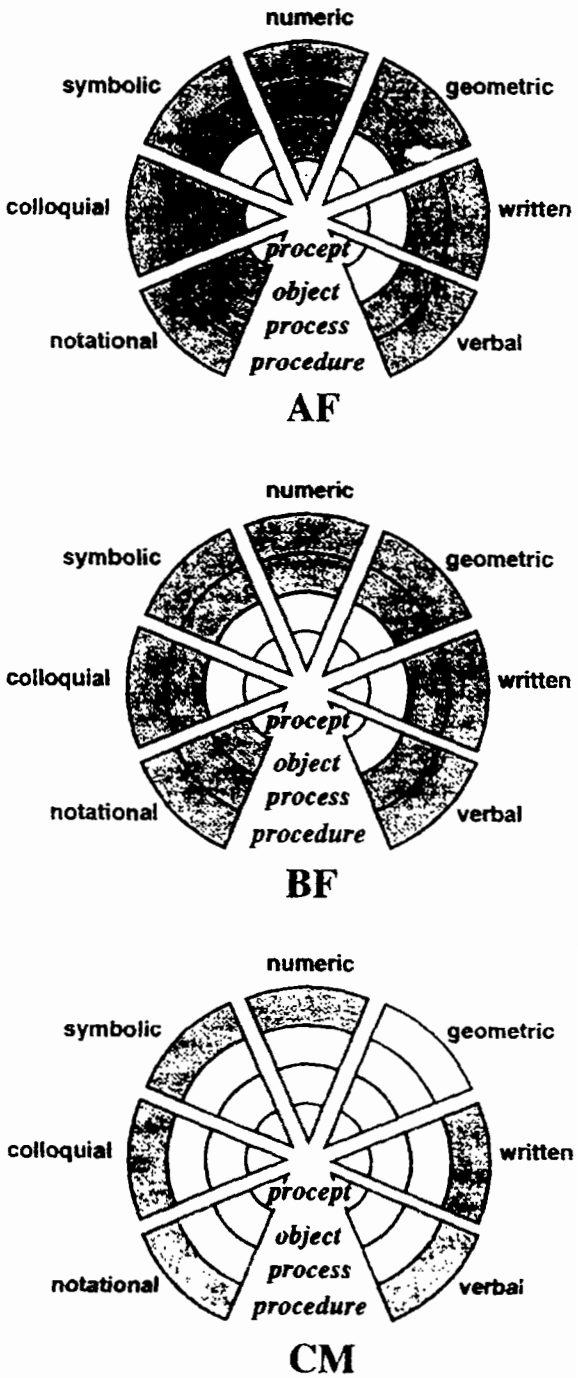

Figure 6: Student profiles

BEST COPY AVAILABLE

was able to use it coherently. She was not placed in the object layer for the geometric facet because she demonstrated a process-orientation looking at graphs rather than to seeing it as a function object. Her knowledge of the notation facet (for instance the meaning of $y=f(x)$) appeared strong and consistent except for an occasion when she was asked to substitute 44 for y in an equation containing $y(x)$ and said "44 of x." She quickly withdrew this statement and described 44 as replacing $y(x)$. AF was the only student interviewed able to distinguish between $3f(2)$ and $2f(3)$.

Of the three students, BF exhibited the most growth during the course. At the beginning she was judged to be at the procedure layer only on the symbolic facet. By the end, she appeared to be at or near the process layer on all facets surveyed. The numeric and colloquial facets showed some difficulties with process. She was highly procedural in creating an equation from a function machine writing down the steps of the function machine literally. This result carried over to the interview. Her choice of tables that represent functions focused on those tables in which a clear procedure or pattern was present. Her strongest facet seems to be notation which she interpreted flexibly in both post-course survey and interview although she exhibited difficulty interpreting $3f(2)$ and $2f(3)$ and substituting 44 for y in an equation involving $y(x)$. In the interview she was placedin the object layer for notation because of her ability to discuss the notation as an object. On the symbolic facet, she accepted the constant function as a function, but had trouble with piecewise-defined functions. She was the only student of the three that was able to correctly apply the vertical line test to graphs both on the post-course survey and during the interview. While consistent in her verbal and written definitions, BF was not as comfortable as AF in adopting alternate definitions. She had more difficulty crossing boundaries between facets. She did not easily move from a function machine to an equation and was procedural in using equations. This caused difficulty when given a variable input. She was unsure what to do and was not sure the output made much sense.

CM was the least successful of the three. At the beginning of the course he demonstrated procedure layer knowledge in both numeric and colloquial facets placing him slightly ahead of BF. By the end of the course, he was procedural in every facet except for some movement into the process layer of the symbolic facet. On the post-course survey he showed some ability to reverse a table and some hints of process when selecting tables as functions. The interview suggested that CM was at the procedure layer on all facets except geometric where he remained pre-procedural. In addition, his interview answers in the symbolic, geometric, numeric, and verbal facets were highly inconsistent with those on the post-course survey. He looked for specific procedures when identifying equations or tables as functions and was unable to identify any usable rule when looking at graphs. His written and verbal definitions of functions varied and he could not assimilate any alternate definitions of function into his own. At best, he indicated some use of prototypes when looking at graphs and demonstrated some knowledge of function notation relating only to procedural aspects of equations and the function machine. Neither written nor geometric facets seemed connected to any other facet at all.

Quantitative Data

The class as a whole reflected this spectrum from procedure to mental object conceptions of function. On the pre-test in the colloquial, symbolic and numeric facets, around 70% were able to cope with input-output as procedure or process but only 3% were at this level handling graphs (table 5).

	Colloquial (Function Machine)		*Symbolic (algebra)*		*Numeric (Table)*		*Geometric (Graph)*	
(N = 92)	pre	post	pre	post	pre	post	pre	post
pre-procedure	32%	10%	26%	8%	30%	9%	97%	50%
procedure	20%	18%	54%	51%	14%	11%	2%	21%
process	49%	72%	20%	41%	55%	80%	1%	29%

Table 5: Changes in levels of responses for four facets between pre-survey and post-survey

The table reveals improvement in all four facets. Other data collected during the project implies a corresponding improvement in the verbal, written and notational facets. This suggests that the function concept is accessible as procedure or process for many of these remedial students. The function machine appears to be a sufficiently primitive structure to serve as a cognitive root on which to build the function concept. However, the manner in which these students link the function machine to other facets suggests real difficulties in building sophisticated ideas upon it. All three students AF, BF and CM moved to other facets via algebraic symbolism and only AF used standard algebraic expressions. Many others in the class exhibited similar difficulties moving from the function machine to other representations. Although the function machine is a good candidate as a cognitive root for the full function concept, for many of these students the total concept is too complex to allow a full development.

For instance, student competence with the geometric facet was almost non-existent at the beginning of the course and difficulties persisted throughout even though (or perhaps in part *because*) students had regular access to graphic calculators. While there was a significant increase in response handling graphical problems, by the end of the semester less than half the students were able to use a graph to find output given input and only 19 percent were able to reverse the process. Of our cross-section of students, AF showed good depth in understanding of this facet, but BF and CM had enormous difficulty.

Function notation was also interpreted inconsistently, with many students (including AF) using it correctly in some settings yet unable to translate it to a new, similar setting.

Students are often competent at "plug and chug" mathematics and use this ability to hide weaknesses in their understanding. CM, for example, used the more abstract symbolic facet when the more primitive table failed him. He indicated little understanding of the symbolism, but demonstrated several times that he could evaluate a function. This appears to be an example of "pseudo-conceptual" understanding where he attempted to respond in a manner he sensed was desired by the teacher, yet failed to make appropriate internal connections (Vinner, 1997).

Summary and Reflection

This study underlines the complexity of the function concept. Its inherent richness allows it to be considered as an *organising principle* in mathematical courses such as algebra. The use of function machines provides a new approach in remedial algebra which does not simply reproduce the procedural errors of earlier experience, There are gains in moving students to procedural and process levels of thinking in several facets, but the graphic facet and some of the links between different facets remain problematic. The function machine provides a primitive idea that the majority of the students recognised at the beginning of the course, at least at a procedural level. Theoretically it contains the basic idea of long-term growth – as an input/output procedure and potentially as a mental object that can be operated upon. However, for many students, the complexity of the function concept is such that the making of direct links between all the different representations is a difficult long-term task and, in the case of this course using graphing calculators, the development of graphical ideas had to start almost from nothing and only partial progress was made. An organising principle in theory: yes, but is it a cognitive root for general long-term development? In our judgement the jury is still out.

CREATING A TOOL: AN ANALYSIS OF THE ROLE OF THE GRAPHING CALCULATOR IN A PRE-CALCULUS CLASSROOM

Helen M. Doerr and Roxana Zangor

Syracuse University

Abstract

In this paper, we report the results of a qualitative, classroom-based study on the relationship and interaction between the role and beliefs of the teacher and the patterns and modes of students' use of graphing calculators in support of their learning of mathematics. This interaction led to the creation and development of a set of ways the tool was used in the classroom and related mathematical norms. We found that the teacher's confidence, flexibility of use and her awareness of the limitations of the technology, led to the establishment of (a) a norm that required results to be justified on mathematical grounds, (b) multiple ways for visually checking hypothesized relationships between variables, (c) a shifting role for the calculator from graphing to checking, and (d) the use of non-calculator strategies for periodic transformations.

Introduction

Functions and graphs have been the focus of numerous research studies over the past decade. The study of students' understanding of the concept of function, and their abilities to create and interpret graphical representations, was given strong impetus by the advent of computers and their ready availability in some classrooms. This led to many computer-based studies that analyzed students' reasoning with and about linked, dynamic multiple representations of functions (e.g., Confrey & Doerr, 1996; Yerushalmy, 1991). Furthermore, while the graphing calculator has limitations when compared to a full-screen computer program, its low cost, portability and ease of use have resulted in its widespread use for teaching about functions and graphs in secondary schools in the United States.

Teachers, as well as the developers of standardized tests (such as college entrance examinations), have moved to adapt the graphing calculator into their practice. The National Council of Teachers of Mathematics's (NCTM) curriculum standards (NCTM, 1989) recommend using the graphing calculators to provide students with new approaches, including the use of multiple representations, to the investigation of mathematical ideas. While it might appear that practice has moved independently of and more quickly than research, there is in fact no shortage of research studies on the use of the graphing calculator (Dunham & Dick, 1994; Penglase & Arnold, 1996). However, many, if not most, of these studies are quasi-experimental in design and seek to answer the question of whether or not graphing calculators are effective in achieving certain instructional objectives, which are often left unchanged from traditional

paper-and-pencil approaches. Many of these studies compare the use of the graphing calculator to the use of paper and pencil on the same set of tasks. Such studies give little insight into how and why students use graphing calculators. Furthermore, few studies have attempted to understand the role of the teacher in a classroom where students have ubiquitous use of the graphing calculator and where the tasks have been changed to potentially take advantage of the graphing calculator's functionality (Penglase & Arnold, 1996). Teachers' attitudes and beliefs about the use of the graphing calculator in classroom practice are largely unexamined in the research literature (Tharp, Fitzsimmons & Ayers, 1997). In this paper, we report the results of a study on the relationship and interaction between the role and beliefs of the teacher and how students used graphing calculators in support of their learning of mathematics.

Theoretical Framework

Changes in curriculum are necessary to create an environment in which students can develop the new problem solving strategies that graphing calculator technology makes possible. Such curricular changes must be accompanied by changes in instruction so that teachers can develop new pedagogical strategies that are appropriate for the learners, the curriculum and the technology. In this research, we see teachers' pedagogical strategies as integrative of their views of how students learn, the mathematical content as embodied in the curriculum, and capacity of the technology to support learners in understanding mathematics.

The theoretical framework guiding this research follows the perspective described by Cobb and Yackel (1996) in which psychological and sociological aspects of learning are coordinated as an active process in which students reorganize their thinking through their interactions in the social context of the classroom. This social context includes the tools and representational systems which are shared among students and teachers. The meaning and the role of the graphing calculator as a tool for mathematical learning within the classroom are constructed by both teacher and students through their interactions, communications, and shared use of the tool. As Hiebert et al (1997) have observed, "Students must construct meaning for *all* tools. ... As you use a tool, you get to know the tool better and you use the tool more effectively to help you know about other things." (p. 54,emphasis added). In this study, we seek to describe how the teacher's beliefs about the graphing calculator were reflected in her pedagogical strategies. We then describe how these strategies led to the co-construction, with the learners, of a particular set of ways in which the graphing calculator became a tool for mathematical learning in the classroom.

Methodology and Data Analysis

A pre-calculus curriculum based on modeling problems in an enhanced technology environment (using graphing calculators, calculator-based measurement

probes for motion, temperature and pressure, and computer software) provided a rich setting for studying the role of the teacher and the patterns and modes of graphing calculator use by the students and the teacher. This classroom-based, qualitative case study took place in two classes of pre-calculus students in a suburban setting, taught by the same teacher. The classes were observed over two units of study on exponential functions (ten weeks) and trigonometric functions (seven weeks). The teacher had 20 years of teaching experience and was skilled in the use of the graphing calculator.

In this study, all of the students had either TI-82 or TI-83 graphing calculators. These devices are rich in graphing and statistical functionality, although lacking in symbolic algebra capability. In general, the students had used their calculators for well over a year before taking this course and were quite familiar with its features. The classroom was equipped with a computer, printer and a "graph link cable" that could be used to transfer pictures of the calculator graph to the computer for printing. The link cable could be used to transfer data and programs between the computer and calculator, but this feature was rarely used. On the other hand, students readily transferred data and programs between calculators using the calculator-to-calculator link cable. The classroom was equipped with a view screen that allowed the calculator screen (but not the keystrokes) to be projected using a standard overhead projection unit. The view screen did not allow for individual student's calculators to be projected, but only the particular calculator that was attached to the view screen. The students and the teacher both used that calculator during class discussion.

Classroom instructional activities regularly alternated between modeling problems investigated by the students within a small group and whole class discussion for sharing progress, discussing solution methods and extending results. All class sessions were observed by two or more members of the research team. Extensive field notes, transcriptions of audio-taped group work, transcriptions of video-taped whole class discussion, and interviews and planning sessions with the teacher constituted the data corpus for this study. These data were analyzed and coded for the patterns and modes of graphing calculator use by both the teacher and the students throughout the instructional units. In this paper, we present some of the results of this analysis, beginning with a description of the role and beliefs of the teacher as they were reflected in her pedagogical strategies. We then present some of patterns and modes of graphing calculator use that emerged as the students interacted with the teacher, with each other and with the problem situations.

Results

The teacher was particularly skilled in using the graphing calculator, as was demonstrated during both instructional units by her own use of the calculator and by her ease in answering the students' occasional questions on how to use the calculator for some particular task. The teacher's confidence in her own knowledge about the

calculator's capabilities and its potential uses was reflected in the willingness with which she encouraged the students to use the calculator in their individual and group work. She actively encouraged the students to take over the use of the calculator on the overhead projection unit during class discussions.

The teacher showed flexibility in her use of the calculator, as she would shift among the different representations of functions as tables, graphs, or equations, or shift from various lists to different kinds of regression equations. The teacher had a special preference for table - graph switching, particularly in conjunction with setting the viewing window for the graph. The settings for the window were generally determined via table values. An explicit decision to set the window for a better view of the "complete" graph was often made through an interpretation of the table for the given function. In this way, the table served as a scaling tool for the calculator's viewing window.

The teacher used the table for examining the numerical patterns that identified the structural features of a function. For example, she would ask the students to identify either the constancy of first order differences or the constancy of successive ratios as the defining characteristic of the linear or exponential structure for a given numerical relationship. The teacher also used the table to determining pointwise or local behavior of a function by looking for the intercepts with the axes or for the coordinates of extreme points. This table - graph switching by the teacher constituted opportunities for mathematically normative discussion with the students about the meaning of a complete graph of a function. This meaning came to include the local and global behavior of the function such as zeros, y-intercept, numerical patterns, symmetry, asymptotes and end behavior.

The teacher also believed that the calculator presented certain technological and mathematical limitations. In some instances, she talked about incompatibilities between the two different kinds of calculator, differences in how expressions were evaluated and limitations related to storage space such as the number of lists and the number of elements in one list. But the most important issue she raised concerned the validity of the calculator results. She asked questions such as "Does the calculator always tell the truth?" and "To what extent should we believe the calculator?" These kind of questions were most often posed by the teacher in specific situations when the calculator provided results in contradiction with the mathematically accepted truth. As an experienced teacher and a skilled user of the calculator, she was always aware of the calculator-generated errors and she pointed them out every time, especially because the students were tempted, as some of them said, "to go with what the calculator says."

Over the course of several months, the students became increasingly aware of these "mismatches" between the calculator results and mathematically accepted truth.

They started to develop a skepticism about calculator results. For example, in investigating a decay experiment where approximately half of the M&M candies were removed in each trial (Doerr, 1998), the students decided that an exponential function models this decay process. One student observed that even though in their experiment they ended up with zero candies, the exponential model did not attain a zero value since "you can divide by two infinitely without getting zero." But another student, who was manipulating the calculator with the overhead screen, scrolled down the table for their exponential function until, for very large values of x, the function appeared to take the value zero. This generated considerable discussion about the calculator having limitations and "not always telling the truth." From this situation as well as others, the students developed a reasonable skepticism and learned to interpret attentively and critically calculator-based results. The students began to see the calculator as a tool that should be checked based on their own understandings of mathematical results. Maintaining a reasonable skepticism about the mathematical truth of calculator results thus became established as part of the socio-mathematical norms of this classroom culture.

The teacher believed that the calculator would be a helpful tool for the students to use in finding meaningful responses to problem situations and for extending their mathematical thinking. The norms of the classroom culture came to define what kinds of calculator-based responses were and were not acceptable within this classroom. Two specific calculator-based methods (regression analysis and curve fitting by modifying parameters) were regularly used to solve problems where part of the task was to find an equation of a function to represent the data set of a given phenomena. These two methods were not very popular among the students as a whole, but rather were used extensively by three students. The teacher did *not* explicitly discourage these methods by telling the students not to use them, but rather she required a meaningful explanation of how the numerical results related to the problem situation. This meaningful interpretation of the result could not be given by the students who used either regression analysis or a curve fitting approach. These students did not see their findings as estimates of a mathematically determined model or of particular parameters directly related to the problem situation. Those students who used the calculator's regression functions were focused on the immediacy of obtaining some numbers (coefficients) to use in an equation and not on making sense of the result's meaning through a more mathematical analysis of the problem situation.

The calculator took on a role as a visual checking tool to evaluate how well an equation matched a data set from an experiment. The students developed three approaches for visual checking; these approaches depended on how they found their equation in the first place. In the first approach, the students had determined a function through a meaningful mathematical analysis. Graphical mismatches

between their hypothesized function and the data set of the phenomena often led the students to discover mistakes in their symbolic representation or in a computation. In some instances, the students evaluated the "goodness" of the match through the number of points from the original data set that actually lie on their graph. When they found that this graphical checking was not entirely convincing, the students usually switched to table checking. They then compared the numerical values of their relationship with the data set of the phenomena and evaluate their "closeness".

A second approach (taken by only a very few students) was used when an appropriate regression had minor graphical mismatches with the data set. The students dismissed these mismatches and tended to use "what the calculator says." The third approach for visual checking was that taken by those students who solved this kind of problem through a parameter-based curve fitting strategy. These students started with an equation of some general form, such as y=Asin(B(x+C))+D, and then systematically varied the parameters. In this case, graphical mismatches were crucial in their decision to reject the current graphical representation and search for a better one. This process was iterated until the students were satisfied with the goodness of their match. We found that students varied widely in their persistence in attempting to find a good fit. Criteria for the adequacy of a fit were not made explicit. Occasionally when the data set was small and discrete, some students were explicit about their criteria for the closeness of a fit. In that case, the adequacy was usually judged by the number of points actually on the visual representation of the curve.

The use of the calculator as a visual checking tool also supported the students' thinking about the idea of the non-uniqueness of an algebraic representation for an exponential or trigonometric graph. The activities on transformations of functions in both units were designed bi-directionally, going from the equation to its graph and from the graph to a non-unique equation. Initially, in exploring the relationship between graphs and their equations, the students used the calculator as a efficient graphing tool. The students quickly graphed the equations on their calculator and then sketched the graphs on paper. Later, as the teacher actively encouraged the students to use their knowledge of transformations to sketch a graph or find an equation, they relied more on their knowledge of transformations and of the shape of the parent function to sketch the graph on paper. The calculator's use then shifted from a graphing tool to a visual checking tool. The students merely graphed the equation on their calculator, traced the graph on the screen through relevant points and checked if those points matched the given or expected values.

This shift in the role of the calculator from a graphing tool to a visual checking tool was even more pronounced in the case of the trigonometric functions. The "look alike" feature of the graphs of these functions and the infinite number of

possible algebraic representations became particularly problematic with the periodic functions. (We note, of course, that the exponential functions studied earlier have these same features. However, these features were much more salient for the students with the class of trigonometric functions.) An artifact of the calculator screen is that the scaling on the axes of the graphs is not labeled. This made it particularly difficult for the students to visually identify what portion of the graph they were looking at. This in turn led to a shift to a limited use of the table and sometimes of the "Trace" command to numerically check crucial values on the graph. But this too became problematic for the trigonometric functions, since the values that are most often used for the independent variable are integer or common fraction multiples of π. But in the table these values appear as decimal numbers, which cannot be directly compared to the multiples of π, without a numerical conversion. Hence in exploring the transformations of the trigonometric functions, the teacher and students came to rely on their shared knowledge of transformations, with only the most limited use of the calculator.

Discussion and Conclusions

The teacher and the students in this study created a set of ways in which the graphing calculator supported their mathematical investigations and reasoning. The teacher was confident in her own knowledge of the calculator (especially table - graph switching) and believed that it could be a helpful tool for the students to use in finding meaningful responses to problem situations. She also believed that the tool presented certain technological and mathematical limitations. As a consequence of these beliefs, as they were enacted in her interactions with the students and the mathematical problem situations of the curriculum, the graphing calculator became a particular kind of tool in this classroom.

We found that the teacher and students developed a flexible use of the graphing calculator as a tool that could be used to investigate the complete view of the properties of a function's graph. Both teacher and students easily switched between the table and the graph to find local and global properties of a function. This in turn led to discussions about what constitutes a "complete" view of a graph. The teacher's emphasis on meaningful mathematical reasoning in problem situations led to a de-emphasis on the use of regression equations by all but a few students who did persist in their use. But the norms of the classroom came to require that meaningful coefficients had to be justified in terms of the problem's context, leaving little room for regression equations or trial and error curve fitting.

The teacher's recognition of the limitations of the graphing calculator led the students to develop a reasonable skepticism about calculator-generated results. This in turn led to the establishment of a norm that required results to be justified on

BEST COPY AVAILABLE

mathematical grounds, not simply taken as calculator results. The students' interactions with the tool led to the development of a set of ways of visually checking hypothesized relationships between variables. The role of the graphing calculator was an emerging role, as the students' use of the tool shifted from using it as a graphing tool to using its table and trace features as a checking tool. In the case of periodic functions, the teacher and the students came to rely on their shared strategies for transforming functions rather than use the calculator.

The graphing calculator was not a tool with some independent role and existence in this classroom. But rather, the teacher's attitudes and beliefs, as reflected in the role she took in the classroom, led to the calculator being used by the students and by the teacher in a particular set of ways that created and then reflected the graphing calculator as a tool that supported the mathematics learning in this classroom.

ARGUMENTATIVE ASPECTS OF PROVING: ANALYSIS OF SOME UNDERGRADUATE MATHEMATICS STUDENTS' PERFORMANCES

Nadia DOUEK
I.U.F.M. Creteil

Abstract: *This paper examines conjecturing and proving in mathematics through analysis of texts written by undergraduate mathematics students. These students reported their reasonings while trying to generalize a property concerning natural numbers and prove the generalized property. Important reference knowledge remained implicit, and non-standardised, appropriate representation of explicit reference knowledge played an important role in students' performances. Referring to semantically rooted arguments was crucial for many students. Subordinating the proving process to the formal requirements of proof as a final product had negative consequences for some students.*

1.Introduction

During this century, the specificity of mathematical proof has frequently been an object of heated debate among mathematicians and philosophers. Particularly, keeping mathematical proof (and, more generally, mathematics) free from recours to "meaning" has been upheld as a possibility or even a necessity by someone (see Whitehead, 1925: *'Mathematics is thought moving in the sphere of complete abstraction from any particular instance of what it is talking about'*). By contrast, others opposed it as an illusion or even a danger (see Hardy, 1929:"*A formal proof is a kind of X-ray picture of an actual or possible piece of reasoning, revealing the bones [the form] but making the flesh [the content, the meaning] invisible.*"). Cognitive aspects of mathematical proof were not so extensively investigated. And in mathematics education it was only in the eigthies that a systematic effort was made to establish links between epistemological, cognitive and educational perspectives while tackling the specificity of mathematical proof in relationship with argumentation (see Balacheff, 1988; Hanna, 1989; Duval, 1991).

The study reported in this paper is part of a personal research project concerning the comparison between argumentation and mathematical proof and its implications for teaching. In Douek (1998) I sought to outline some possible guidelines for this kind of investigation, mainly considering a modern-day mathematician's reflection about his own work (Thurston, 1994) and Duval's analysis of the cognitive functioning of formal mathematical proof (Duval, 1991). In doing so, I considered the distinction between ordinary mathematical proof and formal mathematical proof (i.e. proof reduced to a logical calculation); and the distinction between the process of proof construction and its product (the final text of proof- see section 2. for more details).I sought to support the following position:

In spite of the undeniable epistemological and cognitive distance between ordinary argumentation and formal mathematical proof, argumentation and ordinary mathematical proof have many aspects in common, both as processes and as products.

In particular, I sought to show analogies between argumentation and ordinary mathematical proof, especially as concerns the use of both implicit and explicit reference knowledge, its dependence on social (and historically evolutive) constraints, and the need for semantically rooted arguments. Concerning the processes (arguing and proving), I sought to show how both are generally built up

through *'transformational reasonings'* (Simon, 1996) and heuristics. The analyses were mainly based on "evidence" from the history of mathematics, mathematicians' testimony or from what usually happens in school.

The aim of the research reported in this paper is to analyse in depth the mathematical activity of conjecturing and proving by exploiting a corpus of texts written by Italian undergraduate mathematics students; they wrote their reasonings while trying to generalize a property concerning the system of natural numbers and then prove the generalized property. In particular I will try to seek for the ways students exploited and represented their mathematical knowledge.

2. Theoretical Background

In this paper I will analyse students' protocols concerning production of conjectures and construction of proofs in an open-ended problem; in addition I will study how students exploit their mathematical and meta-mathematical knowledge in this activity. For these purposes the theoretical construct of **Theorem**, by M. A. Mariotti, seems to be appropriate. According to her (see Bartolini et al., 1997) a "theorem" is a statement, its proof and the reference theory - distinguishing between axioms, definitions and theorems of the specific theory in play, on the one hand, and general meta-knowledge about proving and theorems, on the other. In the same perspective I will consider **"Cognitive unity of theorems"**: this theoretical construct of Garuti's (Garuti & al, 1998) concerns the links that exist between the activity of conjecturing (especially as concerns the production of arguments for the plausibility of the conjecture) and the activity of proving.

I will consider argumentative aspects of proving. We cannot accept any discourse as an argumentation. Henceforth in this paper, the word **argumentation** will indicate two things: the process that produces a logically connected (but not necessarily deductive) discourse about a given subject (from the Webster Dictionary: *" 1. The act of forming reasons, making inductions, drawing conclusions, and applying them to the case under discussion");* and the text produced through that process (Webster: *" 3. Writing or speaking that argues"*). On each occasion, the linguistic context will allow the reader to select the appropriate meaning. The word "argument" will be used as *"A reason or reasons offered for or against a proposition, opinion or measure"* (Webster), and may include verbal arguments, numerical data, drawings, etc. So, an "argumentation" consists of one or more logically connected "arguments".

Argumentation is frequently opposed to **formal proof**, i.e. a proof reduced to a logical calculation. According to Duval (1991), in argumentatative reasoning, *"semantic content of propositions is crucial"*, while in deductive reasoning *"propositions do not intervene directly by their content, but by their operational status"* (defined as *"their role in the functioning of inference"*).

But what are the relationships between formal proof and what has been in the past and is today recognized as mathematical proof by people working in the mathematical field (for this reason, I will refer to it as **"ordinary mathematical proof"**)? My research work has been strongly influenced by the position of Thurston (1994):

"We should recognize that the humanly understandable and humanly checkable proofs that we actually do are what is most important to us, and that they are quite different from formal proof. For the present, formal proofs are out of reach and mostly irrelevant: we have good human processes for checking mathematical validity."

In the analysis of students' protocols I will distinguish between the **process of proof construction** (i.e. "proving") and its **product** (as a socially acceptable mathematical text): for a discussion, see Douek (1998, Section 4). Ordinary mathematical proof can be considered as a particular case of argumentation.

Argumentation and proof use references, and I will analyse how students do it. The expression **reference knowledge** will include not only reference statements but also visual evidence, etc. assumed to be unquestionable (i. e. "reference arguments", or, briefly, "references", in general). In Douek (1998, Section 4.1.) I have discussed the necessary existence (in ordinary argumentation as well as in ordinary mathematical proof) of references which are not made explicit.

3. Method

3.1. The educational context

I study written production of conjectures and their proofs in a task related to elementary number theory. The output in question was produced by 43 university students over four consecutive years (from 1995 to 1998) while completing their undergraduate studies in mathematics at the Genoa University. At this level, the students are capable of mastering the mathematical knowledge and the rules of algebraic calculation they must deal with. They are following a mathematics education course and work under a contract (explicitly established with their teacher) that requires them to write down every idea that come to them during their work, even if they change their mind about its validity or its usefulness. This contract is intented to obtain productions regularly for use by the whole group for didactical and cognitive analyses of problem solving activities.

3.2. The task

The students were to generalise a proposition (*"The sum of two consecutive odd numers is divisible by four"*), then prove the generalised proposition. The fact that they had to build up their own conjectures makes their work very different from ordinary school proving, where students have to gather arguments to support a proposition they might never have thought of before. In our case we may suppose that the act of forming a conjecture fixes the conjecture very firmly in their minds, and the proof can be strongly influenced by the steps that led to the insight of the conjecture (see Garuti et al., 1998: "cognitive unity of theorems").

3.3. Modes and criteria of analysis of students' performances

I considered 14 texts (by the 1997/98 students) in particular detail, and then checked analogies and possible differences with the whole set of 43 texts. Reference will only be made to the 14 texts analysed in detail, but the aspects described are recurrent in the other texts as well. Some excerpts from two texts (by Students [1] and [2]), chosen as representatives of opposite behaviours, are reported(see Annex).

Bearing in mind the aim of this study and the theoretical framework, each text has been analysed according to the following modes and criteria:

A) overall account of student's conjecturing and proving (global effectiveness of their performance, etc.);

B) implicit and explicit reference knowledge backing students' argumentation. I distinguished (see Bartolini et al, 1997: "theorems") between:

- content reference knowledge;

- meta-knowledge about the operations that the task called for (generalising, etc).

I also analysed the external representation of explicit reference knowledge. Concerning this issue, our attention focused particularly on personal (verbal, schematic, etc) expressions that would be unusual in a normally acceptable written mathematical production.This kind of analysis was needed in order to explore in depth how these undergraduate mathematics students used their knowledge;

C) occurrence of algebraic-syntactic or semantically based steps of reasoning and the relationships between them. This analysis was needed in order to understand better how the two kinds of reasoning are functionally interlinked and connected to the solution of the problem.

D) relationships between the proving process and the proof as a product (and the consequences of matching the former to the latter).

4. Students' behaviour

4.1. Overall account of students' work

Within the 14 texts, only four (Students [1], [2], [11], [13]) tried to prove something distinctly: two (Students [1] and [11]) prove their conjectures: and Student [13] a partial result of a confused conjecture. Student [2] (see Doc. 2) tries to prove a result that is stronger than the conjecture expressed in words; his proof lacks a fundamental step (justification of the formula used, which derived by generalisation from numerical examples). Let us call these four students the "proof group". But as we can hardly distinguish the processes of construction of conjectures from construction of proofs in the work of the students, we may as well study more texts from the perspective of proof construction. Another important argument to support this shift in the study from proof to conjecture construction is that five students do not achieve their proofs (even though they were on the right track) probably because of a lack of active mathematical practice combined with the unusual situation of having to build their own conjectures. So we can consider the constructive work of nine students (we may call "conjecture group", which includes the "proof group") and take, as comparative examples, elements of the work of the other five ("failure group").

4.2. Reference knowledge and its representation

The task called for elementary content reference knowledge: elementary arithmetics, algebraic language and its rules of calculation. Some students tried to use other reference knowledge such as functions and series. Concerning algebra, we may remark that the process of formalisation (i.e. the passage from content to formula) was not easy for many students, especially when they wanted to write the sum of K odds: for instance, some of them wrote $(2n+1) + (2n+3) + \ldots + (2n+?)$

and then stopped; few were able to express *?* as *2K-1*: see **(E)** in Doc.1. Writing the result of the sum was not easy either: it demanded a semantically rooted conversion of a known formula (the formula for the sum of the first n natural numbers - cf. Szeredi & Torok, 1998), or the re-construction of an ad-hoc formula: see **(F)** in Doc. 1

As concerns the external representation of content reference knowledge, I have found many organisations of data and schemas with visual effects that reveal regularities and help to express algebraically some arithmetic relations; we also found symmetries in the disposition of data and formulas, which provide hints for the calculus (see figures in Doc. [1] for two examples).

We may remark that these behaviours are related to knowledge which is not always recognised as an important tool for solving problems, though it is itself constructed knowledge (cf. Briand,1993, for similar remarks concerning counting strategies). We may also remark that in other fields of mathematics (such as numerical analysis or category theory) schemas and organisational schemes are crucial tools.

Meta-mathematical knowledge was made explicit especially when it was almost algorithmic (see Student 2) or referred to the task (*"What does it mean 'to generalize'"*), but appeared only implicitly when it was complex (actually richer) and nearer to the mathematicians' behaviour (see Thurston, 1994). Summing up the analyses performed, I may say that, concerning meta-mathematical knowledge, shared explicitable knowledge was much narrower than the actual knowledge used globally by the group. I found that eight students referred explicitly to methods for solving problems of this kind, but, to take an example, "organisation of data" was never mentioned even in partial explicitations of methods though it was a key strategy for four students and useful for three of them. Only one of the fourteen students (Student [12]) seemed to have no idea of possible strategies for solving problems of this kind: she seemed lost, mixed up different steps undertaken and produced several unfinished propositions. For Students [1] and [13] ("proof group") I detected very rich implicit meta-mathematical knowledge about how to solve the problem.

The implicit problem-solving methods I could detect globally were: change of representation; interpreting calculations in words and vice versa; visually organising data and calculations, up to a geometrical regularity. I could also detect changes of mathematical frames: arithmetic, algebra, series, etc: this is common in the process of proving for mathematicians.

4.3. Algebraic-syntactic or semantically based steps of reasoning

I have listed numerous breaks during calculations, which were needed to re-interpret the mathematical content of calculus in words. This can be seen as a sign of the primacy of semantical content over algebraic calculation during the process of conjecture and proof construction. As an example, we can consider the need of Student [1] to express algebraic propositions in words when seeking to recognise possible conjectures. This attitude displays the search for a semantically consistent

grasp of the algebraic signs. We can interpret it by saying that constructive work in mathematics cannot evolve only within formal expression.

On the other hand, if we observe the students who did not express the results of their calculation in words richly (five of the fourteen students), three (Students [3], [4], [12]) are in the "failure group" of five students and two ([2] and [13]) in the "conjecture group" of nine students. So the majority of the "conjecture group" (seven out of nine) needed semantic interpretations to pursue their work. I recall that Student [2] did not recognise the strong result obtained, and that [13] was confused in expressing his conjecture - it was not clear to this student what was proved by the calculation.

4.4. Proof as product and proof as process

Let us compare two examples that are representative of some others in the whole group of 43: in the first, proof as a product is close to proof as a process, while in the other the distance is very great.

Student [2] is considered skillful (good notes, etc), but sticks very closely to her explicit method and her presentation is very close to that of a formal presentation. This approximation to a formally correct mathematical text (cf Hanna, 1989) bears negative consequences on the productivity of the student's work: her research is linear and no change of strategy is found at any level. There are long repetitive arithmetic calculations, quite astonishing for the only student in the group who usually managed algebraic tools very well; more remarkably, the student arrives algebraically at a strong conjecture and interprets it in words as much weaker. And finally she does not produce a complete proof.

Analysing the text of Student 1, we can observe frequent changes of strategy, organisation of data and calculations, as well as a frequent effort to interpret in words. This variety, this need for change might help technically, but these were also "interpretation" efforts. They helped understanding and often stimulated the developement of new ideas. This could be called a "transformational reasoning attitude" (see Simon, 1996; Harel and Sowder, 1998). Some of these very useful forms disappeared in the final draft of the proof (**P**), where the logical link between the propositions became a priority. In addition, justification of the research method disappeared from the product (while examples of the interwoven presence of meta-mathematical arguments in mathematical reasoning were frequent in the construction stage). Her conjecture is strong and her proof is almost complete.

5. Conclusions

We have seen that important reference knowledge remained implicit in the students' proving processes and that some of the different references concerned the content, while others related to the meta-knowledge about the activity to be performed. We have also seen how non-standardised, appropriate representation of explicit reference knowledge had an important role in the students' performances. We have seen that when elaborating a productive process many students found syntactic arguments insufficient, and so semantically-rooted arguments became critical. Finally, we have collected some experimental evidence about the negative

consequences of subordinating the proving process to the formal requirements of proof as a final product.

As concerns the educational implications of the analysis performed in this paper, it can be argued that formal proof (which is sometimes imposed or proposed to students of any school level as a rule of construction of mathematical proof: see Hanna, 1989) is very distant from the effective activity of conjecturing and proving. This is true even for undergraduate mathematics students facing a new, challenging situation. Furthermore, the effectiveness of their activities seems to depend on intellectual qualities that are fully developed even during ordinary, demanding argumentative activities other than proving.

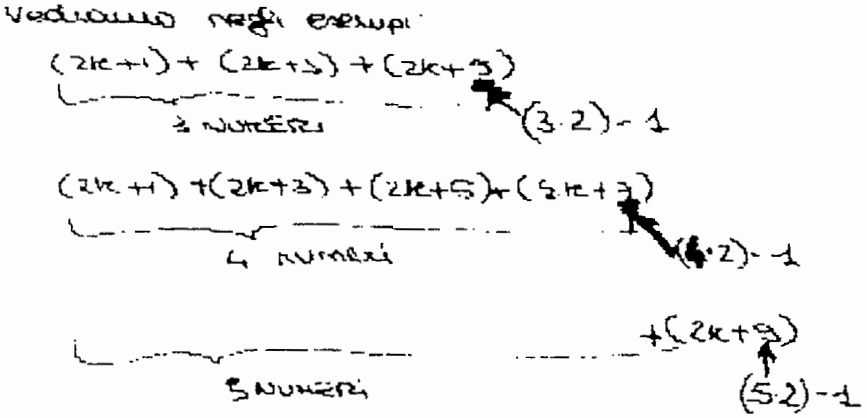
DOC.1: Excerpts from the text of Student [1]; it contains seven large, spatially organized pieces, like the two reported below, and many arrows, connecting lines and encirclings.

"I have some difficulties in understanding in what direction I must generalize. It might be: 'by adding two odd or even consecutive numbers I get a number divisible by 4' [she performs some numerical trials]. *This does not work. I shall try to generalize in another way:*



I was looking for something that could help me [...] but I got nothing.

BEST COPY AVAILABLE

[other trials, with a rich spatial organisation: two consecutive even numbers, two consecutive odd numbers - here she gets divisibility by 4; then three, four, five, six, seven consecutive odd numbers. By performing calculations, she gets the following formulas: *3(2K+3); 8(K+2) 10K+25=5(2K+5); 12K+36=12(K+3); 14K+49=7(2K+7)*]. *Is the result of the addition of n consecutive odd numbers (n odd) divisible by n? (2K+1)+(2K+3)+..(2K+ What must I put here?*

(E)

[she performs an unsuccessful trial by induction; then she considers n numbers in general]

n numbers: (2K+1)+(2K+3)+...(2K+(2n-1))=2nK+1+3+5+...+(2n-1)=2nK+ (I am thinking of the anecdote of "young Gauss":

(F) *it makes 2n.n/2=n²) = 2nK+n²= n(2K+n) OK!!*

[Trials performed by applying the preceding formula $2nK+n^2$ in the cases n=2, n=4, n=6, n=8: she gets: *4K+4 divisible by 4; 8K+16 divisible by 8; 12K+36=12(K+3); 16K+64=16(K+4) divisible by 16*]. *Then if I add n consecutive odd numbers (n even), I get divisibility by 2n. Let us try a proof:* **(P)** *(2K+1)+(2K+3)+...(2K+2n-1)=2nK+(1+3+....2n-1)=2nK+(2n.n)/2=2nK+n²*

[....]= 2n(K+n/2); n even implies that n/2 is an integer number: so I get divisibility by 2n. [...]

DOC.2: Excerpts from the text of Student [2]; spatial organization is almost linear, like that in the following trascript.

Student [2] starts her work by checking (on numerical examples: 3+5; 5+7; 101+103) the validity of the given property, then proves it. Then she writes: *"When I must tackle a problem, I try to see how it works in particular cases and then I generalize, as I have done in this case - although I knew the solution. I reason in this way because the particular case allows me to understand better how I can reach the solution of the problem in general (and this method works even when I do not know the solution). Thinking in arithmetic terms and then in algebraic terms helps me to solve the problem. For the original property the generalization comes fairly automatically, because* [she explains why in detail].

What does it mean 'to generalize' ? It means considering a property in which there are some closed variables (two odd numbers, or divisibility by 4) and getting a property in which variables are open. I change the number of odd consecutive numbers to add. For instance, I consider 3 [crossed out] *4 consecutive odd numbers 2n+1, 2n+3, 2n+5, 2n+7 and make the addition: 2n+1+2n+3+2n+5+2n+7=8n+16=8(n+2)=4(2n+4). Then I find a number that is divisible by 8, so it is divisible by 4. I perform the addition of 6 consecutive odd numbers* [similar calculations]=*24n+37=6(2n+6).*

Then I find a number which is divisible by 12, so it is divisible by 6. I try with 8: [similar calculations]=*8.2n+64=8(2n+8) Then I find a number that is divisible by 8, so it is divisible by 4. Following my reasoning, for an even number K of odd consecutive numbers I get: 2n+1+2n+3+....+2n+1S+....=K(2n+K)=2K(n+K/2); but K is an even number, so it is divisible by 2 and (n+K/2) is an integer number. Then 2K is divisible by 4 (because K is odd). So I have found that the given property is still valid if I add up an even number of odd consecutive numbers.*

Students' Views of Learning Mathematics in Collaborative Small Groups

Julie-Ann Edwards and Keith Jones

The University of Southampton, United Kingdom

Approaches to mathematics teaching which offer an alternative to stating facts and demonstrating procedures have been criticised for undermining the base for teachers' sense of their own effectiveness. Data from an ethnographic study of the classroom practice of an experienced teacher of mathematics who has developed an inclusive (or emancipatory) pedagogic approach indicate that while establishing collaborative groups in the classroom may take some time, students across the attainment range come to appreciate the effectiveness and efficiency of working in such a way. This is in some contrast to research findings about using cooperative groups, a quite different method of teaching. Such findings may support other teachers of mathematics developing an alternative pedagogic approach.

Introduction

The ways in which the actions of the teacher impact on the learning of the students in their class is reasonably well-documented, at least in general terms (see Brophy 1986 or Sylva 1994 for reviews). The development in mathematics education of a model of inclusive pedagogy (Murphy and Gipps 1996, Solar 1995) entails the teacher employing such actions as open-ended, problem-based learning within collaborative small groups. This pedagogical approach is designed with the intention of securing the success of all pupils in mathematics.

Such an approach is quite different from what Smith (1996) calls teaching by "telling", where the teacher's main role is stating facts and demonstrating procedures. Smith argues that teaching by "telling" provides a clear-cut basis on which teachers can build a sense of efficacy, the belief that they can affect student learning. Basing teaching on "telling", Smith suggests, builds a sense of efficacy for teachers by defining a manageable mathematics content and providing clear prescriptions for how to teach that content. In Smith's terms this means that adopting an inclusive pedagogy "undermines the base for teachers' sense of efficacy that teaching by telling provides" by de-emphasising "telling". This suggests that research is needed on how teachers who have adopted an inclusive pedagogic approach build new foundations for their sense of efficacy in teaching mathematics.

The research results presented in this paper may contribute towards what Smith has called a central question for empirical studies of mathematics teaching: how teachers who have moved away from teaching by telling are able to "reconceptualise their causal agency in teaching mathematics". The conclusions also point to what might be a fundamental difference between collaborative and cooperative group work in mathematics. The data come from a collaboratively designed and carried out

ethnographic study of the classroom practice of an experienced teacher of secondary mathematics (see Edwards and Jones, under consideration). The aim of this component of the study was to document the views and opinions of students who had experienced collaborative small group work as a means of learning mathematics through being taught by a teacher who had an inclusive pedagogical approach. In this paper we show how well the full range of students understood the effectiveness and efficiency of collaborative small group work as a means of learning mathematics. Yet, it seems, such understanding took some time to develop. These findings may prove useful for other teachers of mathematics seeking to adopt an inclusive pedagogy by suggesting a basis upon which they can judge their efficacy.

Theoretical Framework and Related Research

In attempting to understand the complexities of learning in schools, knowledge of the student perspective has come to be seen as crucially important. As a result, children's understanding of classroom processes and their own role in learning have become an area of increasing study (for examples, see Brown 1995, Christou and Philippou 1998).

An inclusive (or socially-just or emancipatory) pedagogy is being developed from work in feminist and other emancipatory endeavours. With such an approach, the teacher is intent on recognising and valuing a plurality of forms of knowledge and ways of knowing (Becker 1995, Povey 1996, Solar 1995). In the mathematics classroom, this might entail using open-ended, problem-based learning based on social and environmental curriculum contexts using collaborative team approaches within a diversity of teaching and assessment methods.

Some of the theoretical basis for this pedagogic approach comes from the socio-cultural, Vygotskian field. For example, collaborative group work, in which students work jointly on the same problem at all times, is linked with ideas such as situated cognition, scaffolding, and the zone of proximal development. As Damon and Phelps (1989) make clear, this is fundamentally different from cooperative learning which refers to distinct principles and practices such as specific role assignments in a group, and goal-related accountability of both individuals and the group.

A good deal is known about cooperative small group learning (for reviews, see Good, Mulryan and McCaslin 1992, or Cohen 1994). Much less is known about collaborative small group work (Lyle 1996). As a result, little has been reported about a range of issues such as how the composition and dynamics of groups affects their ability to function effectively (for a recent report, see Barnes 1998), or whether the students themselves find it an effective way of working. What is known is that the composition of collaborative groups needs careful consideration, and that there is a vital role for the teacher in establishing collaborative group practice, planning such work, and choosing and structuring appropriate tasks.

The study reported in this paper was designed to elicit the views on collaborative group work from secondary school students who had been taught for varying lengths of

time (from two to four years) by a teacher who had developed an inclusive pedagogical practice. A study of students' perception of *cooperative* small group work in mathematics by Mulryan (1994), which involved interviewing students in secondary mathematics classrooms, was designed to gauge the consistency of their understanding of the processes of cooperative work with that of their teacher. Mulryan found that with cooperative group work the perceptions of high achieving students were more in line with those of their teacher than those of low achieving students. Such a finding might suggest that *cooperative* group work could *increase* the separation between high and low achieving students, a possibility implied in other studies of cooperative learning (Good, Mulryan and McCaslin 1992 p172-173 and 176-177). One aim of the study we report in this paper was to examine the perspectives of both high and low achieving students who had experienced *collaborative* group work in secondary mathematics for a considerable period of time to see whether there was a difference in their perceptions of working in such a way.

Methodology

An ethnographic case study using semi-structured interviews was most suitable for this research for two reasons. First, it allowed the students to say what they wished about their experiences of collaborative group work within the framework of the interview schedule (Hammersley and Atkinson 1995 p25). Secondly, semi-structured interviews are known to be suitable for gathering information and opinions and exploring people's thinking and motivations (Drever 1995). Strict procedures were adopted for the interviews in order to minimise any potential bias introduced by the interviewer.

The sample

A random sample of seven students were chosen for the study, selected from the classes of a teacher who taught in a UK inner-city comprehensive secondary school whose mathematics results in national testing were approximately in line with the national average. The classes from which the students were chosen were a Year 11 low attaining class (students aged 15-16) who had experienced small group collaborative work in mathematics for the previous four years, a Year 10 high attaining class (students aged 14-15) who had experienced small group collaborative work for the previous three years, and a Year 8 middle attaining class (students aged 12-13) who had experienced two years of small group collaborative work. The seven students were selected in the following way: two from the low attaining Year 11 group, three from the high attaining Year 10 group, and two from the middle attaining class Year 8 class (attainment was defined by the school in terms of performance on standardised non-verbal reasoning tests). All the students had been taught by the same mathematics teacher throughout their experience of collaborative group work in mathematics.

The interview

An interview schedule based on the headings used by Mulryan (*ibid*) was utilised as a set of general prompts. Questions were based around the following pupil perceptions:

- perceptions of the purpose and benefits of collaborative small group work in mathematics

- perceptions of teacher expectations for appropriate student behaviour during small group work
- perceptions of the characteristics of small groups that are important for successful groups
- perceptions of the extent to which individual and group accountability exist in small groups
- perceptions in relation to the stability of membership of small groups

The opportunity was also offered to the students for more open comment on their experiences of collaborative small group work.

Analysis of data

Following transcription of the audio tapes, each response was systematically coded for a particular category or categories. These categories were developed in an on-going way as new student respondents contributed different categories until there was a stable set of categories. This process of grounded theorising was necessary as the sample size was too small to use the particular categories devised by Mulryan, who, even with a sample of 48 students, had no more than 5 responses in any one category. As part of this analytical process, some categories were grouped to reflect similar themes.

The following grouped categories were amongst those identified from the interview transcripts:

- Benefits of working together/ collaborating/ working as a team/ working as a group. This theme was evident in all seven respondents' descriptions of their experiences of collaborative group work. For example, R (low attaining Year 11) said "I think its really good, because we're able to work ... as a team ... you just understand more about maths than you do just by writing down on pen and paper". S (high attaining Year 10) said "you might only look at a problem one way, but ...if you give lots of different people a problem, and they look at it in different ways". V (middle attaining Year 8) said "it's lot easier to work in a group because you can help each other and you can find out the answers and make sure yours are right".
- Putting ideas together/ contributing/ using different skills (described as a process). As for the theme above, this was widespread throughout the transcripts. R (middle attaining Year 8) said "you put all your ideas together, and by putting everyone's ideas together, you come up with good ideas and just get good knowledge". R (low attaining Year 11) describes a similar experience, "and even if one person did say ... this is the right answer, we wouldn't just write it down, you'd, you know, make it more deeper and everybody'd put more to extend the answer". J (high attaining Year 10) related that "K came up with an idea once, and then we .. started working on that, and then other people ... put in other ideas on top of it, so we were always building up".
- Listening to/ respecting others in the group/ sharing knowledge.

This theme is distinct from merely recognising the skills offered by others. It is described by R (middle attaining Year 8 class) in the following way: "We can all listen to people's ideas, which I think is good and ... we all bring up our own ideas," and in the high attaining Year 10 class by S: "people come up with different ideas ... and you get to explore other people's ideas which helps". Z (low attaining Year 11) said "someone would say [something].. and then we all would .. put our different words in and talk about it".

- Confidence building/ feeling successful/ being motivated

  Some pupils, including the higher attaining students, described collaborative group work as a vehicle for increasing their mathematical confidence. For example, L (high attaining Year 10) said "I think in my case, ... if I know someone else thinks the same thing, I'm more confident about what I think". There were several instances of pupils describing the experience of group work as making them feel more successful. J (also high attaining Year 10) explained "I just think its better than working by yourself, really. I think you learn a lot more". Pupils also seemed to find the group dynamics a more motivating learning environment. Z (low attaining Year 11) affirmed "we just didn't want to leave it ... we used to stay behind lessons ... we wanted to get the work done ... I prefer doing maths ... with group work ".

- Friendship/ knowledge of collaborators/ stability of groups.

  Questions about group structure revealed that all the pupils believed that their performance in a group was positively affected by working with others who were well known to them. Friendship seemed to provide successful working relationships in the view of all those interviewed. V (middle attaining Year 8) explained "If you're not friends with somebody, ... you might not get along with them, and they might start getting into a bit of an argument about the answers". R (low attaining Year 11) said "no others could be as good as working with some friends". S (high attaining Year 10) said "well, obviously, you've all got to get on quite well, you've got to know ... I think it's easiest if you know each other first".

- Speed/ volume of learning.

  Students across the age and achievement range thought that collaborative learning in small groups allowed learning to happen more quickly and that they could learn more. J (high attaining Year 10) summed this up: "I think you learn a lot more, ... I think if people ... work together you can get a lot more done and you ... understand a lot more ... I think its probably quicker, because if you're working by yourself, it's you that does all the work,". R (middle attaining Year 8) said "it's easier if you do group work because you can get through it quicker and .. get to know a lot more". R (low attaining Year 11) offered a more reflective comment "I don't think it's quick or slow, it's in the middle, but because it's like that, you get a deeper meaning, you know what you're doing, you don't just skim it over the top".

Other categories of student response included: helping one another, thinking hard, enjoyment, autonomy and independence, and awareness of the possibilities of distraction. All the students were also aware of the expectations of the teacher in terms of what was appropriate for successful collaborative group work in mathematics.

Discussion

This analysis of the interview transcripts for the categories described above allows some comment to be made, both on emerging global patterns in the student responses and on local patterns within groups. Examples of such local patterns relate to the age of the students and the length of their experience of collaborative small group work.

Overall, the full range of students in this study seemed to recognise the benefits of collaboration. They realised the necessity of listening to one another, felt collaborative working made them confident and successful, and judged that they learnt more mathematics more rapidly by working in that way. There also appears to be clear indications that working with friends, that is working with those with whom you get on well, is important. It may be that this helps with the sharing and respecting of each others ideas and that, in the end, this helps with learning. These benefits of working with friends are noted by Zajac and Hartup (1997) in their review. Whicker and Nunnery (1997), in their study of cooperative groups in secondary school mathematics, found that their students "disliked having groups pre-assigned and permanent, and suggested alternating group membership".

Yet the responses of all the groups were not identical. In particular, the responses of the younger students from the Year 8 class, who had only experienced collaborative small group work in mathematics for two years, were different in several respects. These students found it more difficult to articulate their perceptions of collaborative group work. Overall, their responses during the semi-structured interviews were much shorter, less reflective, and demonstrated less understanding of the pedagogic process, than the older students. In addition, the younger students seemed more orientated towards outcome, rather than process or understanding. For example, student V, middle attaining Year 8, said that working in a group means "you can find out the answers and make sure yours are right", and, later in the interview, that it was more enjoyable to work in a group because "you can get more accurate answers from it".

Such responses from the younger students, and the contrasting answers from the older students, may indicate that, in addition to maturation, it takes quite some time for the teacher to establish fully collaborative groups. The research on cooperative groups has already established that simply placing the students in groups does not mean that group work will take place. Indeed a frequent complaint about common practice in UK primary schools is that the pupils are arranged in groups in the classroom yet they do essentially individual work. Training in cooperative working was found necessary for successful cooperative group work, and research on collaborative learning suggests that for collaborative group work some form of teaching of relevant skills is required (Gillies and Ashman 1996). A range of other factors is likely to influence the

successful development of collaborative group work, including, in secondary schools, the experience of the students in other curriculum subjects.

Finally, unlike Mulryan (1994), we found no difference between the perceptions of high attaining students and those of low attaining students. All the students in our sample felt that collaborative group work had a positive effect on their rate of learning and depth of understanding. The reason for this difference, however, may not lie solely with the grouping structure. In our study it is likely that the philosophical and epistemological stance of the teacher, in developing a strongly inclusive pedagogy, is the influencing factor.

Concluding comments

Smith (1996), in calling for research on how teachers, who have moved away from a pedagogic approach based on "telling", build new foundations for efficacy in teaching mathematics, suggests that studies should focus on "how teachers themselves *see and understand the effects of their practice on students*" (emphasis in original). In the case of the teacher in our study, one of the ways the teacher judges her efficacy is in terms of the success of the collaborative group work for all her pupils. Hence our focus in this paper on the student perspectives of working in collaborative small groups.

It is not the intention of this study to produce a typology of categories of student responses, nor to test a theoretical model. Our aim has been to describe the perspectives of secondary school students who have had considerable experience of collaborative small group work in mathematics. It is, in both the sense of the case size itself and in the sense of the time scale used, a "microethnography" (Hammersley and Atkinson, *ibid*, p 46). The lack of comparative cases "necessary for developing and testing an emerging set of analytic ideas" (Hammersley and Atkinson, *ibid* p205) is one difficulty of using a naturalistic situation to study. Furthermore, the data comes from one UK school and hence its generalisability is greatly limited.

Nevertheless, we hope we have provided a useful contribution to research both on collaborative group work in mathematics and on inclusive and emancipatory mathematics pedagogy. Such a pedagogic approach, given its coherent philosophical and epistemological basis, provides the teacher in this study with a strong anchor with which to judge her efficacy.

PLAYING OR TEACHING?

THE INFLUENCE OF DYAD FRAMEWORK ON CHILDREN'S NUMBER EXPERIENCES IN MATHEMATICS GAME PLAYING AT HOME

Fiona R. Ell and Kathryn C. Irwin

University of Auckland

Families' use of a Maths Games Library was investigated using a socio-cultural framework. The Maths Games Library was a home-school communication project, initiated by parents and teachers in a primary school of 421 pupils. Analysing the interaction between parents and five-year-olds on audio tapes revealed two frameworks for game playing activity: a game-focused framework and a mathematics-focused framework. The characteristics of these frameworks resulted in differential experiences with number for the children playing the games. Teacher-pupil dialogue suggested an evaluative framework. The study highlights the significance of activity as the agent of development, indicating that the nature of interaction between players in a game can make a difference to children's learning in mathematics.

Introduction

A Maths Games Library is used as the focus of this study. It is a collection of games and activities which children take home weekly to share with their parents. This Maths Games Library was established in 1996 at North Primary, a predominantly white, middle-class school in Auckland, New Zealand. A committee of parents and teachers worked together to make the games, and a class set is used in every classroom from Year 1 to Year 3. This study was conducted in 1998 and the use of the Maths Games Library had become an established routine for parents and teachers. North Primary emphasised home-school communication and was eager to meet parents' needs for information.

Parents of children in New Zealand primary schools receive a reading book to share with their child each day. This provides an important link between home and school. The Maths Games Library was intended to provide a similar link for communication about children and their mathematics learning. What was unknown was what the parents and children did with the games in their homes. As a joint activity between an adult and a child, the game playing setting appears to have rich potential. This study aimed to look beyond whether or not the games were used at home and consider what happened between the parent and child as they used the games, using a socio-cultural framework.

Lerman (1998) describes the use of a cultural, discursive psychology to view mathematics education. He presents the 'zone of proximal development' as a research tool "...for analysis of the learning interactions in the classroom (and elsewhere)" (Lerman, 1998, p. 71). This study employs Lerman's proposed psychology in considering the interaction of parents and children in the zone of proximal development. Lerman (1998) hints at this in his addition of 'elsewhere' to places for analysis, but describes mathematics education as beginning in classrooms. Literacy research conducted within the socio-cultural framework outlined here suggests that the family is a powerful site for the development of emergent understandings and for the support of learning after entry to formal schooling. This study explores that notion, using a school-based initiative to explore children's experiences at home.

A theoretical viewpoint which highlights the importance of social interaction in development sees this game-playing setting as a potentially critical site for the formation of concepts and the growth of cognition. It involves an expert and a novice working together to construct meaning from materials. Language is used to establish intersubjectivity and to construct new ideas. Parent and child work together, co-constructing understanding through the progress of the game. The interaction of the three key elements - parent, child and game - result in a unique pattern of activity. This activity is situated within the home organisation and routine, and may constitute a family practice.

The social interaction between the players may be internalised as personal understanding through the game playing (Vygotsky, 1978; Wertsch & Stone, 1985). The role of participating in activity as the agent of learning is defined by Rogoff (1995), who suggests that settings such as the game playing described here can be seen as guided participation. This guided participation leads to participatory appropriation by individuals, who each form their own ideas about the activity based on their experience. Learning can thus be seen in the activity, rather than within the child. Activity therefore becomes the unit of analysis.

The game playing activity described in this study has several important features in terms of this framework. The presence or absence of an adult expert will affect the way the learning is mediated. There is potential to observe the transfer of responsibility from the expert-adult to the novice-child, or to see the use of scaffolding to support the child's learning. Establishing intersubjectivity through activity and language, as discussed by Lerman (1998) should be evident. Situating the game-playing within the home may have a key influence on how it proceeds; using the same materials at school might invoke a different set of rules.

Abreu (1998) explores this in considering Brazilian children and their home and school mathematics. While she focuses on the mathematics of 'real life' outside school, rather than on game playing, within the culture under investigation in this study game playing is a common form of interaction between parents and children (Wylie & Thompson,

1998). Abreu (1998) notes the diversity of the children in their engagement with home mathematics and their success in mathematics in school, despite apparent similarities in the community. The study presented here begins to look for the origin of such differences within activity; in culturally and situationally determined interaction patterns and systems, which may critically influence children's mathematics learning.

Analyses of adults and children working together suggest that contingent responsiveness may be a key element in exchange which results in development. Pratt, Green, MacVicar and Bountrogianni (1992) view parents solving division problems with their children. Although more directive than teachers, results show parents as responsive to the child's level of ability and to the difficulty level of the material. Lehrer and Shumow ('997) investigate the alignment between home and school after teachers have completed inservice to reform practice. While parents agreed with many of the new techniques, as viewed on video, they did not use them with their children. They provided more direction and instruction while solving word problems than the children's teachers did. Responsiveness to everyday mathematics has been found to be important in developing mathematical understandings. Young-Loveridge (1989) describes a literacy-oriented family with a child who is making slow progress in mathematics. This family had focused on literacy to the exclusion of numeracy, and did not utilise the opportunities presented by the environment or the child. Observing interaction rather than using an interview (Young-Loveridge, 1996) revealed that very little contingent responding about mathematics occurred in the context of cooking. This highlights that it is not involvement in cooking which builds mathematical understanding, but having mathematical ideas posed and responded to in this context. This may hold true for the Maths Games Library - it may not be using the materials that promotes understanding, but the interaction that takes place. Examining the nature of this interaction is therefore crucial.

Methodology

This study used activity as the unit of analysis, as proposed by the socio-cultural framework (Wertsch, 1995). The activity of game playing was captured using small tape recorders, which were unobtrusive and resulted in collection of the verbal interaction between players. This interaction formed the basis of the analysis, being the evidence of activity and the proposed mode of learning and development, as this social interaction becomes internalised. While studies of problem solving (Lehrer & Shumow, 1997; Pratt, Green, MacVicar & Bountrogianni, 199_ have used hierarchal analysis of support in order to show scaffolding, a game does not necessarily have this structure. Thus categories of utterance, with distinct purposes, were derived, rather than a measure of directiveness.

Method

Participants

Thirteen families recorded their game playing. Five of the target children were boys and eight were girls. The study child's place in the family varied from being an only child, to being the sixth of six children. Only two of the children had no pre-school experience, with seven children attending private pre-school in addition to public kindergarten. The children were all aged five at the time of the study, and had been at school no longer than two terms prior to the study.

Materials

Two games were selected from the Year One Maths Games Library. 'More Dots' was selected as an easy game, and 'Oops!' as a hard game. The games were brought home in a brightly coloured bag, complete with equipment and instructions. Isomorphs of the games were made for play with the teacher. These used dice instead of cards, but followed the same rules.

Families were provided with a small tape recorder and audio tape on which to record their game playing. They also completed a questionnaire after playing the game.

Procedure

The games were sent home as part of the usual routine for sending home games. Tape recording equipment was added to the bags of the target games, and the researcher specified which families should receive the games each week. The teacher played the games with two of the target children during a mathematics teaching session. This was recorded in the same way as the families'.

Data Analysis

Both games proceeded by the players turning over a card. This was used as the unit of interaction, and utterances after each card turn were coded and numbered. Contributions were numbered and attributed to the parent or the child. Thus the interaction could be reconstructed from the coding, in terms of the purpose and order of the utterances. The length of interaction after a card turn could be determined, as could the format of the interaction - be it turn-taking or several utterances by one person.

Results

Analyses of the families' tape recordings revealed two distinct patterns of interaction, or frameworks. These are summarised in Table 1. A case study example illustrates that the tone and content of the exchanges while the game progressed also reveal the characteristics of these two frameworks. These examples are from the same tape, where the child plays the game with her mother and her father. Her father is in a game-focused framework, her mother in a mathematics-focused framework. In game-focused play over half the time was spent playing in silence. In mathematics-focused play turns are punctuated by comment and discussion.

Game-focused play - Examples of interaction

Example 1.

P: What do you think this helps you with T.? Does it help you with counting?

C: Yup.

Example 2.

C: Dad, this is how you learn numbers isn't it?

P: (no response)

Example 3.

C: Two and two. Look Dad!

P: (no response)

Example 4.

C: Who wins that one?

P: It's two pairs.

These examples indicate the type of interaction occurring during game-focused play. These examples represent the additional mathematics talk undertaken by the father and daughter. The father attempts once to link the game as a whole to his daughter's mathematics learning (example one). This is done in an abstract way, rather than as part of the game play. T. later reflects this back to her father by asking if this is how you learn numbers (example two). This is not picked up on by her father. T. attempts to initiate dialogue in the two other examples. Both instances go no further than the examples given here, despite openings for further dialogue, such as what two and two might be, or what a 'pair' is. From the laughter and other talk present on the tape, it is clear that both father and daughter are enjoying the game, and enjoying it within a game-focused framework.

Mathematics-focused play - Examples of interaction

Example 1.

P: How come I win that?

C: 'Cause you got 3 and I got 1.

P: And how many more do you need to make 3 dots?

C: 3 more.

P: No.

C: 2 more.

P: Good girl. So if you had two more dot w many would you have?

C: 3

P: And how many would I have? Three as well. I've got three as well.

Example 2.

P: You've got to say how many there are

C: 4.

P: Four dots.

Example 3.

P: How many dots does that make altogether?

C: Five.

P: So 4 plus 1 equals

C: Five.

P: OK. So four plus one equals five. Right? So if I take one away, how many does that leave?

C: Four

P: If I take four away, how many does that leave?

C: One.

These three examples from the mathematics-focused play of the mother and daughter are typical of a pattern of exchanges which continue throughout their playing of 'More Dots'. The mother poses questions for T. to answer, using the cards turned over. These questions relate only superficially to the playing of the game, but use the cards to expand T.'s ideas about addition and subtraction. The mother then alters the rules of the game, to make it the lower card that wins on each turn. This leads to discussion about what 'the lower' is, and who will now win. T. and her mother work towards clarifying the language and the concept behind the idea of the 'lower number' over several turns. This drive towards making the game more difficult and drawing the mathematics out of it is not seen in game-focused play. The mathematics-focused play described here results in a different experience for the child.

Table 1: Characteristics of the game-focused and mathematics-focused frameworks.

Game-focused	Mathematics-focused
There are may one-contribution turns and fewer long turns	There are a greater proportion of long turns and fewer one-contribution turns.
Few questions are asked.	Many questions are asked.
The inherent mathematics content is covered.	Additional mathematics content is covered.
Silent turns are common.	Few, if any, silent turns.
There is a low percentage of turns with contingent contributions.	There is a high percentage of turns with contingent contributions.
Players take their own turns, doing their own 'work' on their turn.	Parents ask children to help them with their turns.

This overall pattern reveals a trend in parent support that is not obvious in closer analysis. The two target games were chosen to be of different difficulty levels, but in practice the children found them both easy. There is thus little failure by the children, and therefore no chartable pattern of adjustment in adult level of support. However, parents who rated 'Oops!' as less than very easy for their child on the questionnaire, all adopted a

mathematics-focused framework for their interactions in this game. While some parents adopted the mathematics-focused framework in games that their child found easy, no-one adopted a game-focused framework with anything other than a very easy game. Twelve playing sessions followed a mathematics-focused framework, and thirteen followed a game-focused framework.

In the game-focused framework, players simply play the game. Issues which are directly related to the game's progress are discussed. Many turns pass unremarked, or are punctuated by laughter or sighing. There is less discussion, and each turn of the card is more likely to yield a short exchange. Players who are working in a mathematics-focused framework use opportunities to introduce and discuss aspects of mathematics which are not essential to the game's progress. More questions are used, and the playing of the game is commented on frequently. A 'running commentary' develops between the players. Longer exchanges occur more frequently, and play partner's comments are more often followed by a contingent response.

The teacher data is limited, as she was only able to play with two of the target children, but her interaction pattern suggests a third framework - an evaluative framework. It follows the performance of the child closely and includes elements which allow the teacher to view independent performance. The teacher in these interactions does not attempt to teach anything. She follows the lead of the child's responses to explore their knowledge, but does not add to this. Her stance is evaluative, and responsive to the child.

These results suggest that children have different mathematical experiences with these games, depending on the framework selected. Children who play the games in a mathematics-focused framework are exposed to more mathematical concepts, explain their ideas and are questioned more often. Language is used by both parents and child to discuss ideas. Other analyses not presented here suggest that key influences on framework selection are the difficulty level of the game and the child's attitude. Further work with teachers and other groups of parents needs to be undertaken to consider issues of 'fit' between home and school. While games are used here as the 'bridge' between home and school, other issues of cultural, language and experience can be considered in a similar way. What is taken to and from school may be less visible than a maths game bag, but may have important consequences. The use of the socio-cultural framework to view this game playing reveals that important differences in interaction do occur, and that these may impact on children's learning.

Profiles of Development in 12-Year-Olds' Participation in a Thought-Revealing Problem Program

Lyn D. English
Queensland University of Technology

Abstract

Five classes of 7th-grade students participated in an 11-week program of thought-revealing problem activities, comprising problem-posing and model-eliciting experiences. This paper presents profiles of development of three students who displayed different levels of achievement in number sense and novel problem solving. Among the issues addressed are developments in the students' facility with problem structures, including recognising related structures and posing new problems from given structural elements, students' development of divergent and flexible ways of thinking, and their processes in conceptualising and working a model-eliciting task.

Introduction

The ability to reason and converse mathematically in a range of problematic situations is becoming increasingly important in students' development. As highlighted in the recent *Principles and Standards for School Mathematics* (discussion draft; NCTM, 1998), students need to develop a mathematical disposition to analyse situations more carefully in mathematical terms, to formulate new problems, to explore mathematical structure, to investigate situations, and to make and test conjectures. Such development requires learning experiences which go beyond the usual scenario of students applying learned strategies to produce a "short-answer," predetermined solution to a well-defined word problem. While such problem experiences have an important place in the curriculum, they nevertheless are inadequate for students' problem solving and decision-making in the forthcoming era (Burrill, 1998; Greeno & Hall, 1997).

Thought-Revealing Activities

One approach to redressing this situation is to incorporate "thought-revealing" (Lesh et al., in press) problem activities within the mathematics curriculum. Such activities require students to externalise their thinking and reasoning processes by describing, explaining, constructing, modifying, and refining their mathematical understandings and viewpoints, *while* they are dealing with a problem situation. Thought-revealing activities thus enable us to learn more about the nature of students' developing mathematical knowledge and the thinking processes that produce this knowledge. At the same time, these activities *promote* development because they support the "productivity of *ongoing* learning or problem solving experiences" (Lesh et al., in press).

The thought-revealing activities of the present program encompassed problem posing and model generation. The importance of mathematical problem posing in the curriculum has been well documented, yet research in the domain is limited (English, 1998; Silver, 1994; Silver & Cai, 1996). Likewise, model-eliciting activities have not received the attention they warrant. These activities engage students in important mathematical processes (such as quantifying, organising data etc.) and require them to produce a model that describes certain relationships, patterns, and operations inherent in a real-life situation. A variety of concrete, graphic, symbolic, or language-based representation systems may be used to portray these relationships and patterns.

Model-eliciting activities provide rich learning experiences because they (i) require students to develop explicit mathematical interpretations of meaningful situations, (ii) develop important mathematical understandings (e.g., proportional ideas), (iii) emphasise the kinds of problem understandings and abilities that are needed for success in real-life situations, and (iv) cater for, and promote, a broader range of mathematical competencies (Lesh et al., in press).

Theoretical Framework

The program was designed within a framework that has been developed and refined over several years of research (e.g, English, submitted). This socio-cognitive framework has three main components, as follows:

(i) Understanding and Reasoning (e.g., understanding and utilising problem structures, and recognising related structures; understanding problem design; thinking and reasoning in mathematically constructive ways, including reasoning by analogy (English, in press) and thinking in flexible and divergent ways);

(ii) Mathematical Self-Awareness (e.g., students' perceptions of, and dispositions towards problems, problem solving, and problem posing; expressing mathematical ideas, opinions, and beliefs; and applying metacognitive abilities such as planning and monitoring one's actions); and

(iii) Participation in Philosophical and Inquiry-Oriented Communities (e.g., where students engage readily in open questioning and mathematical inquiry, participate freely in constructive dialogue and debate, provide constructive feedback on one another's creations, and work collaboratively in group situations; Baroody, 1998; English, Cudmore, & Tilley, 1998; Stein, Silver, & Smith, 1998). Establishing this learning community was considered essential to the program. Such an environment has the potential to motivate students to explore mathematical situations that are intriguing, problematic, challenging, and inviting. Students have opportunities to build on, shape, and modify one another's ideas, to offer and analyze reasons for arguments put forward, and to help one another formulate questions and generate mathematical problems and models (cf. Splitter & Sharp, 1995).

Methodology

A qualitative research paradigm was followed in this study, with videotaping as the primary means of data collection. Small groups of students, individuals, and teacher-led classroom discussions were taped. Iterative refinement cycles for videotape analyses of conceptual change are being used in the data analyses (Lesh & Lehrer, in press). In addition to the videotape transcripts, data sources include students' journals documenting their responses (including their critical analyses of one another's work), other student artefacts, classroom field notes, notes from informal interviews with students and teachers, and feedback on the program from the students and teachers. The components of the above theoretical framework provide the windows through which the data are being analysed.

Participants and Selection of Case Studies

Five classes of seventh-grade students (12 years) from a non-state boys' school participated in the study, which was conducted during 1998. Nine students were selected for case studies. These students were selected on the basis of their responses to assessments of number sense and novel problem solving, which were

administered during the second term of the school year prior to program implementation. The tests were modelled on examples that had been used successfully in previous, related studies (e.g., English, 1997, 1998). The number sense test focused on facility with number and routine computational problem solving, while the novel problem-solving test included problems that required a range of reasoning processes (e.g., deductive, combinatorial, spatial reasoning), as well as general problem-solving processes.

The nine students chosen for case studies displayed one of three types of achievement on these tests: (i) high in number sense, but low in novel problem solving (i.e., at least one SD above/below the mean), (ii) low in number sense but high in novel problem solving, and (iii) high in both number sense and novel problem solving. Prior to commencing the program, each of the nine students was individually interviewed on a comprehensive set of problem activities. A parallel set was presented after the program. These sets addressed several of the components of the framework (e.g., students' attitudes and perceptions, their problem preferences, recognition of problem structure and related structures, problem posing).

Program Implementation

During the first half of the school year, meetings were conducted with the class teachers to discuss the philosophy and content of the program, and to seek their feedback. The program was then implemented in each class during the third and final terms of the school year (1.5 hours per week). Individual work, small-group activities, and whole-class discussions were incorporated in the program. The students maintained journals of their responses.

The program commenced with a strong focus on developing the students' mathematical self-awareness. which was maintained throughout. The first two weeks of the program were devoted to problem exploration and general discussions on problems, problem solving, and problem posing. Problem sorting (according to structural similarity) was also included. These beginning weeks were designed to improve students' understanding of, and attitudes towards problems and problem solving, to improve their confidence in dealing with mathematical problem situations, to help them become more creative and flexible in their approaches to problems, and to increase their confidence in, and willingness to talk openly about mathematics.

During weeks 3-6, the students explored the structures of a wide range of problems, identified similar structures, discussed how structures differed, why some structures were more difficult than other[illegible]nd so on. The students then posed new problems based on familiar structures (use of analogical reasoning), and progressed to posing problems from selected structural components (i.e., from open-ended statements, such as, "Mrs Mack has a blue pot, a red pot, and a green pot for her new plants. Her new plants are a rose bush, a gardenia, and a gerbera," and from other sources, such as travel brochures and newspaper items.) An important part of the students' problem posing was completing critical analyses of one another's problems. These analyses were followed by problem improvement and extension.

The remaining weeks of the program engaged the students in model-eliciting activities, where they worked on real-life situations (e.g., those reported in the print

media) to construct models that would deal with these situations mathematically. Three activities were included, with the first one, "The Good Old Daze," based on a timely newspaper report comparing the cost of living today with that of a previous era. Related tables of data on the costs of everyday items now, and 12 years ago, were also supplied for the students. Based on their discussions and research, the students were to write a short article for their school magazine where they debated whether or not 12-year-olds have a better standard of living today than their counterparts of a selected bygone era. In supporting their arguments, the students were encouraged to make use of effective representations (e.g., tables, graphs, student-generated mathematical procedures/rules). The main reasoning pattern required in working this activity is proportional reasoning, of the form, a/b = c/d.

After deciding on a bygone era, the students had to determine which issues to address in framing their argument. They then had to determine how to examine these issues. In doing so, the students were faced with decisions such as, "Which items will we consider?" "Why?" "What has happened to the cost of items? Have all items increased in price?" "How will we organise our data?" "What kinds of patterns or relationships appear to exist?"

Profiles of Development

Profiles of development of three case studies are addressed here. The students are (1) Nathan, who displayed high achievement in number sense, but low achievement in novel problem solving, (2) Tom, who was the reverse of this, and (3) Homer, who achieved highly in both domains (all names are pseudonyms). Data are drawn from the two sets of problem activities (presented to each student before and after the program) and from one of the model-eliciting activities completed during the program (samples of student artefacts to support the following will be included in the paper presentation).

Nathan (High in Number Sense, Low in Novel Problem Solving)

Nathan's views on his mathematical competence reflected his levels of achievement. For example, Nathan claimed that he enjoys mathematics and thinks "it is fun doing all the sums and working all the answers out," but did not enjoy solving mathematical problems very much, "because I usually get them wrong." Following the program, Nathan stated that he enjoyed the program because "it is very interesting to actually do maths differently." He also considered he was "definitely" better at problem solving after participating in the program, "because I find them easier to do; I have never been really strong at problem solving but it is starting to get easier now." Likewise, Nathan felt he was better at problem posing because he now knows "how to write a question."

Not surprisingly, Nathan preferred problems that involved computations and was adept at doing quite complex problems mentally. Prior to the program, he displayed competence in explaining the structural features of such problems, yet when asked to sort a set of problems, Nathan focused on contextual features. That is, he grouped problems that "asked the same question," irrespective of the operation required for solution. He was, however, able to correctly match the two combinatorial problems. On the post-program activities, Nathan still had trouble

sorting the computational problems into groups of similar structure, and displayed some difficulty in distinguishing addition from subtraction in comparison situations. Nevertheless, Nathan could match the two deductive and the two combinatorial cases.

After participating in the program, Nathan displayed a distinct improvement in his ability to turn open statements into problems, and to model a new problem on a given problem. Initially, Nathan lacked diversity of thought in his problem creations, was unable to pose a division problem, and could not create problems from a travel brochure. After the program, however, Nathan showed diversity of thought in his use of both mathematical structure and context.

Tom (Low in Number Sense, High in Novel Problem Solving)

It was interesting to note that Tom was very confident in his mathematical abilities, despite the fact that his number sense was rather poor. Tom claimed he liked mathematics because, "mostly, I am pretty good at it." In particular, he enjoyed solving mathematical problems the most, but "not ones with fractions." In reflecting on his participation in the program, Tom stated that he had not improved in problem solving because "I already knew all the problems," but felt he had improved in problem posing because he had not done any of this before.

Tom developed his ability to identify and work with problem structures during the program. On the pre-program interview, Tom sorted most of the problems by context (e.g., "They're about collecting."). After completing the program, however, Tom could readily match the corresponding deductive and combinatorial problems, and could clearly justify his actions. Interestingly, though, Tom placed all of the remaining problems in the one group because they all involved operations: "Well, we are given information and you have to work it out--like you have to minus $63 or times it or something like that to get another number that you need, like how much did class 7c raise." It was evident that Tom was sorting the problems according to whether or not computational procedures were needed, as he could clearly explain the structures of each problem and could show how they corresponded. Tom was no doubt influenced here by a previous class discussion on ways of classifying problems.

Developments were also noted in Tom's ability to pose problems from open statements. Prior to the program, Tom had some difficulty in posing such problems, and displayed quite convergent thinking in doing so. On the other hand, although Tom interpreted a multiplication situation in terms of repeated addition, he nevertheless was able to create two different division problems from a given division statement (e.g., *A ruler was 56 cm long. If someone chopped it into quarters, how long would each piece be?*). While Tom was also unable to generate a problem from a travel brochure, he could model a new problem on a given problem (albeit, retaining the same context). After completing the program, however, Tom was readily able to pose problems from open statements, and showed great diversity of thought in doing so. Likewise, Tom could easily pose problems from a travel brochure, and created diverse contexts when modelling new problems on given examples.

It is particularly interesting to note that the problems Tom posed were more diverse and more structurally complex than those generated by other members of his group (e.g., Tom was the only member to incorporate fractional ideas in some of his

problems). In fact, one of the problems that Tom generated from the travel brochure was chosen to be critically analysed by all class members. The nature of Tom's responses reflect previous findings, in which children classified as low in number sense and high in novel problem solving displayed divergent thinking and posed problems that were structurally complex (English, 1998; English, submitted).

Homer (High in both Number Sense and Novel Problem Solving)

Homer was a keen student who adopted leadership and monitoring roles in group activities. However, when his team members would not cooperate, he would withdraw and work independently. Homer was an enthusiastic participant in class discussions on problems and problem solving.

When questioned initially on whether he enjoys mathematics, Homer said that he does not enjoy it all the time, especially "when we are going over something, over, and over again; I don't like that." However, he did like working all types of mathematical problems, but stated that he does not like problems involving fractions, because "I am no good at vulgar fractions. I like decimal fractions though." Homer also considered he was "not very good at spatial problems."

It was pleasing to see Homer express a good deal of satisfaction with the program, stating that he liked the problems because "they are real life and were on paper." He felt more confident in both solving and posing problems after participating in the program, "because I have had a look at the different types of problems. . . and we have all done lots of better problems."

Homer's responses to the problem sorting activity were interesting, as was the case with Tom. Homer was easily able to sort the problems prior to the program, and could justify his method. Following the program, however, Homer sorted the problems into two groups, namely, the deductive examples and those involving operations (including the combinatorial problems where he stated, "You could use a tree to work these out, but it is a lot easier just to times it.") In justifying his grouping method, Homer explained, "I put all these together because you can use a number sentence to work them out." In other words, Homer sorted the problems into routine and nonroutine problems, as did Tom. Nevertheless, Homer was able to identify and explain corresponding structures, improving on his initial performance.

Homer also improved in his ability to pose problems from open-ended situations. Although prior to the program, Homer was able to pose deductive and combinatorial problems from the open statement, "Mrs Mack has a blue pot . . .," he had difficulty in making other open-ended situations into problems. For the problems he could create initially, Homer displayed little divergent thinking. After completing the program, though, Homer was readily able to construct different types of problems from a given open-ended statement, and could clearly explain the problem's structure and its solution. Furthermore, Homer was far more divergent and flexible in his thinking when creating several problems from other open-ended statements.

Model-Eliciting Problem Activity During the Program

Of the three case studies, Homer was the only student who expressed initial interest in working such problems. Like many of his peers, Nathan found it difficult to accept these as mathematical problems, and did not consider himself to be competent in

working them ("because I'm not a very good imaginer"). Tom considered these model-eliciting problems to "take too long, and you have to explain everything, and you have to put it down on paper, which is very boring."

Consideration is now given to the beginning responses of the students to the model-eliciting task, "The Good Old Daze." These responses reflect elements of the modelling cycles described by Lesh et al. (in press). It is only possible here to address the first two phases of problem conceptualisation, in which the students attempted to (1) determine which bygone era to address and the issues to examine, and (2) draw comparisons between selected items of data.

During the first phase, the teams in which Nathan, Homer, and Tom worked, began the task with a good deal of unconnected and, frequently, off-task discussion. The goal of the task was quickly ignored as the students became bogged down with irrelevant detail and procedural considerations. It was also during this phase that the students established roles for each member of the team, as can be seen in the following excerpt from Nathan's and Homer's team (Homer's role is clearly evident.)
Lachlan: *What year do we want to talk about?*
Nick: *Let's talk about last year because that's when I turned 12. I'm older than you.*
Homer: *Let's talk about a reasonable time.*
Alex: *Let's talk about when Lach was born!*
Homer: *<u>When</u> are we going to decide on a time?*
Following further irrelevant discussion, Homer stated: *Order in the court." "What are we going to do? Are we going to do the 1950s or the 1960s?*
Nick: *You make the decision, Homer.*
During this phase, the students also spent time trying to decide which issues they should address in developing their arguments:
Greg: *Let's look at university education, and health too.*
Tom: *OK, or life expectancy.*
Greg: *Do life expectancy.*
Chris: *Like expectancy for a male today is 75, or is it 70?*
Greg: *Tell me what to write down.*
Chris: *Life expectancy for a male is 70. . . . .*
Tom: *So what are we doing? Oh, male expectancy. I could do a bar graph that goes up, to show this* (his intention was to compare it with life expectancy in the 1960s).
Tom: *The male expectancy is one more year than a female life expectancy in 1960.*

When Homer and Nathan's class teacher intervened in the team discussions, the students identified issues such as crime, the cost of basic commodities, and wages as worthy of examination. Using the data sheets provided, the students began identifying various items for comparison, such as the cost of a loaf of bread in the 1985 with the cost today. Discussion then led to the students commenting that, to compare the prices, they needed to look at "the amount of pay." One student further commented that "you have to look at the ratio." The students then resumed their team discussions, which led them into the next phase of conceptualisation:
Alex: *Oh, let's look at the Coke and the lollies!* (off-task discussion followed)
Lachlan: *Men's dress shoes in 1985 were $49.95 and in 1997, $140.*

Homer: *Hey guys! Look at the miscellaneous items. Some of the things have gone down! This one's* (Fuji film) *gone down by a dollar!*
Chris: *CD players have gone down by $300.*
Alex: *A microwave was $359 and now it is $140. . . . well, it's gone down because most of the time when it first came out, everyone thought it was a success and they bought it, but now there is a better range . . .*
Lachlan: *Wow, the US Open tickets were $500 and now they are $2500! That's a really big jump!* .....(Students in other groups also noticed that some prices remained the same.) To this point, the goal of the task was still in the background for these students. They were more interested in comparing prices per se, rather than considering these in relation to the wages of the two eras, that is, the students were still engaged in primitive pre-proportional reasoning.

In sum, the program appeared to be a positive and productive learning experience for the students. Given that most of the activities were new to the students, it would seem that such a program can be effective in fostering some of the understandings and processes required for their success in the coming years. At least this appeared to be the case for the present sample of students.

THE RELATIONSHIP BETWEEN PROFESSIONAL KNOWLEDGE AND TEACHING PRACTICE : THE CASE OF SIMILARITY.

Escudero, I., Sánchez, V. (Universidad de Sevilla. Spain)

Abstract: This is part of a research study into the relationship between professional knowledge and teaching practice for the secondary school Mathematics teacher, when he/she teaches specific mathematical topics, in our case, similarity. Here, we show what happens when a mathematical content appears in mathematics classes other than the one scheduled by the teacher, the reasons and justifications provided and how the teacher handles this content. The results highlight the strong interrelation between the structure of the lesson and the way of understanding the mathematical content, allowing us to observe the cognitive integration of the different domains of knowledge in decision-making.

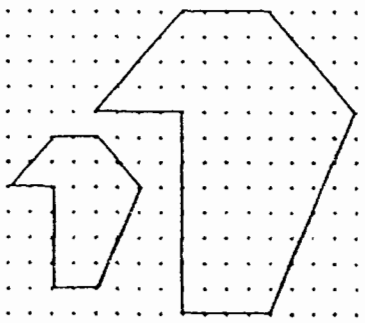
The relationship between the professional knowledge of the Mathematics teachers and their practice is one current research topic that has been dealt with from different perspectives. From a cognitive perspective, Leinhardt and her collaborators consider teaching as a "complex cognitive skill", that is supported by two basic systems of teacher knowledge: knowledge about the structure of the lesson and knowledge about the subject matter that he/she teaches (Leinhardt and Greeno, 1986). For these authors, the first system of knowledge includes "the skills needed to plan and run a lesson smoothly and to pass easily from one segment to another, and to explain material clearly" (Leinhardt and Smith, 1985, p. 247). They use the term *schemata* to refer tc knowledge about the set of organised actions relating to activities of teaching. The schemata for activities of teaching includes structures that these authors call *information schemata*, which allow the teacher to retain and subsequently use the available information in the course of the lesson. For these authors, the lessons in mathematics classes are not homogeneous with respect to teacher or student activity. They are segmented into discernible parts, called "segments" or "activity structures" (Leinhardt, 1989; Stodolsky, 1988).

The second system of knowledge considered by these authors is subject-

matter knowledge. This knowledge is understood by Leinhardt as: "the knowledge that a teacher needs to have or uses in the course of teaching a particular school-level curriculum in mathematics" (Leinhardt et al., 1991, p.88). The teacher's knowledge about the subject matter that he/she teaches influences his/her explanations. In this sense, they consider that the two systems of teacher knowledge proposed are interconnected and integrated. These authors propose that the conduct of a lesson is based on the teacher's agenda, understood as "the teacher's dynamic plan for a lesson. It is a mental plan that contains the goals and actions for the lesson" (Leinhart et al., 1991, p. 89). We may consider the agenda as a dynamic plan whose components may be modified during the course of the instruction.

We have also taken into account the studies that conceptualise practice as the work that the teacher faces when performing his/her professional tasks (Bromme, 1994; Bromme and Tillema, 1995), and the works by Llinares (1995) that consider teacher knowledge to be within the framework of the situated cognition (Brown et al., 1989). We admit teacher knowledge is generated and developed through the interaction with the situations, with a cognitive integration of different domains of knowledge being performed (García, 1997). All of the above-named is a reference framework in which to situate our work in relation to the teacher's professional knowledge.

This paper forms part of a research work which aims to obtain information about the relationship that exists between the professional knowledge and teaching practice for the secondary school mathematics teacher, when he/she teaches specific mathematical topics, in our case, similarity. Here, we are going to show: a) what happens in mathematics classes when mathematical content appears different to that scheduled by the teacher, b) the reasons and justifications provided and c) how the teacher handles this content.



METHOD

The participants in the research were two secondary school mathematics teachers, deemed as "expert" teachers by their peers, who offered to collaborate voluntarily. The pupils belonged a two classes without any special characteristics (3^{rd} and 4^{th} years of Obligatory Secondary Education, 14-15 and 15-16 years of age, respectively). The mathematical content of the teaching was similarity.

In the design of the research the following were used: video recordings of all the lessons about similarity, observations of the classroom and several interviews:

interview for planning, interviews prior to and after each recording and a final interview. The interviews and the video recordings were transcribed in full. The teacher's agenda was described from the interviews. Using the transcriptions of the video recordings and of the screening of the videos, we identified different segments of teaching. We characterised these segments in relation to the notion introduced and the specific actions that he/she carries out. This allowed us to observe different aspects of the teacher's handling of the mathematical content, such as: use of an example for achieving a definition, a property, a theorem, with the constant intervention of the teacher and pupil, explanation through an example for reaching the definition, a property ..., with minimum or nil intervention from the pupils, amongst others. It also allowed us to observe the way in which the teacher incorporates the information that is generated during the course of the lesson for keep the class flowing, in order to achieve the objective of the scheduled mathematical content.

In relation to the subject matter, we identified the aspects of the concept that are relevant for the teacher (similarity as a teaching-learning object). Henceforth, we describe and analyse the content of the different components of the teacher's professional knowledge that take part in the situations studied. The form in which the teacher handles the mathematical content, during the teaching, may show us the role played by the different components of teacher knowledge. We consider the appearance in the class of a mathematical content other than that originally scheduled by the teacher to be a suitable space for obtaining information about the relationship between professional knowledge and the teaching of Mathematics.

Teaching episode: Emergence of radicals in the teaching of the ratio of perimeters in similar polygons.

The class starts out with the correction of some tasks that the pupils had to do at home. The tasks consisted of the construction of shapes similar to an irregular polygon drawn on a square grid. Once the tasks had been corrected, the two similar figures that are shown (see Figure) were drawn on the blackboard. The teacher asks the pupils to calculate the perimeter and the area of both figures. His objective is to introduce the ratio of perimeters and the ratio of areas for similar figures.

T. Calculate the area and the perimeter of the figure [...] in the original and for that one. We shall see the area, do you remember last year in the grid how we did it? How did we get the area?
S1. By dividing the biggest squares in other squares.
T. By counting the little squares that were left inside, that was the easiest way for the figure that was strange ... counting nothing more than ...

(The pupils start working on the problem, whilst the teacher carries on answering any questions from the pupils who had not used the grid in previous academic years).

S2. Is this the way we did it?
T. What? These are the square root of five, ... one, two, three, four square root of five. Don't be scared of the radicals that you haven't studied yet ... don't be frightened, those of you who studied them with me last year shouldn't have any problem ... the only thing is that you can measure ... if you do this ... these diagonals are not a single one, it is the diagonal of a square ... what is the square root of ...? What will this be?

From then on, the teacher applies Pythagora's theorem to explain how the diagonal of a square and a rectangle can be calculated. Carrying out calculations with radicals takes up the main part of the presentation. After this explanation, the pupil who had known how to carry out the calculations, jointly with the teacher, calculates the perimeters of the two polygons. To do so, he counts on the grid, using *the side of the small square as* a unit of measurement for the length, and using Pythagora's theorem for the measurements between points that are in a diagonal position. The teacher finishes off this process with the following comment:

T. You can all see it, can't you? Well, he got it right ... look carefully, What ratio is there between the two perimeters?. What are the perimeters like?. The figures were ... What were they like? (On the blackboard the pupil has written the values: $P1 = 10 + 4\sqrt{2} + 2\sqrt{5}$; $P2 = 20 + 8\sqrt{2} + 4\sqrt{5}$).

In this way, he establishes the ratio between the perimeters as a quotient.

The previous example shows us how the teacher handles some pupils' difficulty in dealing with the grid and the appearance of radicals.

As he states in the interview for planning, the teacher knows that the pupils may have difficulties with the grid, since only part of the pupils studied with him in the preceding academic year, in which they worked with grids. According to the teacher, one of the problems that the pupils may encounter is how to keep on the grid the equality of the corresponding angles. However, he considers the use of the grid to be useful. This may be the reason why in the correction of homework, the task selected uses precisely the grid as the "medium". Hence this episode shows how the teacher starts off a new segment of the presentation for the introduction of the ratio of the perimeters and the ratio of areas in similar figures. In the interview for planning, the teacher had already pointed out: "I'll start off by telling them to draw a two similar figures and that they should choose the size that they want ..." That is to say, the teacher has planned to use different figures that the pupils themselves may choose, without any type of restriction, though he foresees: "... I think that they will draw squares and rectangles".

However, either because the teacher feels pressurised by the time already used up or by the difficulties with the grids provided by the pupils in the correction of the tasks (information that the teacher receives through the schemes for information), he takes the decision to use the two similar figures that had come out in the corrected task (drawn on the grid), asking them to calculate the perimeter and the area for them both.

This decision changes the way of introducing these concepts, and it has several knock-on effects:

1) When trying to obtain the perimeter, the pupils continue to have difficulties when using the grid. Although the teacher tries to make these difficulties disappear, he ends up converting the use of the medium (the grid) into the objective. This gives rise to the introduction of contents that the teacher had not scheduled: use of Pythagora's theorem, the appearance of radicals and the operations with them. A new segment of presentation appears with a new mathematical content in order to account for an objective that was not originally scheduled (measuring in the grid and work with radicals). This new segment of teaching has some characteristics for the management of the mathematical content by the teacher (explanation using an example) different to that of the main segment (use of an example for achieving it).

The teacher justifies, in the interview following the recording, the decision to introduce the new content because "it seemed to me that since we were already dealing with grids that they could see, those who had not had classes with me last year, how you can calculate the area on a grid without having to use any formula...

that could be used to study at home and that the others would see something that they had not seen before". Moreover, he also justifies it to establish connections with the calculation with radicals, that "the fact of putting the radicals on the blackboard again is to remind them a little, because later we are going to study radicals ...". That is to say, "he unifies" the pupils' knowledge in relation to the grid and tries to connect it to a content that he is going to introduce later.

2) The teacher uses a great deal of time in dealing with this new content (measuring on the grid and work with radicals). This implies that the introduction of the ratio of perimeters and ratio of areas does not stand out very much (which is noted in the development of subsequent classes).

DISCUSSION:

All that we have showed till this point is an example of how the "action" developed in the classes is not a linear process. It does not involve assessing the quality of the planning by comparing what has been planned and what has been taught, but rather it means studying the reasons why new contents appear, how the teacher handles this and the arguments given by the teacher himself. The teacher's knowledge about the difficulties that the pupils may encounter with a specific teaching material, and the possibilities that he sees in that material, makes him select, for the correction of homework, a concrete task. In the pupils-content-teacher interaction, the difficulties that arise provide data that the teacher incorporates in his schemes of information and that, on the one hand, corroborate the difficulties foreseen and, on the other side, tell him that these difficulties have not been solved when correcting the tasks.

The teacher's action in the subsequent presentation highlights the fact that, either because he is pressed for time or through the information incorporated beforehand, he changes in the action the scheduled way to introduce the ratio of the perimeters, opting for a different introduction. The teacher for introducing the scheduled content and, at the same time, for going deeper into the difficulties perceived, he takes advantage of part of the same task that had been corrected. This indicates the teacher's capacity to adapt to the situation that is posed.

In the subsequent interaction, the teacher carries on adding information (from the schemes of information), which tell him that there are still difficulties with the calculations of the lengths of the segments on the grid. In order for the flow of the class continues in the proper manner, the teacher takes the decision in the action to go on to introduce the content that is causing the difficulties

(measuring in the grid used as a medium) as a new content (measuring on the grid and calculus with radicals), not scheduled originally. The way of handling it has the usual structure that he uses for contents that he deems that the pupils do not know. His curricular knowledge also intervenes in this decision, since the teacher knows that that content will be used later.

In relation to the main objective, the decision taken meant a change in the way for introducing the concept (for presenting the ratio of perimeters and ratio of areas in similar figures through different examples proposed by the pupils themselves to presenting it through a given example, selected by him), that differs from that stated in the original planning, and that shows the difference between what was "espoused" and what was "enacted".

To sum up, so far we have shown how the different systems of teacher knowledge are interconnected and integrated, and the strong interrelation between the domains of teacher knowledge and practice. It has been observed how decision-making in action, in relation to the mathematical content, is one of the basic skills for a teacher, with some characteristics of the integration of the different domains being noted in that decision-making.

STUDENTS' UNDERSTANDING OF REGRESSION LINES [1]

Antonio Estepa, Franciso T. Sánchez-Cobo *University of Jaén (Spain)*

& Carmen Batanero *University of Granada (Spain)*

In this paper we present and discuss undergraduates' difficulties in finding the mean of a variable from the following data: mean of a related variable, slope and intercept of the regression line. Difficulties of the students in interpreting regression lines are described and implications for the teaching of regression are finally suggested.

1. INTRODUCTION

Correlation and regression are highly relevant in the Statistics curriculum for introductory level University students, not just in itself, but as a prerequisite in understanding other statistical concepts and procedures, such as multiple regression, analysis of variance and most multivariate methods. Despite this importance, mathematics education researchers have carried out very little research on this topic, though some research work on correlation can be found in Psychology.

Most psychological research has only concentrated on 2x2 contingency tables. Some psychologists have studied people's ability to estimate correlation from scatter plots or from a set of paired values of two variables (Erlick, & Mills, 1.967; Jennings, Amabile, & Ross, 1982; Lane et al., 1.985). The general conclusion is the adult's poor ability to estimate correlation, the better performance with positive and strong coefficients and the effect of previous beliefs on intuitive estimates. Within mathematics education, Estepa & Batanero (1994, 1996) studied the students' strategies in judging correlation in scatter plots, as well as their misconceptions concerning association. Truran (1997) described the understanding of association and regression by first year economics students. Morris (1997, 1998) studied the conceptions and understanding of correlation by undergraduates, as well as changes after a teaching experiment based on LINK (a computer assisted learning program for correlation). Evolution of students' understanding of association after teaching experiments based on computers have also been described in Batanero, Estepa, & Godino (1997), Batanero & Godino (1998), and Batanero, Godino, & Estepa (1998).

In this paper we analyse the students' performance in solving a problem about regression and their understanding of the regression lines. This is part of a wider study on the meaning of the correlation and regression in undergraduates (Sánchez, 1999), which include the assessment of conceptual and procedural knowledge on this topic.

2. RESEARCH AIMS AND METHODOLOGY

In Estepa & Sánchez-Cobo (1998) we found scarce attention in textbooks as regards the centre of gravity in scatter plots, and the distinction between dependent and independent variables. This distinction was a main difficulty in our previous studies of understanding of association in contingency table (Batanero, Estepa, Godino, & Green, 1996). The current research was aimed to confirm our previous findings, and assess the learning of these concepts, as well as of the meaning of the parameters in regression lines after an introductory statistics course in the first year of University studies.

The content of course included the fundamentals of descriptive statistics, distribution tables and graphs; location, spread and order statistic; skewness and kurtosis; two-dimensional statistical variables, contingency tables, covariance and correlation, linear and polynomial regression, sampling, sampling distribution, interval confidence and hypotheses testing. Planning of the lessons by the lecturer and notes taken from two students along the course were analysed to get an insight of the type of teaching received by the students. This followed a traditional approach based mainly in lecturing and solving computation problems. Scarce time was devoted to interpretative and application problems.

Sample:

104 University students in their first year of Business studies (37 boys and 67 girls) and 89 University students in their first year of Nursing studies (20 boys and 69 girls) answered a written questionnaire. There were a total of 193 20-year-old students (average age). 109 of them had followed a scientifically oriented curriculum at secondary school, whereas the remaining 84 students had followed a humanities-oriented curriculum. Most students (117 or 60.6%) had not studied statistics in their secondary education. We asked the students about whether they consider statistics to be useful for their future professional work. 162 students (83.9%) found statistics to be sufficient, quite or highly interesting for their professional training; 155 students (80.3%) found correlation and regression to be sufficient, quite or highly interesting as a component of statistics.

Questionnaire

The complete questionnaire consisted of 12 multiple- choice items, 6 tasks where the student should estimate the value of the correlation coefficient and two application problems. In this paper we discuss the results concerning one of these problem:

> **Problem.** The slope of a regression line is 16 and its intercept is the point y = 4. If the mean value of the independent variable is 8, which is the mean value of the dependent variable?

This problem was taken from Cruise & al. (1984, p. 288). As the students had never solved a similar problem along the course, this could be considered to be an mathematical problem, for them, as it was *"a situation that involves a goal to be*

achieved, has obstacles to reaching that goal, and requires deliberation, since no known algorithm is available to solve it. The situation is usually quantitative or requires mathematical techniques for its solution, and it must be accepted as a problem by someone before it can be called problem" (House, Wallace and Johnson, 1.983, p. 10).

In the Problem the students were asked to find the mean of the dependent variable, from the following data: i) the regression line slope, ii) the regression line intercept, and, iii) the mean of the independent variable. Since the students had not been explicitly been taught a standard procedure to solve this type of problem, they had to use their statistical, algebraic and geometric knowledge to find the solution. In particular students needed to remember the meaning of the parameters in the equation of the right line, and Cartesian representation, and to relate them to the notions acquired in the teaching received on linear regression. They had also to remember that the point with co-ordinates $(\bar{x}, \bar{y})$ belongs to both regression lines and discriminate the meaning of the independent and dependent variables, as well as interpret correctly the meaning of the slope and intercept (Truran, 1997).

Table 1. Frequencies and percentages of correct and incorrect solutions, according to solving procedures

Solving Procedures	Solutions		
	Correct	Incorrect	Total
1. $y = bx + a$	31	50	81
	38.3	61.7	
2. $y - \bar{y} = \frac{\sigma_{xy}}{\sigma_x^2}(x - \bar{x})$	8	15	23
	34.8	65.2	
3. Using both 1) and 2)	2		2
	100.0		
4. $x = b'y + a'$	2	7	9
	11.1	88.9

Below, we analyse the students' answers, grouping them according to the procedures used. We then discuss the obtained results, where percentages are referred to the 129 students that provided a solution (67% of the total sample). The remaining

students gave no answer, which is indicative of the task difficulty for these students. Results are shown in Table 1.

4. RESULTS AND DISCUSSION

Results in Table 1 show that the majority of the 129 students answering the problem used one or both regression lines to solve the problem (94.6%). 106 students (82.17%) chose the correct regression line Y/X, while 13 students (10.1%) confused the regression line and used X/Y instead. Finally 3 students (2.3 %) used both lines. Below we analyse the student's errors and misconceptions depending on the procedure followed.

4.1. Use of the regression line Y/X.

From the 106 students using only the regression line Y/X (the first three rows in table 1), 81 students used, exclusively, the explicit equation $y = bx+a$, 23 students used only the point-slope expression $y-\bar{y}=\frac{\sigma_{xy}}{\sigma_x^2}(x-\bar{x})$ and 2 students employed both equations. Below we describe the thinking process involved in each of these procedures and the difficulties involved in the same.

Using the explicit equation of the regression line, y = bx +a

Giving the data in the statement of the problem, this procedure can lead to the immediate correct solution which was reached by 31 students (38.6% of those using this procedure), in the following way:

$$"a=4=intercept,\ \ b=slope=16,\ \ \ y=a+bx,\ \ \ \bar{x}=8;\bar{y}=4+16.8=132;"$$

The main cause of failure with this procedure was confusing the dependent and independent variables, which led 27 students (33.3% of those using this procedure) to exchange the mean of X with that of Y, and, consequently, to an incorrect solution. This confusion was also described in the studies by Batanero, Estepa, & Godino (1.997) and Batanero, Godino, & Estepa (1998). An example of this confusion is

$$"a=4,\ \ b=slope=16,\ \ \ y=a+bx,\ \ \ \bar{y}=8"$$

shown in the solution given by the student n. 46:

A second difficulty arises when the student did not realise that the gravity centre $(\bar{x},\bar{y})$ is a point belonging to the regression line, and, consequently, this point must verify the equation $\bar{y}=b\bar{x}+a$. In the teaching carried out, this fact was not explicitly taught, though the gravity centre was defined as being the intercept of the two regression lines.

A third main difficulty was exchanging the meaning of the parameters *b* and *a* in the equation $y = bx + a$, as well as assigning them incorrect values (9 students). For example, the student 146 gave the following solution: *"$y = a + bx$, $y = 4$, $a = 16$, $b=8$, $x = ?$, $4 = 16 - 8x$, $12 = 8x$, $x = 12 / 8 = 1.5$".*

Using the point-slope expression $y-\bar{y}=\frac{\sigma_{xy}}{\sigma_x^2}(x-\bar{x})$

Because in this case $\frac{\sigma_{xy}}{\sigma_x^2} = 16$, we obtain $4-\bar{y}=16(0-8)=128;\bar{y}=132$. The main difficulty when using the point-slope equation of the regression line of Y/X was finding the point *(x, y)* needed. Only 8 students (34.8% of those using this equation) realised that this point was the intercept with the ordinate axis. Other difficulties arose from using an inadequate equation of the regression line Y/X, with a frequency of 7 students. For example student number 4 gave the following answer, where the slope and intercept of the equation are also confused:

$$"y-\bar{y}=\frac{\sigma_{xy}}{\sigma_x^2}(x-\bar{x}),\bar{x}=8,y=4,y-\bar{y}=16-8,\bar{y}=8-4,\bar{y}=4"$$

Here we found again the confusion between the dependent variable and independent variable in 7 students, as Student number 57, who gave the following solution: "$\frac{\sigma_{xy}}{\sigma_x^2}=16,(0,4),\bar{y}=8,y-8=16(0-\bar{x}),-4=-16\bar{x},\bar{x}=\frac{1}{4}$"

The type of the equation of the regression line used seemed to influence the interpretation of the slope, since when the equation used was $y = bx + a$, we found more difficulties in interpreting the slope than when using $y-\bar{y}=\frac{\sigma_{xy}}{\sigma_x^2}(x-\bar{x})$, where most students seemed to understand that the slope is expressed by $\frac{\sigma_{xy}}{\sigma_x^2}$.

Other procedures

Two students use both the explicit and point-slope equations. These students did not realise that the gravity centre belongs to the regression line $y = mx+n$. However, they observed that the mean of the dependent variable can be found from the point-slope equation. Then the students compared both equations and determined the mean of the dependent variable, like in the following case (Student 33):

$$"y=bx+a,y=16x+4,y-\bar{y}=\frac{\sigma_{xy}}{\sigma_x^2}(x-\bar{x}),b=\frac{\sigma_{xy}}{\sigma_x^2}=16$$

BEST COPY AVAILABLE

$$a = \bar{y} - \frac{\sigma_{xy}}{\sigma_x^2}\bar{x}, a = \bar{y} - 16.8, \bar{y} = 132"$$

4.2. Use of the regression line X/Y

13 students (10.1% out of the 129 answering the problem) used the regression line of X/Y. From the 9 students who used the explicit equation of the regression line, $x = b'y + a'$, only 2 got the correct answer, with the following procedure: "*$x=a' + b'y$; $y=8$;* $0 = 16 \cdot 4 + a', = a' = -64, \bar{x} = -64 + 16.8, \ \bar{x} = 64$"

Four additional students used the point-slope equation of the regression line $x - \bar{x} = \frac{\sigma_{xy}}{\sigma_x^2}(y - \bar{y})$. The difficulties described in the previous section were repeated, such as the confusion between dependent and independent variable. Below we reproduce this difficulty in Student 105's answer, who, also confuse the meaning of the intercept:

"*$x = a' + b'y$, $x = 8$, $y = 4$, $b' = 16$, , $8 = a' + 16 \cdot 4$, $8 = a' + 64$, $a' = 64 - 8 = 56$*"

Other mistake was exchanging the meanings of the intercept and the slope, such as shown in Student 89's answers: "$a' = \bar{x} - b'\bar{y}, \ 16 = 8 - 4\bar{y}, \bar{y} = \frac{8-16}{4} = 2$"

With respect to the point-slope equation of the regression line X/Y, the only confusion shown was that between the dependent and the independent variable, such as in student 122: "$x = 0, y = 4, \bar{x} = 8, x - \bar{x} = \frac{Cov(X,Y)}{\sigma_y^2}(y - \bar{y}), x - 8 = 16(4 - \bar{y}),$ $0 - 8 = 16(4 - \bar{y}), 16\bar{y} = 16 \cdot 4 + 8 = 72, \ \bar{y} = 4.5$. *The equation of the line is defined as $x - x_1 = b'(y - y_1)$ being m the slope of the line. As we know the slope, the value of y, and we know that the line intercept the axis Y in the point 4, where $x = 0$, when substituting, the answer is 4.5*"

4.3. Use of both regression lines Y/X and X/Y

Three students used both regression lines Y/X and X/Y. We consider that this is the best procedure, since, both variables X and Y can play the role of dependent or independent variable if the context of the problem is not specified. Thus Student number 67 provided both solutions:

"*Lets suppose we take the line Y / X : then*, $x = 0, y = 4, y = bx + a, 4 = 0 + a, a = 4, a = \bar{y} - bx,$ $4 = \bar{y} - 16 \cdot 8, 4 = \bar{y} - 128, \bar{y} = 132$. *Lets suppose we take the line X/Y : in this case,* $x = b'y + a', 0 = 16 \cdot 4 + a', a' = -64, a' = \bar{x} - b'\bar{y}, \ -64 = \bar{x} - 16 \cdot 8, \ \bar{x} = 64$"

Finally, 7 students out of the 129 who attempted to solve this problem used other statistical concepts, such as those of mean or covariance getting an incorrect solution.

5. FINAL REFLECTIONS

From the above analysis we conclude that the most frequent difficulty for the students in our sample was distinguishing the role of dependent and independent variables. This lead to failure to 36 out of the 84 students who got incorrect solutions (42%), which confirms our previous findings that this is a main problem in understanding association (Batanero, Estepa, Godino, & Green, 1996). The fact that correlation ignores the distinction between independent (explanatory) and dependent (response) variables, whilst in regression this difference is essential might have received not sufficient attention in the teaching received by the students. This teaching should take into account that relationship in regression depends of the type of covariation presented in the problem context. If there is a causal dependence, the explanatory and response variables are univocally determined. However in other type of covariation - interdependence, indirect dependence, concordance and spurious covariation - the student must decide the best regression to employ.

Though both the explicit and point-slope equations of the regression line are, formally, equivalent, the later served better to our students to identify the slope that in the explicit equation; their more frequent use of the explicit equation was probably due to stated of the problem. Confusions about the meaning of the parameters and unability to relate the problem data to the regression line equation was also found.

We finally conclude that more research on the teaching and learning of association and regression is needed for achieving a teaching of quality. This research should be based on the didactical an epistemological analysis of the topic for searching their internal structure, emphasising the fundamental contents, and relating new findings to previous research work. Thus we can contribute to a better planning of the teaching that facilitate students' construction of a meaningful learning.

The Motivation to Learn Mathematics

David Feilchenfeld

The Hebrew University of Jerusalem

This paper characterizes the motivation to learn mathematics among first year practical engineering students studying electronics. The motivation is directly measured by the students' self evaluation, relatively to their motivation to study other subjects. In addition, an analyze has been held of the manner in which students attribute the reasons of success in mathematics studies in comparison with the reasons of success in studying electricity. It was discovered that the motivation to study electricity is higher than the motivation to study mathematics. This result is ascribed to two reasons: I. The incentive value of achievement in electricity is considered to be higher than the incentive value of achievement in mathematics, because of its immediate relevance to electronics. II. According to the students, success in electricity is dependent on effort, more than success in mathematics. This is why it is more appropriate to devote to electricity more time and effort than to mathematics.

Introduction

Motivation, Attribution of Causes for Success, and Self Esteem

The motivation to learn mathematics is not different from the motivation to achieve in any other domain. The motivation to achieve is usually ascribed to three factors: the incentive value of the achievement, the subjective expectation for success, and achievement-related needs (Atkinson, 1957, 1964). The achievement-related needs are individual emotional drives and will not be discussed here. The incentive value of achievement is based upon the manner it is perceived: as a trifling matter or as something of importance. For example, the value of winning a chess game against a weak or inexperienced opponent is lower than the value of winning chess game against an excellent opponent. Weiner suggested that self-esteem following the incentive value of success are determined by the locus of the source of a cause (locus of causality) (Weiner, 1986 p. 128; 1992 p. 271). When the source of a cause is internal (within the student) the incentive value of success is higher, and when the source of a cause is external the incentive value of success is lower. As the incentive value of success is growing up, there is a tendency to attribute the cause of success to oneself, and thereof the pride and self-esteem improve. The success in a mathematics exam in which everybody succeeded (because it was easy, or because the grades were distributed generously) is considered to be of low value. On the other hand, success in a mathematics exam in which everybody failed is considered to be of high value, since the cause of the success is attributed to oneself, thus improving one's self esteem. In this principle, Weiner suggests that the effect of success or failure on self-esteem is due to the locus of causality.

Weiner had also treated the expectancy of success proposing what he called the "Fundamental Psychological Laws" (Weiner, 1985 p. 558). Weiner's Expectancy Principle says: "Changes in the expectancy of success following an outcome are influenced by the perceived stability of the cause of the event." As the expectancy of success is considered to be an important factor of motivation, Weiner's principle deserves some attention. This principle has three corollaries: "1. If the outcome of an event is ascribed to a stable cause then that outcome will be anticipated with increased certainty, or with increased expectancy, in the future. 2. If the outcome of an event is ascribed to an unstable cause, then the certainty or expectancy of that outcome may be unchanged or the future may be anticipated to be different from the past. 3. Outcomes ascribed to stable causes will be anticipated to be repeated in the future with a greater degree of certainty than outcomes ascribed to unstable causes." In this principle and its corollaries Weiner suggests that an individual subjective expectancy for success or failure is a consequence of his perceived stability to the cause for success or failure.

In order to analyze more finely the casual attribution, Weiner suggested an additional dimension to those two which were described (Weiner, 1979). This dimension of controllability was formed mainly to separate the causes perceived both as internal and stable into two sub-groups. Controllable causes were separated from arbitrary causes. The controllability level of a cause is linked to the level of responsibility it imposes upon the individual, and to the level of intentionality of the cause.

The manner in which a cause for success or for failure is perceived, is illustrated accurately and in all simplicity with the aid of the three dimensions of controllability, stability and locus of causality. The categorization of a cause has implications on the achievement's incentive value, the subjective expectation for achievement, the individual's motivation, and the arousal of emotions. The attribution of successes and failures to causes arouses various emotions depending on the category the cause is related to (Weiner, 1986), as described in table 1.

Attribution to	Emotions Aroused Following Success	Emotions Aroused Following Failure
External Controllable Cause	Gratitude	Anger
Internal Controllable Cause	Pride and High Self Esteem	Guilt and Low Self Esteem
Internal Uncontrollable Cause	Pride and High Self Esteem	Shame and Low Self Esteem
Stable Cause	Hope	Fear and Hopelessness

Table 1: The emotions which are aroused following a casual attribution (according to Weiner, 1986).

Method

A. The construct is a combination of three different and independent questionnaires. The motivation to learn mathematics may be changed for a concrete persona in different conditions. Thereof, it was only natural to try to examine the way the students themselves estimated their own motivation to learn mathematics. This was done by the students' estimations of their actual effort, in the variety of topics they learn, and grading them. Every student was requested to grade the first three subjects in which his attendance at class was highest. Similarly, he was requested to grade the first three subjects to which he dedicated the longest duration of studying, the first three subjects in which the largest amount of work was demanded, and the first three subjects which were most challenging.

B. The second questionnaire was based on a former one written by Fennema (Fennema, et al. 1979) which relied on what was then considered to be Weiner's Theory of Attributions (Weiner, 1974). I introduced few changes in respect of Fennema's questionnaire. Some changes are due to bringing it up to date according the changes which went over Weiner's theory (i.e. introducing the controllability dimension). Other changes are a consequence of emphasizes in this research. The questionnaire is related to eight events, half of which describe success in mathematics and half describe failure. Five causes have been attributed to each event. The five proposed causes for each event are considered to be part of five distinct categories as described in table 2.

	Category	Locus	Stability	Controllability
1	Aptitude of Deeper Understanding	Internal	Stable	Uncontrollable
2	Procedural Aptitude	Internal	Stable	Uncontrollable
3	Long Term Effort, Laziness, Industriousness	Internal	Stable	Controllable
4	Objective Task Characteristics, Friends, Lecturers	External		
5	Temporary Exertion, Mood, Chance and Luck	Internal External	Unstable	

Table 2: The five categories of causes for success and failure in mathematics, which were included in this research, and their classifications according to the locus of causality, stability and controllability.

The separation between the first two categories was not held in reliance on the attribution theory, but rather on a distinction, which exists among the mathematics teaching researchers community, between conceptual versus procedural understandings. (Different researchers relate to it in a variety of terminologies).

The students were asked to write down the degree of their consent to each of the forty causes (8 events x 5 causes) regarding the learning of mathematics, and the degree of their consent to the same causes regarding the learning of electricity. The answers were given on a four level scale. Attribution rates were extracted from the two levels of agreement (i.e. agree and absolutely agree). The differences in attribution rates of the causes regarding mathematics and electricity have been calculated.

C. The third questionnaire was destinated to map the characteristics the students attribute to each of the 40 causes. It is customary to assume that the causes fall within discrete and dichotomic categories such as internal or external, stable or unstable, and controllable or uncontrollable. This assumption may oversimplify the model because different people attribute to any concrete cause different values for the locus of causality, the stability and the controllability. In order to check how, in the students' view, each cause falls within a category, there were eight types of a second questionnaires distributed, each concerning one event (of success or failure in mathematics) and five possible causes for it. The questionnaire was based on Russel's Casual Dimension Scale (Russel, 1982). This scale, which relates to a unique cause, contains nine items, three of which are pertinent to each of the casual dimensions. Russel has demonstrated that this scale has the properties of an "acceptable psychometric instrument." For each of the nine items, a nine level scale (1 – 9) was presented to the students with opposite statements attached to the two ends.

Results

I. Motivation

Four parameters were used in order to evaluate the motivation to learn mathematics: attendance at class, duration of studying, amount of work demanded, and challenge. The picture received from all four parameters was similar. In all parameters the two dominant subjects were electricity and mathematics, and electricity over dominated mathematics. According to the students, the rate of attendance in electricity class was higher than in mathematics class. Likewise, the actual duration of studying electricity was higher than mathematics, the amount of work that was demanded in electricity class was higher than in mathematics class, and electricity was found more challenging than mathematics. This trend was observed throughout the whole population examined.

The group of students that perceived themselves as successful both in mathematics and electricity (75% of the population) deserve special attention. When looking at the grading of these students, a more powerful picture is obtained. These students have graded their attendance in electricity class in first or second places in a higher rate (85%) than the rest of the students (69%). At the same time these students have graded their attendance in mathematics class in first or second places in a lower rate (48%) than the rest of the students (64%). While there is no meaningful difference (5%) in attending electricity and mathematics classes among other students, there is one (16%)

among the students, which perceived themselves as successful both in mathematics and in electricity. Among these successful students there is a remarkable preference of attending electricity over mathematics classes, and utilizing more time in favor of electricity than in favor of mathematics studies, despite all lecturers of these subjects were very much appreciated by the students. Within the limits of their resources, they have actually spent less time on mathematics and more time on electricity, compared to the rest of the students. Within this group, the rate of grading first the time spent on studies of electricity was more than three times the rate of grading first the time spent on studies of mathematics. In spite of this powerful and impressive picture, it is impossible to evaluate, on the ground of these gradings, the extent of which electricity studies are more time consuming than mathematics. This is due to the questionnaire itself, which does not relate to the differences' values, but only to the gradings.

II. The Effect of the Hedonic Bias

The most striking result from the third questionnaire was the difference in the students' attitudes towards causes for success and causes for failure, particularly in the dimension of stability and to a lesser extent in the dimension of locus of causality. The average perceived stability of causes for success was 5.05, in contrast to a 2.93 average of causes for failure. In addition, the causes for success were treated by the students as more internal (average of 6.41) than the causes for failure (average of 5.43). This result may evolve from the well-established phenomenon known as The Hedonic Bias. This term relates to the tendency people have to credit themselves for successes, in contrast to their unwillingness to accept responsibility for failures. It is generally accepted, among the psychologist's community, that this behavioral pattern maximizes the pleasure of success as well as it minimizes the pain, which derives from failure. This is the source of the term. On the basis of this bias, it may be expected that students will perceive the causes for success as internal and stable, while the causes for failure will be perceived as external or as unstable. The students' desire for hope, and their reluctance from fear or helplessness, may have brought the students to perceive all the causes for failure as unstable, and all the causes for success as stable. The dominance of the Hedonic Bias in the stability and locus of causality dimensions overshadowed possible differences which may have been found out between attributing causes for success in mathematics and in electricity.

Average Perceived Stability of Causes:			
Regarding	Aptitude of Deeper Understanding	Procedural Aptitude	Effort
For Success	6.13	5.83	5.57
For Failure	3.56	3.21	2.68

Table 3: Averages of perceived stability for different categories of causes according to the students' views.

In spite of the above, it was found that the perceived stability of causes (for success or failure) regarding aptitude of deeper understanding was higher than the perceived stability of causes regarding procedural aptitude, which itself was higher than that of causes regarding effort, as is shown in table 3. Although the differences in perceived stability between the three categories are less meaningful then those between success and failure, they exist and seem to be consistent.

III. The controllability Dimension

The controllability value of each cause is an average of the students' perception of the extent the cause is controllable, intentional, and imposes responsibility. It has been clarified that the longer a cause for success concerning effort is lasting, the more it is perceived by the students as controllable and responsibility imposing. In addition to that, meaningful and consistent differences have been found in all three parameters between causes concerning aptitude and effort. The causes concerning effort were perceived as more controllable, more intentional, and more responsibility imposing than the causes concerning aptitude. This result is illustrated in chart 1, where the controllability values (averages of the three parameters) of causes concerning effort are higher (6.50-7.50) than of the causes concerning aptitude (4.94-6.51).

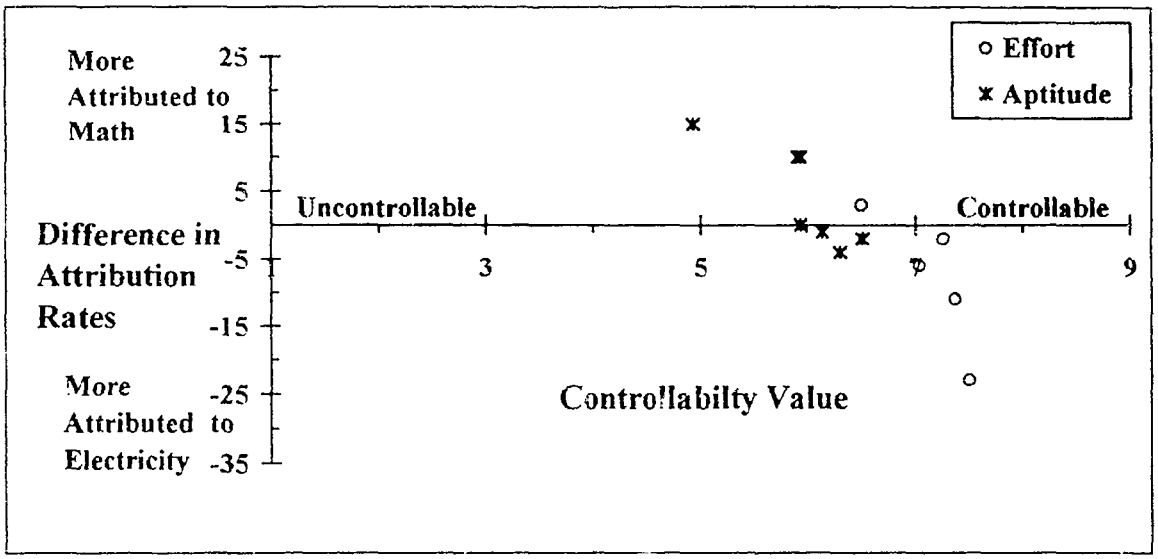

Chart 1: The relation between the controllability level (average between the students' perception of the extent the cause is controllable, intentional, and imposes responsibility) of internal causes for success and the rate differences (in percentage) in attributing the causes to mathematics or to electricity studies.

An interesting result (that is illustrated in chart 1 too) is the tendency to attribute causes concerning effort more to the studies of electricity, and causes concerning aptitude more to the studies of mathematics. Regarding the causes concerning effort and aptitude I found a relation between the controllability value and the differences in attributing them to electricity and to mathematics studies. The higher the perceived

controllability value of a cause, the less it is attributed to mathematics, compared to electricity studies. Because the results came from two different questionnaires, correlation between the two series of results could not be calculated. Nevertheless the correlation between the two series of averages (i.e. the average difference of attribution rates for every cause, versus the average perceived controllability value of the same causes) was calculated and found to be –0.86. These results show that students attribute causes concerning aptitude (which are perceived as less controllable) more to success or failure in mathematics, than to success or failure in electricity. On the other hand, students attribute causes concerning effort (which are perceived as more controllable) less to success or failure in mathematics, than to success or failure in electricity.

Discussion

As one of the research aims was investigating the motivation to learn mathematics, it is interesting to compare the results concerning mathematics with a different subject. The objective level of motivation to learn mathematics, the degree of affection towards mathematics, and the importance the students attach to it, beyond the rhetorical declarations, are not measurable. The reason to it is not the absence of an acceptable measure, but a more essential one. When a student has a high motivation for mathematics, it means he prefers studying mathematics to other alternatives available to him at that moment. The mathematics motivation level should therefore be relative to the motivation levels of the alternatives, and should not have absolute values. It is more than reasonable to compare it to other topics and their motivation levels. The two subjects, for which the highest motivation levels were found, among practical engineering students in electronics during their first year of studies, were electricity and mathematics.

It can be concluded that the motivation for studying electricity is higher than the motivation for studying mathematics. This difference is partly due to the higher value of importance attributed to electricity compared to mathematics, and to different strategies needed for success in the different areas. According to the students, success in electricity is more effort dependent than success in mathematics, while success in mathematics is more aptitude dependent than success in electricity. It is appropriate therefore to exploit in favor of electricity studies a larger slice of the limited resources of time and energy, and only a smaller slice in favor of mathematics studies.

Whereas the strategy taken by the students who perceived themselves as successful both in mathematics and electricity had proved itself, it should be closely examined. These students attended electricity classes more than mathematics classes, and spent more time studying electricity than mathematics. The students in this group have taken this strategy, in a more extreme route than the rest of the students, in spite of their estimation of the amounts of work that were demanded in the courses, which was similar to the other students' estimations.

It is only natural to perceive causes regarding aptitude and ability as more stable than causes regarding effort. Aptitude is usually considered to be a constant personal trait, and sometimes even as an inborn trait. On the other hand, effort is an outcome of personal traits like laziness or industriousness, as well as unstable conditions like motivation or social milieu, and is therefore considered to be less stable. Of special importance is the differentiation made by the students in the way they perceive the stability of causes concerning different kinds of aptitude. The perception of aptitude of deeper understanding as more stable than procedural aptitude (in mathematics) is an evidence for a distinction ability, as well as an evidence for a whole trend of perceiving different personal traits in different degrees of stability. Regarding Weiner's Expectancy Principle, it may be concluded that success as a result of causes concerning aptitude of deeper understanding, is expected by the students more than success as a result of causes concerning procedural aptitude. This corollary is very interesting considering the fact that it came out of students that most of their mathematics studies are procedural.

AN ALGEBRAIC APPROACH TO ALGEBRA THROUGH A MANIPULATIVE-COMPUTERIZED PUZZLE FOR LINEAR SYSTEMS

José Eduardo Ferreira da Silva

Roberto Ribeiro Baldino
Grupo de Pesquisa-Ação em Educação Matemática - GPA - UNESP, Rio Claro, SP, Brazil

ABSTRACT

Relying on Marx's maxim "human anatomy contains a key to the anatomy of the ape" we argue that the relation between arithmetic and algebra is a difference of essence, *hence a dialectical discontinuity much more radical than is conveyed by words such as "gap" or "cut". We argue that the transition from arithmetic to algebra is impossible, and we characterize arithmetic as an* obstacle *to algebra. We present a manipulative and computerized puzzle to introduce linear systems as a possible alternative approach to the teaching of introductory algebra.*

Introduction

The literature about mathematics education seems to indicate a *discontinuity* between the arithmetic and algebraic domains. Filloy & Rojano [1989] consider "cut points" separating the two kinds of thinking; Linchevski & Herscovics [1996] indicate a "cognitive gap" that they endeavor to "cross" and overcome"; Schmidt&Bednarz [1995:84] refer to a "dichotomy" between arithmetic and algebra. Kieran [1981] distinguishes between arithmetical and algebraic uses of the equality sign.

However, the vocabulary used to express the relation arithmetic/algebra also indicates continuity. At least in one case, the word *continuity* appears explicitly: the Argentinean school programs "emphasize continuity with arithmetic" [Panizza, Sadovski & Sessa, 1996:107]. Continuity is also hinted at by signifiers such as "progress" (from informal to formal level of doing algebra) [Reeuwijk, 1995:1-143], "transition" (from arithmetic process-oriented thinking to proceptual algebraic thinking) [Graham & Thomas, 1997:10], "evolution" (from arithmetic to algebraic language) [Filloy & Rojano, 1989:19], and "transition from arithmetic to algebra" [Bouton-Lewis et al 1997:185]. In spite of arguments that "algebra cannot be considered as a arithmetical generalization" [Bodin & Capponi, 1996: 587], expressions denoting continuity like "generalized arithmetic" are still current [Wong, 1997:285; Graham & Thomas, 1997:9; Sfard & Linchevski, 1994:195,197; Kutscher & Linchevski, 1997:169].

The aim of this paper is 1) to argue that the discontinuity between arithmetic and algebra and, in general, between *operational* and *structural* ways of thinking [Sfard, 1991], is more radical than announced by words such as "cut", "gap", "dichotomy" or "duality"; 2) to argue that attempts to teach algebra starting from arithmetic [Linchevski & Herscovics, 1996] lead to difficulties, if not to impossibility; 3) to

argue in favor of a manipulative-computerized puzzle to solve linear systems of two equations in two unknowns to teach introductory algebra courses.

The dialectical discontinuity: a difference of essence

According to Sfard [1991] the literature on epistemology of mathematics teems with allusions to various dichotomies: abstract/algorithmic, declarative/procedural, process/product, dialectical/algorithmic, figurative/operative, conceptual/procedural, instrumental/relational. She proposes another opposition, operational/structural, that should be considered not as a dichotomy but as a *duality*. She argues:

> "The structural approach should be regarded as the more advanced stage of concept development. We have good reasons to expect that *in the process of concept formation, operational conceptions would precede the structural"* [10]. "The history of numbers is "a long chain of transitions from operational to structural conceptions" [14].

We have some difficulty in conceiving of a duality relation in terms of "precedence" and "transition". However, if we take the idea of precedence in the sense of ancestry, hence of *genesis*, we cannot avoid verging upon Marx's famous aphorism: "Human anatomy contains a key to the anatomy of the ape" [Marx, 1973:105]. Can we infer that structural thinking contains a key to operational thinking that "precedes" it? What does this mean?

> "Although it is true that the categories of structural thinking possess a truth for all forms of thinking, this is to be taken only with a grain of salt. They can contain them in a developed or stunted, or caricatured form etc., but always with an *essential difference*. The so-called presentation of cognitive development is founded, as a rule, on the fact that the latest form regards the previous ones as steps leading up to itself, and since it is only rarely and only under quite specific conditions able to criticize itself (...) it always conceives them one-sidedly" [The paragraph is a parody of Marx, 1973:106] ([1]).

Since "twentieth-century mathematics seems to be deeply permeated with the structural outlook" [Sfard, 1991:24], and since the structural way of thinking is "the more advanced stage of concept development" [ibid. 14], we infer that structural thinking (for example, developed algebraic thinking) will tend to regard all forms of computational thinking preceding it (for instance arithmetic) as steps leading up to itself. From this point of view, algebraic thinking contains arithmetic regarded as a

---

[1]. Here is the original text. "Although it is true, therefore, that the categories of bourgeois economics possess a truth for all other forms of society, this is to be taken only with a grain of salt. They can contain them in a developed or stunted, or caricatured form etc., but always with an essential difference. The so-called historical presentation of development is founded, as a rule, on the fact that the latest form regards the previous ones as steps leading up to itself, and since it is only rarely and only under quite specific conditions able to criticize itself –leaving aside, of course, the historical periods which appear to themselves as times of decadence– it always conceives them one-sidedly" (...)" Although Marx's categories refer to political economy, the parody is valid because only its logical content is considered here.

step leading up to itself (hence continuity) but also as a caricatured form *essentially different* from itself (hence discontinuity). In order to overcome this one-sided view of arithmetic as a step leading to itself, the upper form will have to "criticize itself". What does this mean? We resort to another author who has thoroughly discussed the quote from Marx cited above from Hegel's perspective.

> "This *essential difference* –and here is the decisive point– should be considered as crossed by destruction and generation. The movement from a continuity to a discontinuity perspective corresponds to the movement from a naive to a critical focus on the upper form" [Fausto, 1987:18].

Therefore, in its self-criticism, structural (algebraic) thinking should recognize itself as being generated insofar as the previous operational (arithmetical) thinking is being destroyed as such, and incorporated into it as something *essentially different*. The mathematician's movement back and forth from computational to structural approaches to a problem is not autonomous because the structural outlook is not reversible.[2] According to this argument, no "progress", "transition", "evolution" or "generalization" can lead from arithmetic to algebra. Simultaneous destruction-genesis (death/birth is just a non-simultaneous approximation) is the decisive dialectical concept to understand how arithmetic is embodied in algebra: the tree has to die so that the flower can be born from its rotting trunk. This conclusion will be important for teaching.

Looking at the continuity/discontinuity ambiguity pointed out at the beginning, from the point of view of the Piagetian theory of equilibration, what our argument amounts to is that instead of thinking about the relation arithmetic/algebra as a *completive generalization* [Piaget and Garcia, 1984, p. 10] we should think of it as an *abstractive reflection* [Piaget, 1975, p. 39] which implies a difference of essence.

Didactical difficulty of the continuity point of view

The prevalent teaching strategy in introductory algebra courses is to conduct the student step by step from procedural to structural thinking following a supposedly continuous path. Research is then organized to observe, evaluate and encourage progress along this path using teaching experiments, mathematical ability tests and interviews [Linchevski & Herscovics, 1996]. Instructional materials are supplied as needed: geometric models [Filloy & Rojano, 1989], balances [Linchevski & Herscovics, 1996, Aczel, 1998, da Rocha Falcão, 1995] or spreadsheets [Arzarello, Botazzini & Chiappini, 1995].

In their teaching experiment, Linchevski & Herscovics [1996] adopted a clear continuity strategy. They accepted the initial use of the inverse operations in reverse order naturally employed by the students for solving equations with a single occurrence of the unknown and let them proceed until their method became "lengthy and tedious". Then they assumed that the students were "ready to be exposed to new

[2] This is clear from Sfard's examples [p. 25, 26]; once we take a look into the structural solution, we cannot pretend that we have not seen it and just come back to the computational approach. The relation is not of duality but of irreversible spiral.

points of view" [40] and started teaching them a decomposition-and-cancellation method to solve equations with two occurrences of the unknown on the same member. Next, they introduced equations with the unknown on both sides. To the students they "pointed out that none of the methods they knew could effectively solve this type of equation" [53] and introduced the balance model to help them. However, in spite of all efforts, the students continued to solve the equations with only one occurrence of the unknown by performing reverse operations in reverse order. "It should be pointed out how stable this procedure remained in the seven months since our initial assessment" [59]. So, the step by step strategy did not lead to the expected change. Why?

How much do these students praise the arithmetical undoing strategy that they have learned for solving one-unknown equations? When they found it "lengthy and tedious" and claimed that "there must be another way" [62], were they actually ready to be "exposed" to another point of view? What is the effect of "pointing out" to a student that his/her method is not "effective"? What is the nature of the change expected by this strategy?

The authors do not seem to acknowledge that the students may have a special taste for wrong answers as long as they are *their* answers, obtained by *their* methods and make *them* big, strong and worthy of love for the gaze that they imagine to be cast upon them. Will they recognize in the instructors eyes the referential gaze for which they are willing to play the scene of their lives? What should be the *nature of the demand* provoked by these eyes if the expected change is to be produced?

Drawing on previous research, the authors attribute certain students' answers in ability tests about first degree equations to a "*limited view* of algebraic expressions", "*failure* to grasp the meaning of operations", and "*inability* to spontaneously operate with or on the unknown" [39-40, emphasis added]. Next, inability is identified with an *obstacle*: "This inability to spontaneously operate on or with the unknown constituted a cognitive obstacle" [41]. The teaching experiment was designed to cross this obstacle.

Thus, a too restrictive conception of *obstacle* [Brousseau, 1997:82] considered to be a mere "failure", seem to have presided over the whole teaching experiment. The students had to conform to new methods or... fail. Would they be willing to recognize in the instructors eyes the referential point of their imaginary identifications? Or did they recognize in these eyes the gaze of the school system, always ready to classify their answers as "failure" and "inability"? "The students experience we conjecture is not of a straightforward switch from arithmetic to algebra; their storying backdrop needs to be extended at the same time" [Brown & Wilson, 1998:171].

> "So far as *obstacles* appear as repetitions of failure, they provide a measure of the persistence of the subject's *jouissance organization*: the subject hesitates to abandon what worked well in previous situations and insists on justifying his statements in terms of the notions that he does not want to give up. This is why the nature of the demand makes a big difference in the didactic situation" [Baldino, 1997: 237].

So, not only did Linchevski & Herscovics' [1996] teaching attempt based on continuity assumptions reveal itself to be difficult but it also indicated that *the obstacle to pass from arithmetic to algebra is arithmetic itself.* Arithmetic is the knowledge that the students refuse to *destroy* in order for structural thinking to be *generated.* For the students, learning has the dimensions of death, this is why it is difficult. Insofar as the authors' teaching method started by recognizing the students' arithmetical procedures, they could only reinforce the obstacle and make students more confident of their arithmetical knowledge, more attached to their past life stories, instead of developing the courage of reformulating these stories from an algebraic point of view. Paradoxically, the more we focus on the supposed "gap" in order to consciously try to bridge it, the wider it becomes. If there is a "gap" between arithmetic and algebra, it is not to be crossed; it has to be *ignored, forgotten, dissipated.* If we want the students to think algebraically, we have to start by assigning them typical tasks of the algebraic domain. We have to seriously take into account that reflective abstraction implies that "every cognitive system relies on the following one for guiding, and the achieving its regulation" [Piaget, 1975:40]. There is no path to the top of the mountain; we have to parachute the students up there. This is the objective of the following puzzle in its settings: manipulative and computerized.

An algebraic puzzle: the *doublequal*

The material consists of a board with two pairs of squares connected by equality signs, and black and white pieces of three different shapes, say black and white stones (▲, △), black and white buttons (●, ○), and black and white Montessori cubes (❑, ■). To start the activity, four handfuls of randomly chosen pieces are spread in each of the four squares. This will be called the *initial situation.* Examples of initial situations are in figures 1a and 1b.

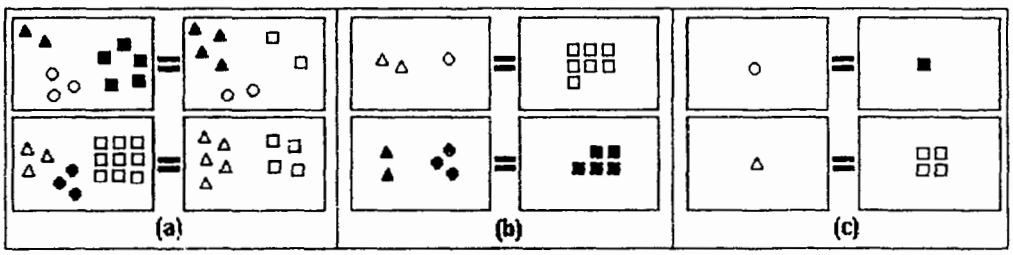

Fig. 1 - **(a) Randomly chosen initial situation**
(b) Simplified initial situation
(c) Final situation

The objective is to pass from the *initial situation* to a *final situation* through a series of *intermediate situations.* In the final situation, square A must contain only white stones (△), square C must contain C only white buttons (○) and squares B and D only Montessori cubes, either white or black (❑ or ■). See figure 1c.

The activity abides by this one single rule: one passes from a situation to the next by simultaneously adding (or removing) *equivalent handfuls* of pieces to (from) squares A and B or to (from) squares C and D.

The equivalence of handfuls is given by the following rules:

1. two handfuls of pieces are equivalent if they are made of the same number of pieces of each shape and color (general equivalence) or if:
2. they occupy squares A and B or squares C and D in any of the situations (local equivalence).
3. A handful of pieces consisting of equal number of pieces of different colors is considered equivalent to the empty handful (cancellation).
4. Dividing or multiplying the number of pieces of two equivalent handfuls by the same integral number leads to equivalent handfuls.

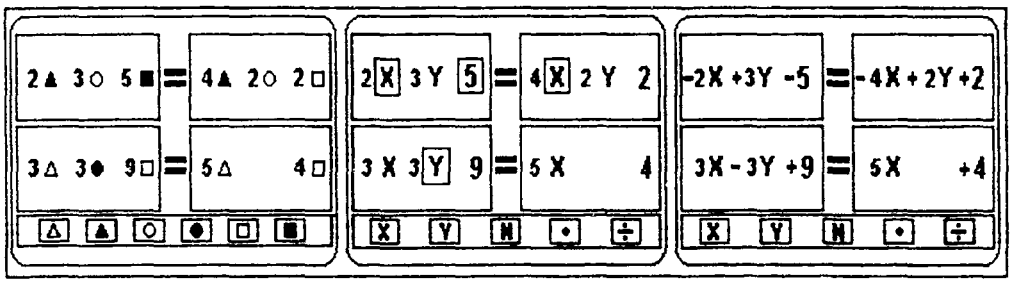

Fig.2 - Computerized settings II, III and IV.

Besides the manipulative, there are four computerized settings. The first one reproduces the manipulative setting (fig. 1). The following settings are shown in figure 2. Notice that in the last setting, *predicative signs* are turned into *operative signs*.

Discussion of pilot studies

Unlike Dienes and Gategno, we are not "trying to realize a perfect correspondence between the structure of the mathematical knowledge involved and the structure of the educational material" [Szendrei, 1996:420], nor are we assuming that the puzzle hides any kind of "hidden or frozen mathematics" [Gerdes, 1996:914]. We are assuming that buttons, stones and cubes are three-dimensional signifiers whose meanings are given by positions, movements and gestures. The material should be regarded as an amplifier of language resources, nothing else.

Pilot studies on the manipulative material were carried out with mathematics teachers, pedagogy and computer undergraduate students and high school 6th–graders. The aim of the preliminary studies was to: 1) adjust the written form of the rules; 2) verify the amount of extra help that should be given for the players to understand the rules; 3) verify whether the students became engaged in solving the puzzle.

The single rule of the *doublequal* is the pivotal point offered to the students around which they can start developing a new life story; a story of operational proficiency instead of one of failure. Further studies may determine what will become of the arithmetical domain for students who have passed through the doublequal: will

they use algebraic strategies to solve former arithmetic problems? Will they spontaneously group multiple occurrences of the unknown and operate simultaneously on both sides?

The pilot studies[3] revealed that the nature of the demand makes a big difference. In the first experiments, we made reference to a balance in order to introduce the operational rules. Whenever we tried this simplification, most of the groups started developing trial and error strategies. We tried to assign more difficult tasks to these groups, forbade them to use pencil and paper, and proposed situations where the solutions would not be integers. Instead of looking for another method, they stubbornly went on specializing their method of systematically investigating solutions with denominators 2, 3, etc. When we finally showed them the substitution methods, they revolted and complained that we were "cutting their creativity". However, even in groups with expert mathematics teachers, it took quite some time to identify the presence of a linear system behind the idea of the puzzle.

The computerized setting is programmed according to the mathematical rules of the linear systems, not according to the step-by-step manipulation to pass from one situation to the next, as stipulated in the rules. Therefore, the players may skip situations by condensing several transformations into one. Mathematically, this amounts to performing composition of operators *in action*. Operations on operators are necessary in order for them to become reified as objects.

"A person must be quite skillful at performing algorithms in order to attain a good idea of the 'objects" involved in these algorithms; on the other hand, to gain full technical mastery, one must already have these objects, since without them the process would seem meaningless and thus difficult to perform" [Sfard, 1991:32].

COGNITIVE PROCESSES IN A SPREADSHEET ENVIRONMENT

Alex Friedlander
The Weizmann Institute of Science, Rehovot, Israel

This paper investigates the way two students used spreadsheets to solve an algebra task and analyzes some cognitive aspects of their work. Frequent attempts to generalize the problem situation and to justify these attempts and repeated revisions of their solution, led the students along a rather intricate solution path. Some cognitive skills seem to have been promoted, but also some difficulties were raised, by the use of spreadsheets.

Introduction

Various studies have reported on significant cognitive processes that occur when students work with spreadsheets in the early stages of learning algebra. Sutherland and Rojano (1993), from their own and colleagues' findings, found that processes such as naming a variable, representing and testing mathematical relationships, generalizing from arithmetic, and extending informal arithmetic strategies, are facilitated by work with spreadsheets. Rojano (1996) concluded that current studies on learning algebra in a spreadsheet environment "show that spreadsheets can be a substantial support in the development of essential aspects of algebraic thinking".

In this study, I examine cognitive and metacognitive processes supported by the use of spreadsheets, as students solve investigative algebraic tasks. The analysis is based on the observation of a pair of students in a beginning algebra class, working with spreadsheets (Excel) on an activity. The particular videotaped section was selected from fifteen videotapes of pairs of seventh graders working on algebra tasks, recorded during a whole year of weekly observations. The section is taken from three lessons considered by the four observers as representative of both the nature of the tasks, and of the learning processes observed throughout the year, and therefore worth analyzing in depth. I will focus on processes of generalization and justification, in general, and of algebraic modeling and explaining in a spreadsheet environment, in particular. In addition to the role of the computer, the social interaction between the two students was an important factor in the development of the solution path. However, due to the limits of this paper, the social aspect of the students' activity will not be analyzed.

Background

The spreadsheet environment described in this study is part of a beginning algebra course in a technology-based curriculum development project for grades 7 to 9. The course for grade seven includes the use of Excel, at the rate of one or two (of five) lessons per week. Most of the learning units are based on open-ended problem-situations. The use of computers in this project in general, and of spreadsheets during the first year of learning algebra, in particular, is aimed to support

- students' active construction of knowledge and cognitive abilities such as experimentation, prediction of results, modeling, generalization of patterns and justification of outcomes (Friedlander et al., 1989).
- students' ability to produce and analyze a variety of representations of a problem situation and of its solution.
- the development of students' metacognitive abilities, such as reflection upon observed phenomena, awareness to their own thought processes, self-regulation and control (Hershkowitz & Schwarz, in press).

The cognitive and metacognitive processes involved in working with Excel will be discussed by analyzing the videotaped work of two 13 year-old students (a boy and a girl) on a quite complex problem. The two students attended an urban, selective (although not aimed for the mathematically gifted) school, and were described by their teacher as having high mathematical ability.

The twenty-minute section discussed here occurred during the last period in a sequence of four lessons, devoted to the *Chocolate Cake* problem-situation. Figure 1 presents the problem and a generalized pattern of its solution.

A baker in the *Land of Oz* bakes cubical cakes. The edge length of the cube is called *the cake number*. He covers the cakes with chocolate icing (including the bottom...), cuts them up into unit cubes (called *slices*) and sorts them into four categories, according to the number of sides covered by icing. Then, for each cake, the baker packs *all* the slices of the same kind into a bag. The price of a bag is determined by the number of slices and by their kind. The chocolate is the only expensive ingredient, and it costs 1/2 zooz (an extinct, ancient currency) per A.U. (area unit). The completely uncoated slices are "given away to charity" and will not be considered.

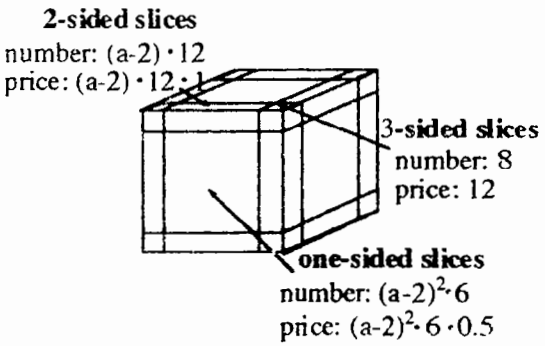

Figure 1. *The Chocolate Cake* Problem and its generalized solution for an a x a x a cube.

During the first three lessons, the students investigated the structure of a cube and the location and the *number* of slices in a whole cake. The goal of the last lesson in this sequence was to use previously obtained results about the *number* of slices, to model and investigate ways of pricing slices of different categories. Figure 2 presents possible expressions (written in spreadsheet syntax) that students are expected to use in order to complete the price table.

	A	B	C	D	E
1	Cake No.	Price of 3-sided slices	Price of 2-sided slices	Price of one-sided slices	Total price
2	1	0	0	0	3
3	2	12	=(A3-2)*12	=(A3-2)^2*6*0.5	=B3+C3+D3
4	3				

Figure 2. Price table for *The Chocolate Cake* Problem.

Cognitive Processes

The observed students worked relatively quickly and their familiarity with general expressions was apparent, as expected. However, they followed a rather "zigzag" solution path, in which the repeated attempts to generalize the price of the slices of a certain kind were not followed through systematically. Figure 3 presents an overview of their solution -- the formulae produced, their rationale and the reason for each revision. The task required the students to make four generalizations -- three for the price of different kinds of slices and one for the total price. For each generalization the students made two to four revisions, until they obtained a formula which they considered satisfactory. The revisions were caused by a variety of reasons, such as unreasonable computer output, peer discussion or intervention by a neighbor or by the teacher.

In the following, I analyze cognitive aspects of the students' work, in three categories: (a) generalizing, (b) analyzing results and (c) explaining and justifying. The numbers in square brackets refer to the versions of the formulae in Figure 3.

a) Generalizing. The activity took place after two months of weekly sessions with Excel. The students were familiar with the language of Excel and employed it naturally in their work and for communication. The observed pair produced their expressions in Excel format, from the start. Occasionally, the discussion of a formula was accompanied by verbal interpretations, as in [2.2]:
